

# GENERAL THETA FOUNDATIONS I: WORD PROFILES AND ARITHMETIC FLUCTUATIONS OF NUMERICAL MEMORY

QIAN QI

ABSTRACT. We associate two finite-scale quantities to a finite orthogonal command alphabet: an optimized word-packet distortion and a compatible convex-enclosure contraction. The first bounds every hidden stochastic realization through a nonuniform interval budget; the second constructs exact realizations with common command rows. Neither requires a spectral gap. In the planar case, optimal packet distortion has a finite second-order cone formulation. These profiles yield a numerical-memory exponent  $r/(2r + 1)$  for every  $r$ -angle alphabet of minimal ordinary dual Diophantine type, a class of full Lebesgue measure; explicit logarithmic bounds hold almost everywhere. For every irrational single angle we identify a sequence of horizons on which width has cubic-root order. For every Liouville angle the logarithmic width exponent has lower limit zero and upper limit at least one third, so a single power law need not exist. All lower bounds allow arbitrary hidden states and time-dependent stochastic rows, and the upper constructions preserve each numerical probability exactly. The resource is nonuniform clocked atomic-row label width, with a fixed signal, a fixed sufficiently small wordwise error, and one selected terminal query.

## 1. INTRODUCTION

A finite-dimensional orbit may admit a small positive factorization at each time and still require a growing register when those factorizations must be executed by one causal machine. For a fixed alphabet, that growth also depends on the distribution of its finite words. A qualitative assertion that all spectral gaps vanish loses precisely the arithmetic information which distinguishes such examples.

We study the numerical response

$$(1.1) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, U_w x \rangle}{2}, \quad b \in \{-1, 1\},$$

where the command word  $w$  has prescribed length  $N$ , the seed  $x$  is a unit vector, and only one final coordinate  $j$  is queried. The matrices in  $U_w$  are orthogonal. A classical register must preserve these probabilities, or approximate every one of them within a fixed binary total-variation error. Its stochastic rows may vary arbitrarily with the epoch. Section 2 defines the resource without a uniformity or finite-random-bit assumption.

The first main result is a pair of operational bounds in terms of finite data. For words of length  $B$ , let  $\Gamma_{\mathcal{A}}(k, B)$  be the largest, over word distributions, of the smallest spherical distortion after replacing the word orbit by  $k$  centroid directions. This definition optimizes the converse law and permits every initial direction. Theorem 3.3 charges  $-\log(1 - \Gamma_{\mathcal{A}}(K_t, B))$  to any interval of length  $B$  ending at time  $t$ , even when all other registers are unrestricted. A finite interval recurrence combines all such charges and bounds actual final error. In the opposite direction, Theorem 3.5 turns a finite polytope and its worst command contraction into common stochastic rows. These are distinct lower and upper profiles; we do not assume that an optimal hidden realization must be a vector-state polytope.

For circle actions, Theorem 4.1 removes the continuous search over centroid directions. The exact optimized packet value is a finite second-order cone problem indexed by cyclic partitions of the word phases. Thus a finite packet certificate is computationally different from an infinite harmonic-gap assertion. The theorem is not an efficiency assertion in a succinct word length.

Our arithmetic conclusions go beyond uniform bad approximation. For  $\alpha \in \mathbb{R}^r$  with  $1, \alpha_1, \dots, \alpha_r$  rationally independent, write

$$(1.2) \quad \omega^*(\alpha) = \limsup_{\|m\|_1 \rightarrow \infty} \frac{-\log \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}}}{\log \|m\|_1}.$$

The alphabet consists of the identity and the rotations through  $2\pi\alpha_i$ . Throughout,  $r$ , the alphabet,  $0 < \rho \leq 1/10$  and  $0 \leq \varepsilon < \rho/(2\sqrt{2})$  are fixed.

**Theorem 1.1** (Minimal Diophantine type). *If  $\omega^*(\alpha) = r$ , then*

$$(1.3) \quad \lim_{N \rightarrow \infty} \frac{\log W_{N,\varepsilon}(\alpha)}{\log N} = \frac{r}{2r+1}.$$

*For Lebesgue-almost every  $\alpha$ , and every fixed  $\delta > 0$ , there are positive constants  $c, C$  such that, for  $N \geq 2$ ,*

$$(1.4) \quad c \frac{N^{r/(2r+1)}}{(\log(N+2))^{2r(1+\delta)/(2r+1)}} \leq W_{N,\varepsilon}(\alpha) \leq CN^{r/(2r+1)} (\log(N+2))^{2r^2(1+\delta)/(2r+1)}.$$

*The upper inequalities are achieved by exact common-row machines.*

The exponent in (1.3) need not imply a two-sided constant-factor law. The earlier dual badly approximable theorem supplies the stronger  $\Theta$  conclusion on its stated class, and is recovered in Corollary 5.4. Theorem 1.1 instead allows arbitrarily small Diophantine constants along subsequences. The quantitative arithmetic ingredients are classical; the memory conclusions concern their compatible realization and all-hidden-state converse.

There is also a genuine failure of a single exponent, even for one fixed irrational angle.

**Theorem 1.2** (Irrational horizons and Liouville fluctuations). *For every irrational  $\alpha$  there are horizons  $M_n \rightarrow \infty$  such that  $W_{M_n,\varepsilon}(\alpha) = \Theta(M_n^{1/3})$ . If  $\alpha$  is Liouville, then*

$$(1.5) \quad \liminf_{N \rightarrow \infty} \frac{\log W_{N,\varepsilon}(\alpha)}{\log N} = 0, \quad \frac{1}{3} \leq \limsup_{N \rightarrow \infty} \frac{\log W_{N,\varepsilon}(\alpha)}{\log N} \leq \frac{1}{2}.$$

*Nevertheless  $W_{N,\varepsilon}(\alpha) \rightarrow \infty$ . All displayed upper bounds have exact realizations.*

The upper limit in (1.5) is not determined here. The result establishes oscillation between subpower subsequences and a positive-power subsequence; it does not replace that distinction by a guessed exponent for all irrationals.

Relation to previous work. Finite codebooks, nearest-center partitions and positive convex realizations are classical tools [5, 11]. The endpoint conditional-centroid contraction used below was established in the preceding packet development [7, 8]; we give its complete proof and use it to define a finite alphabet profile. The general interval optimization, the circle word-law program, and the metric and Liouville memory conclusions are the new statements of this revision. Classical Dirichlet approximation, continued fractions and algebraic examples are not counted as new arithmetic. The direct comparison with Dick–Goda–Larcher–Pillichshammer–Suzuki [4], including their Theorem 3.9 and Lemma 3.11, is made in Section 8.

| Quantity                             | Meaning                                                              |
|--------------------------------------|----------------------------------------------------------------------|
| $K_t, W_{N,\varepsilon}$             | Available labels at a cut; minimum whole-run peak.                   |
| $\Gamma_{\mathcal{A}}(k, B)$         | Best finite-word distortion against $k$ endpoint directions.         |
| $\mathcal{I}_N(K_{\bullet})$         | Maximum sum of distortion charges over disjoint intervals.           |
| $\lambda_{\mathcal{A}}(k, a)$        | Least common enclosure dilation with $k$ vertices and inradius $a$ . |
| $\psi_{\alpha}(H), \eta_{\alpha}(q)$ | Dual separation and simultaneous rational-approximation errors.      |

## 2. THE NUMERICAL EXPERIMENT AND THE REGISTER

Let  $V = \mathbb{R}^D$ , let  $\mathcal{A}$  be a nonempty finite alphabet, and fix orthogonal matrices  $U_a$ ,  $a \in \mathcal{A}$ . Write  $U_w = U_{a_N} \cdots U_{a_1}$  in the order of execution. Let  $X \subset \mathbb{S}^{D-1}$  be a nonempty finite seed set and  $0 < \rho < 1$ . The required law is (1.1). Commands are externally supplied, not chosen by a policy inside the simulator. No distribution on command words is part of the specification.

**Definition 2.1** (Clocked atomic-row realization). At horizon  $N$ , a machine consists of finite sets  $S_t$  with  $|S_t| = K_t$  for  $0 \leq t \leq N$ , an initialization probability row  $E_x$  on  $S_0$ , stochastic matrices  $T_{t,a} : S_{t-1} \rightarrow S_t$ , and terminal columns  $d_j : S_N \rightarrow [-1, 1]$ . Its numerical mean is

$$E_x T_{1,a_1} \cdots T_{N,a_N} d_j.$$

After the atomic query  $j$ , it draws and holds the binary answer with that mean. The final answer cut has two labels. Its peak is  $\max(2, K_0, \dots, K_N)$ . Available labels count even when unreachable; adding unused normalized rows is permitted.

All persistent randomness, input history and protocol distinctions must be in the current label. Only the external epoch, the prescribed horizon and the read-only row tables are free. Table construction, lookup, arithmetic and exact sampling of known real stochastic rows are uncharged. Matrices, rows and state sets may depend on  $N$ ; this is nonuniform positive-realization width, not uniform computational space. A common-row construction uses the same command matrices at all command epochs but may still have an  $N$ -dependent decoder. It need not answer at earlier stopping lengths.

Let  $W_{N,\varepsilon}$  be the least peak among machines whose every binary row differs from (1.1) by at most  $\varepsilon$  in total variation. For fixed finite  $K_{\bullet}$  the optimal actual error  $\mathcal{E}_N(K_{\bullet})$  is attained: the row parameters lie in a finite product of compact sets and the error is a finite maximum of continuous functions. For planar results we use  $X = \{\pm e_1, \pm e_2\}$  and include the identity letter. We keep  $\rho \leq 1/10$  and  $\varepsilon < \rho/(2\sqrt{2})$ .

**Lemma 2.2** (Calibration under any external test law). *Fix a seed  $x \in X$  and any law on the complete command word, independent of private initialization. Let  $Y_t = U_{a_t} \cdots U_{a_1} x$ ,  $Z_t = \mathbb{E}[Y_t | S_t]$  and  $q_t = \mathbb{E}\|Z_t\|$ . Every machine with row error at most  $\varepsilon$  satisfies*

$$(2.1) \quad q_N \geq \kappa := \rho/\sqrt{D} - 2\varepsilon.$$

*At a boundary preceding an independent complete packet, the next boundary admits the conditional-mean identity used in Lemma 3.2. No single-step independence inside a packet is asserted.*

*Proof.* For a fixed word, every coordinate of  $\mathbb{E}[d(S_N) | w] - \rho Y_N$  has modulus at most  $2\varepsilon$ . Since  $\|Y_N\| = 1$ , averaging gives

$$\mathbb{E}\langle Y_N, d(S_N) \rangle \geq \rho - 2\varepsilon\sqrt{D}.$$

On the other hand this pairing equals  $\mathbb{E}\langle Z_N, d(S_N) \rangle$  and is at most  $\sqrt{D}q_N$ . This proves (2.1). Combining terminal columns is a proof device, not a requirement to provide their joint output distribution.  $\square$

### 3. FINITE WORD PROFILES AND COMPATIBLE ENCLOSURES

The results in this section apply to every finite orthogonal alphabet, including noncommuting alphabets. No connectedness, arithmetic condition or spectral gap is assumed. Invariant directions may make a converse profile zero; this is a property of the stated profile, not an omitted hypothesis.

**3.1. An optimized distortion.** For  $B, k \geq 1$  and a probability vector  $p$  on the actual words  $\mathcal{A}^B$ , define

$$(3.1) \quad D_k(p) = 1 - \max_{\substack{u \in \mathbb{S}^{D-1} \\ v_1, \dots, v_k \in \mathbb{S}^{D-1}}} \sum_{w \in \mathcal{A}^B} p_w \max_{1 \leq j \leq k} \langle v_j, U_w u \rangle,$$

$$(3.2) \quad \Gamma_{\mathcal{A}}(k, B) = \max_{p \in \Delta(\mathcal{A}^B)} D_k(p), \quad \chi_{\mathcal{A}}(k, B) = -\log(1 - \Gamma_{\mathcal{A}}(k, B)).$$

We allow  $\chi = +\infty$ . Repeated product matrices can be merged for the optimization: their probability masses add. Their representative words must still be executed one ordinary command at a time.

**Proposition 3.1** (Finite-data properties). *The maxima in (3.1)–(3.2) are attained,  $0 \leq \Gamma_{\mathcal{A}}(k, B) \leq 1$ , and the profile is invariant under simultaneous orthogonal changes of coordinates. It is nonincreasing in  $k$  and unchanged by duplicating a letter. For two indexed orthogonal alphabets  $U, V$ ,*

$$(3.3) \quad |\Gamma_U(k, B) - \Gamma_V(k, B)| \leq B \max_a \|U_a - V_a\|_{\text{op}}.$$

*For a fully listed finite alphabet of real-algebraic matrices and fixed integers  $k, B, D$ ,  $\Gamma_{\mathcal{A}}(k, B)$  and an optimizing word law are real-algebraic and can be determined by real quantifier elimination.*

*Proof.* All parameter spaces are compact and the objective is continuous. Its maximum over directions is convex in  $p$ , so  $D_k$  is continuous and concave. The maximum scalar product is at most one. By choosing a single direction parallel to  $\sum p_w U_w u$ , the inner maximum is nonnegative; hence  $D_k \in [0, 1]$ . Conjugating all directions proves invariance. Additional centers only increase that inner maximum. Product telescoping gives  $\|U_w - V_w\|_{\text{op}} \leq B \max_a \|U_a - V_a\|_{\text{op}}$ , and maxima and minima preserve this uniform bound.

For the last assertion, enumerate the product matrices. Unit-sphere equations, simplex inequalities and finitely many maximum operations define a compact semialgebraic optimization with algebraic coefficients. Maximum operations can be expressed by finite alternatives or auxiliary variables. Quantifier elimination over the real closed field of real-algebraic numbers determines the endpoint of the feasible value interval and a witness [1]. The word table may have  $|\mathcal{A}|^B$  entries; this is not a polynomial-time assertion or a decision procedure for an infinite spectral gap. No logarithm needs to be eliminated: finite budget comparisons can instead use products of  $1 - \Gamma$ .  $\square$

**Lemma 3.2** (Endpoint contraction; inherited mechanism). *Let a complete random word  $W$  with law  $p$  be independent of all information before its start. Internal letters of  $W$  may be correlated. If the endpoint register has at most  $k$  labels, then*

$$(3.4) \quad q' \leq (1 - D_k(p))q.$$

*There is no bound on the intermediate registers.*

*Proof.* Write  $z_s = \mathbb{E}[Y \mid S = s]$  at the start. Composing all internal stochastic rows yields a common endpoint kernel  $T(j \mid s, w)$ . Since the entire word and the machine's fresh randomness are independent of the past,

$$z'_j = \mathbb{E}[U_W z_S \mid S' = j].$$

This is an endpoint identity; it would not generally hold after conditioning on a correlated next letter inside the packet. Choose  $v_j = z'_j / \|z'_j\|$  for nonzero  $z'_j$ , and any unit vector otherwise. Then

$$\begin{aligned} q' &= \sum_s \mathbb{P}(S = s) \sum_w p_w \sum_j T(j \mid s, w) \langle v_j, U_w z_s \rangle \\ &\leq \sum_s \mathbb{P}(S = s) \|z_s\| \max_{\|u\|=1} \sum_w p_w \max_j \langle v_j, U_w u \rangle \leq (1 - D_k(p))q. \end{aligned}$$

Terms with  $z_s = 0$  contribute zero. Replacing an executable assignment by the largest pairing is a relaxation in the correct direction. Arbitrary unobservable hidden coordinates are included in  $s$ ; no statewise observable-vector hypothesis is used. This is the conditional-centroid mechanism of [7, 8], now applied to the optimized finite word datum.  $\square$

For an available profile  $K_\bullet$ , let  $I_0 = 0$  and define

$$(3.5) \quad I_t = \max \left\{ I_{t-1}, \max_{1 \leq B \leq t} [I_{t-B} + \chi_{\mathcal{A}}(K_t, B)] \right\}, \quad \mathcal{I}_N(K_\bullet) = I_N.$$

This is the largest sum of charges of disjoint command intervals, with an interval of length  $B$  ending at  $t$  charged by  $\chi_{\mathcal{A}}(K_t, B)$ . The recurrence depends only on the alphabet and the available profile.

**Theorem 3.3** (A nonuniform interval budget). *Every machine with  $\kappa = \rho/\sqrt{D} - 2\varepsilon > 0$  satisfies*

$$(3.6) \quad \mathcal{I}_N(K_\bullet) \leq \log(1/\kappa).$$

*More generally its optimal actual terminal error obeys*

$$(3.7) \quad \mathcal{E}_N(K_\bullet) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{D}} - e^{-\mathcal{I}_N(K_\bullet)} \right]_+.$$

*For a uniform peak bound  $K$ , every  $B \leq N$  gives*

$$(3.8) \quad \lfloor N/B \rfloor \chi_{\mathcal{A}}(K, B) \leq \log(1/\kappa).$$

*For a fixed  $B, k$  with  $\Gamma_{\mathcal{A}}(k, B) > 0$ ,*

$$(3.9) \quad \#\{1 \leq t \leq N : K_t \leq k\} \leq B - 1 + \frac{B \log(1/\kappa)}{\chi_{\mathcal{A}}(k, B)}.$$

*If  $\chi = +\infty$ , the last fraction is zero.*

*Proof.* Choose any maximizing disjoint interval family in (3.5). On each selected interval put an independently sampled optimizing complete word from Proposition 3.1. All gaps and the final remainder contain fixed deterministic command words. A deterministic orthogonal command followed by a stochastic update cannot increase the conditional-mean norm, by conditional Jensen. Lemma 3.2 therefore gives

$$q_N \leq \prod_{(t-B, t]} (1 - \Gamma_{\mathcal{A}}(K_t, B)) = e^{-\mathcal{I}_N(K_\bullet)},$$

since  $q_0 = 1$ . The chosen law can depend on the available layer sizes, not on private states. Wordwise correctness requires the same machine to pass it. Lemma 2.2 proves (3.6) and (3.7); taking consecutive intervals proves (3.8).

For (3.9), discard candidate endpoints before  $B$ . Select the earliest remaining endpoint, delete all later candidates less than  $B$  away, and repeat. If  $M$  is the original number and  $J$  the number selected, the explicit count is

$$M - (B - 1) \leq BJ.$$

The associated length- $B$  intervals are disjoint and each contributes at least  $\chi_{\mathcal{A}}(k, B)$ . Applying (3.6) gives the result. No restriction on the other registers was introduced.  $\square$

The cap union estimate below is the geometric certificate already used in the predecessor packet method [7]. The finite incidence formulation specifies how to optimize that certificate on a fully listed word set.

**Proposition 3.4** (Uniform cap certificates). *Suppose a law  $p$  on length- $B$  words satisfies*

$$\sup_{u,v \in \mathbb{S}^{D-1}} p\{w : \|U_w u - v\| < \delta\} \leq b.$$

*Then  $\Gamma_{\mathcal{A}}(k, B) \geq \frac{1}{2}\delta^2(1 - kb)_+$ . For algebraic product matrices and algebraic  $\delta$ , the best such  $b$  is the value of a finite linear program once cap incidence types have been decided by real quantifier elimination.*

*Proof.* The union of  $k$  open caps has probability at most  $kb$ . Outside it,  $1 - \max_j \langle v_j, U_w u \rangle = \frac{1}{2} \min_j \|U_w u - v_j\|^2 \geq \delta^2/2$ . For the algorithmic assertion, a subset of the finite word list either can or cannot be contained in one such cap for some  $u, v$ . This is a finite system of algebraic inequalities, including the sphere equations. For every feasible subset  $A$  impose  $\sum_{w \in A} p_w \leq b$ , along with the simplex constraints, and minimize  $b$ . Every actual incidence set is feasible; conversely a feasible subset is included in an actual incidence set and has no greater mass. Thus these constraints give exactly the desired supremum. The exponentially large enumeration is not concealed.  $\square$

**3.2. A separate exact-synthesis profile.** Fix  $0 < a < 1$ . For  $k$  such that the following family is nonempty, let

$$(3.10) \quad \lambda_{\mathcal{A}}(k, a) = \min_P \inf \{\lambda \geq 1 : U_b P \subseteq \lambda P \text{ for all } b \in \mathcal{A}\},$$

where  $P$  ranges over convex hulls of at most  $k$  points in  $\mathbb{B}^D$  containing  $a\mathbb{B}^D$ . An empty family has value  $+\infty$ .

**Theorem 3.5** (Compatible enclosure synthesis). *The finite value in (3.10) is attained and lies in  $[1, a^{-1}]$ . If  $\rho\lambda_{\mathcal{A}}(k, a)^N \leq a$ , there is an exact machine with  $\max(k, 2)$  labels, common command matrices and a horizon-dependent decoder. Each row has at most  $D + 1$  successors. Algebraic matrices and algebraic  $a$  give an algebraically decidable profile value and algebraic row witnesses. For two indexed alphabets with a common feasible family,*

$$(3.11) \quad |\lambda_U(k, a) - \lambda_V(k, a)| \leq a^{-1} \max_b \|U_b - V_b\|_{\text{op}}.$$

*Proof.* Parameterize  $P$  by  $k$  points in the closed unit ball, allowing repetition. Containment of  $a\mathbb{B}^D$  is closed in these coordinates. Every such  $P$  satisfies  $U_b P \subseteq \mathbb{B}^D \subseteq a^{-1}P$ . The containment conditions are closed on this compact set and  $1 \leq \lambda \leq a^{-1}$ ; hence a minimum exists.

Let its vertices be  $v_s$  and  $\lambda$  its dilation. Initialize with a convex representation of  $ax$ . For each  $b, s$ , represent  $\lambda^{-1}U_b v_s$  by the same vertices and use its convex coefficients as the row  $T_b(s, \cdot)$ . Induction gives

$$\mathbb{E}[v_{S_t} \mid w] = a\lambda^{-t}U_w x.$$

The decoder  $d_j(s) = \rho\lambda^N \langle e_j, v_s \rangle / a$  lies in  $[-1, 1]$  and gives (1.1). These are actual rows throughout the run, not independently chosen checkpoint factorizations. Carathéodory gives  $D + 1$  successors; there are  $|\mathcal{A}|k$  command rows, and their construction and storage remain uncharged.

The defining finite problem is semialgebraic: use convex coefficients for transformed vertices and a universal ball containment condition, then eliminate quantifiers. To prove (3.11), set  $e = \max_b \|U_b - V_b\|_{\text{op}}$ . For every feasible  $P$ ,  $V_b P \subseteq U_b P + e\mathbb{B}^D \subseteq (\lambda + e/a)P$ . Interchanging  $U, V$  completes the proof.  $\square$

The two profiles have different quantifiers. The converse tests every hidden machine; the enclosure theorem builds a particular positive realization. Neither theorem asserts that  $\lambda_{\mathcal{A}}$  is the

optimum over hidden machines. This is why finite-scale lower and upper bounds can be used even when they do not match.

**Proposition 3.6** (Bounded word recoding). *Suppose every command of  $\mathcal{A}$  is a product of exactly  $L$  commands of an alphabet  $\mathcal{B}$  on the same space, with the same seeds and queries. Then*

$$\Gamma_{\mathcal{A}}(k, B) \leq \Gamma_{\mathcal{B}}(k, LB), \quad \lambda_{\mathcal{A}}(k, a) \leq \lambda_{\mathcal{B}}(k, a)^L, \quad W_{N,\varepsilon}(\mathcal{A}) \leq W_{LN,\varepsilon}(\mathcal{B}).$$

*An identity letter permits words of length at most  $L$  to be padded. If both alphabets contain an identity and admit such bounded recodings into the other, the existence and value of a logarithmic width exponent agree.*

*Proof.* Push forward a packet law along the word substitution to obtain the first inequality. Iterate the enclosure containments for the second. For the last inequality, compose the  $L$  stochastic rows of a  $\mathcal{B}$  machine into one row for the corresponding  $\mathcal{A}$  command, retaining only the block-end label. All rows may depend on the external epoch. This is an implementation of the atomic  $\mathcal{A}$  interface, not a claim that its physical letters cost  $L$  letters. Applying the two comparisons and monotonicity under final identity padding proves the exponent statement.  $\square$

**Corollary 3.7** (Packing–dilation balance). *Fix a calibrated experiment, an inradius  $a > \rho$ , and positive numbers  $u, v$ . Suppose that for every sufficiently large  $k$  there are a length  $B(k) \leq Ck^u$  and a word law for which*

$$\sup_{x,z \in \mathbb{S}^{D-1}} p\{w : \|U_w x - z\| < ck^{-v}\} \leq (2k)^{-1}.$$

*Suppose also that  $\lambda_{\mathcal{A}}(k, a) \leq \exp(C'k^{-u-2v})$ . Then*

$$W_{N,\varepsilon} = \Theta(N^{1/(u+2v)}).$$

*The same conclusion holds with  $u = 0$  when the lengths are uniformly bounded.*

*Proof.* Proposition 3.4 gives  $\Gamma(k, B(k)) \geq c^2 k^{-2v}/4$ . Equation (3.8) implies  $N \leq C_1 k^{u+2v}$  for a feasible peak  $k$ . Conversely choose  $k$  at a sufficiently large constant times  $N^{1/(u+2v)}$  so that  $C'Nk^{-u-2v} \leq \log(a/\rho)$ , and apply Theorem 3.5. The hypotheses concern finite word orbits and compatible convex containments, and impose no commutativity on the matrices.  $\square$

#### 4. EXACT OPTIMIZATION OF PLANAR PACKETS

For a rotation alphabet, let  $z_1, \dots, z_M \in \mathbb{S}^1 \subset \mathbb{C}$  be the distinct product phases of words of length  $B$ , ordered cyclically. A common rotation of all phases can be absorbed into the decoder centers. The initial direction in (3.1) therefore disappears. Any probability distribution on these phases is implemented by a distribution on representative words of the same length.

Let  $\mathfrak{P}_k$  be the finite set of partitions of the cyclically ordered list into at most  $k$  nonempty consecutive arcs. For  $p \in \Delta_M$ , set

$$(4.1) \quad F_k(p) = \max_{\mathcal{P} \in \mathfrak{P}_k} \sum_{A \in \mathcal{P}} \left| \sum_{i \in A} p_i z_i \right|.$$

**Theorem 4.1** (Optimal word laws as a cone program). *For the planar alphabet above,*

$$(4.2) \quad \Gamma_{\mathcal{A}}(k, B) = 1 - \min_{p \in \Delta_M} F_k(p).$$

*Equivalently, minimize  $t$  subject to  $p \in \Delta_M$  and, for every  $\mathcal{P} \in \mathfrak{P}_k$ ,*

$$(4.3) \quad \left\| \sum_{i \in A} p_i (\Re z_i, \Im z_i) \right\|_2 \leq r_{\mathcal{P},A} \quad (A \in \mathcal{P}), \quad \sum_{A \in \mathcal{P}} r_{\mathcal{P},A} \leq t.$$

*This is a finite second-order cone program with attained optimum. A fixed law can be evaluated by cyclic segmentation in  $O(kM^3)$  arithmetic operations, including computation of all interval sums. The optimization over laws may have exponentially many partition constraints.*

*Proof.* For fixed centers  $v_1, \dots, v_k$  assign each phase to a nearest center in chordal distance; equivalently maximize  $\Re(\bar{v}_j z_i)$ . Distinct centers have connected cyclic Voronoi arcs, bounded by the angular midpoints of adjacent centers. Ties can be assigned consecutively; coincident centers can be merged. For the induced partition, the contribution of a block  $A$  is at most  $|\sum_{i \in A} p_i z_i|$ .

Conversely, for any cyclic partition choose the center of each block in the direction of its weighted complex sum, arbitrarily if that sum vanishes. The best assignment to those centers has value at least the sum in (4.1). Thus the maximum over centers equals  $F_k(p)$ . This proves (4.2); introducing the norm epigraphs proves (4.3). Zero weights follow either directly or by continuity from positive weights.

For a fixed cyclic cut, prefix sums give every block vector in constant time. The usual recurrence for the best  $j$  blocks among the first  $m$  points checks at most  $M$  previous split positions. It costs  $O(kM^2)$  for that cut. Repeating for the  $M$  cuts costs  $O(kM^3)$ . This recurrence evaluates a given law; it is not a polynomial-size representation of all constraints in (4.3). Compactness of the simplex and continuity give attainment.  $\square$

Nearest-center partitions and vector quantization are classical [5]. The additional optimization here chooses the distribution of actual command words, and Theorem 3.3 turns its value into a constraint on arbitrary hidden registers. There is no assertion that static quantization alone characterizes the least whole-run width.

**Proposition 4.2** (A finite exact packet certificate). *For the alphabet consisting of identity and a quarter turn, at word length three the four distinct phases are  $1, i, -1, -i$ . Their uniform law is optimal and*

$$\Gamma(1, 3) = 1, \quad \Gamma(2, 3) = 1 - \frac{1}{\sqrt{2}}, \quad \Gamma(3, 3) = \frac{2 - \sqrt{2}}{4}, \quad \Gamma(k, 3) = 0 \quad (k \geq 4).$$

*Proof.* The distortion is concave in the phase law and invariant under its four cyclic rotations. Averaging any law over those rotations proves optimality of the uniform law. For two centers, adjacent pairs give total  $\sqrt{2}/2$ ; a triple and a singleton give only  $1/2$ . For three centers, one pair and two singletons give  $\sqrt{2}/4 + 1/2$ . For one center the sum is zero; four centers fit all phases. Formula (4.2) gives the values. A uniform phase law is realized by the four ordinary words with zero, one, two or three initial quarter turns and then idle commands.  $\square$

For algebraic rotation matrices, both the general quantifier-elimination formulation and the cone program have algebraic coefficients. No finite list of spherical harmonics is used. For merely computable-real entries, finite numerical approximations are diagnostics unless a rigorous error enclosure is supplied; (3.3) then quantifies how an entry enclosure propagates to a packet certificate.

**Corollary 4.3** (Separated phases). *If  $M \geq 2k$  distinct length- $B$  word phases have pairwise circular distance at least  $s \in (0, 1/2]$ , then  $\Gamma_A(k, B) \geq s^2$ .*

*Proof.* Use their uniform law. Each open arc of circular radius  $s/2$  contains at most one phase. At least half the mass is at distance at least  $s/2$  from every one of  $k$  centers. On  $[0, 1/2]$ ,  $1 - \cos(2\pi t) = 2\sin^2(\pi t) \geq 8t^2$ . The average loss is at least  $s^2$ . This is a lower certificate for (4.2), not necessarily its exact value.  $\square$

## 5. ARITHMETIC PROFILES AT EVERY FINITE SCALE

Now  $\mathcal{A}_\alpha = \{I, R_{2\pi\alpha_1}, \dots, R_{2\pi\alpha_r}\}$ , with  $r$  fixed. Define

$$(5.1) \quad \psi_\alpha(H) = \min_{0 < \|m\|_1 \leq H} \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}}, \quad \eta_\alpha(q) = \max_{1 \leq i \leq r} \|q\alpha_i\|_{\mathbb{R}/\mathbb{Z}}.$$

These are finite functions of the alphabet parameters. The first may vanish in the presence of a rational relation. The upper profile remains usable in that case.

**Theorem 5.1** (Finite arithmetic bounds). *Let  $\kappa = \rho/\sqrt{2} - 2\varepsilon > 0$ . For a machine of peak  $K$ , put  $L = \lceil (2K)^{1/r} \rceil$  and  $B = r(L - 1)$ . Then*

$$(5.2) \quad \lfloor N/B \rfloor \psi_\alpha(B)^2 \leq \log(1/\kappa).$$

For every integer  $q \geq 4$ ,

$$(5.3) \quad N\eta_\alpha(q) \leq q^2/100 \implies W_{N,0}(\alpha) \leq q.$$

Consequently every finite planar rotation alphabet satisfies

$$(5.4) \quad W_{N,0}(\alpha) \leq \max(4, \lceil \sqrt{50N} \rceil).$$

All upper bounds use common command rows and hold also after adjoining reflection in the first coordinate axis.

*Proof.* Construct a word of length  $B$  in  $r$  consecutive segments of  $L - 1$  positions. In segment  $i$  give  $J_i$  copies of the  $i$ th rotation followed by idle commands, independently and uniformly for  $J_i \in \{0, \dots, L - 1\}$ . Differences of count vectors have  $\ell_1$  norm at most  $B$ . If  $\psi_\alpha(B) > 0$ , the  $L^r \geq 2K$  phases are distinct and separated by  $\psi_\alpha(B)$ . Corollary 4.3 and (3.8), with  $-\log(1-x) \geq x$ , give (5.2). If the minimum is zero the displayed inequality is automatic. All letters in a segment are actual commands, not a free count input.

For the upper bound let  $P_q$  be the regular  $q$ -gon inscribed in the unit circle. Choose nearest integers  $p_i$  to  $q\alpha_i$ , and put  $\delta_i = 2\pi(\alpha_i - p_i/q)$ , so  $|\delta_i| \leq \pi/q$ . Elementary chord geometry gives

$$(5.5) \quad R_{2\pi\alpha_i}P_q \subseteq \Lambda_i P_q, \quad \Lambda_i = \frac{\cos(\pi/q - |\delta_i|)}{\cos(\pi/q)}, \quad \log \Lambda_i \leq \frac{4\pi^2\eta_\alpha(q)}{q^2}.$$

Indeed the ray of a rotated vertex meets a neighboring edge at radial coordinate  $\cos(\pi/q)/\cos(\pi/q - |\delta_i|)$ . Integrating the derivative of  $\log \cos(\pi/q - t)$  bounds the logarithm by  $|\delta_i| \tan(\pi/q)$ , and  $\tan(\pi/q) \leq 2\pi/q$  for  $q \geq 4$ .

Take  $\Lambda = \max_i \Lambda_i$ , including one for the identity. Under (5.3),  $\Lambda^N \leq e^{\pi^2/25} < 2$ . Since  $P_q$  contains the half-unit disk, Theorem 3.5 with  $a = 1/2$  applies:  $\rho\Lambda^N \leq 1/5 < 1/2$ . Explicitly, initialize at mean  $x/2$ , represent  $\Lambda^{-1}R_{2\pi\alpha_i}v_s$  by the vertices for each row, and decode by  $2\rho\Lambda^N \langle e_j, v_s \rangle$ . This verifies every numerical word, including any deterministic remainder of a converse packet decomposition.

There are  $(r + 1)q$  common command rows and two decoder columns, each row having at most three successors. These counts exclude row-description and arithmetic costs. Since  $\eta_\alpha(q) \leq 1/2$ , (5.4) follows. Reflection preserves  $P_q$ ; its contracted image uses the same vertex set. The reflected lower bound is obtained simply by restricting to rotation-only words.  $\square$

The pair  $(\psi_\alpha, \eta_\alpha)$  is a specialization of the word-distortion and enclosure profiles. It is not assumed to characterize exact finite width. In particular, (5.2) can be weak when long word packets have clusters; the optimized profile of Section 4 is available without that separation relaxation.

**Lemma 5.2** (Denominators under a general power bound). *Suppose for  $\tau \geq r$  and  $b > 0$ ,*

$$(5.6) \quad \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \geq b \|m\|_1^{-\tau} \quad (m \neq 0).$$

*For every integer  $Q \geq 2$  there is  $q$  with*

$$(5.7) \quad cQ^{r/(\tau+1-r)} \leq q \leq Q^r, \quad \eta_\alpha(q) \leq Q^{-1}, \quad c = (b/r^{\tau+1})^{r/(\tau+1-r)}.$$

*Proof.* The  $Q^r + 1$  points  $j\alpha$  in  $Q^r$  equal torus boxes give integers  $p_i, q$  with  $1 \leq q \leq Q^r$  and  $|q\alpha_i - p_i| \leq Q^{-1}$ . For  $M = \lfloor q^{1/r} \rfloor$ , the  $(M+1)^r > q$  integer vectors in  $\{0, \dots, M\}^r$  have a residue collision for  $m \cdot p \pmod{q}$ . Subtracting gives  $m \neq 0$  with  $H = \|m\|_1 \leq rq^{1/r}$  and  $q \mid m \cdot p$ . Thus

$$bH^{-\tau} \leq \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \leq H/(qQ), \quad bqQ \leq r^{\tau+1}q^{(\tau+1)/r}.$$

Rearranging yields (5.7). This direct residue argument supplies exactly the quantitative transference needed here, without an unspecified transference constant.  $\square$

**Corollary 5.3** (Power bounds at finite Diophantine type). *Under (5.6), for constants depending on the fixed data,*

$$(5.8) \quad c_1 N^{r/(2\tau+1)} \leq W_{N,\varepsilon}(\alpha) \leq C_1 N^{\min\{1/2, r(\tau+1-r)/(\tau+1+r)\}}.$$

*No matching claim is made when  $\tau > r$ .*

*Proof.* From (5.2),  $N < B + b^{-2}B^{2\tau+1} \log(1/\kappa)$ , while  $B \leq r(2K)^{1/r}$ . This gives the lower power after adjusting finitely many initial horizons. Lemma 5.2 bounds  $N\eta_\alpha(q)/q^2 \leq c^{-2}NQ^{-1-2r/(\tau+1-r)}$ . Choose  $Q$  at constant times  $N^{(\tau+1-r)/(\tau+1+r)}$ , large enough to satisfy (5.3) and  $q \geq 4$ . Then  $q \leq Q^r$  proves the second candidate upper power; (5.4) proves the first.  $\square$

**Corollary 5.4** (The retained badly approximable law). *If (5.6) holds with  $\tau = r$ , then  $W_{N,\varepsilon}(\alpha) = \Theta(N^{r/(2r+1)})$ , also with the reflection extension. This is the previously established matched law [8].*

*Proof.* Substitute  $\tau = r$  in (5.8); the two powers coincide.  $\square$

For  $1, \alpha_1, \dots, \alpha_r$  rationally independent, every optimized finite-block action gap on the circle is zero. Indeed simultaneous approximation supplies unbounded frequencies  $n$  with every  $n\alpha_i$  close to an integer. Each fixed rotation word then acts almost identically on its Fourier mode. For the reflected alphabet use the real cosine mode, which reflection fixes. This is the established almost-invariance argument, not a claim that the finite packet distortion vanishes.

## 6. MINIMAL ORDINARY TYPE AND ALMOST-EVERYWHERE WIDTHS

Uniform bad approximation is substantially stronger than the condition needed to determine the logarithmic width exponent. We first deduce the minimal-type assertion without any measure-theoretic hypothesis.

*Proof of (1.3) in Theorem 1.1.* If  $\omega^*(\alpha) = r$ , then for every  $h > 0$  there is  $b_h > 0$  such that

$$\|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \geq b_h \|m\|_1^{-r-h} \quad (m \neq 0).$$

Indeed the definition of the limsup gives this inequality for all sufficiently large  $\|m\|_1$ , and rational independence makes the finite remaining minimum positive. Apply Corollary 5.3 with  $\tau = r + h$ . It gives

$$\frac{r}{2r+2h+1} \leq \liminf_N \frac{\log W_{N,\varepsilon}}{\log N} \leq \limsup_N \frac{\log W_{N,\varepsilon}}{\log N} \leq \frac{r(1+h)}{2r+1+h}.$$

Let  $h \downarrow 0$ . This proves (1.3). No positive uniform constant at exponent  $r$  was used.  $\square$

For completeness we prove a more quantitative metric statement, using only the summable part of metric Diophantine approximation. It does not claim a new metric theorem.

**Lemma 6.1** (A summable logarithmic separation). *For Lebesgue-almost every  $\alpha \in [0, 1]^r$ , and every  $s > 1$ , there is  $b_s > 0$  such that*

$$(6.1) \quad \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \geq \frac{b_s}{\|m\|_1^r (\log(2 + \|m\|_1))^s} \quad (m \neq 0).$$

*Such a vector has  $\omega^*(\alpha) = r$ .*

*Proof.* For a nonzero integer vector  $m$ , the map  $\alpha \mapsto m \cdot \alpha \pmod{1}$  sends Haar measure on the torus to uniform circle measure. There are at most  $C_r H^{r-1}$  integer vectors with  $\|m\|_1 = H$ . Hence the measures of the events

$$\|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} < [\|m\|_1^r (\log(2 + \|m\|_1))^s]^{-1}$$

have finite sum, bounded by a constant times  $\sum_{H \geq 1} [H(\log(2 + H))^s]^{-1}$ . The measure of their tail union tends to zero. Almost every vector violates the unscaled inequality only finitely often. Remove the measure-zero rational hyperplanes and reduce the constant to cover the finite exceptions. Intersecting the full-measure sets for rational  $s > 1$  gives the assertion for every real  $s > 1$ .

This bound implies  $\omega^*(\alpha) \leq r$ . For the reverse inequality, place the  $(M + 1)^r$  values  $m \cdot \alpha \pmod{1}$ ,  $m \in \{0, \dots, M\}^r$ , in fewer than  $(M + 1)^r$  intervals of equal length. A collision gives a nonzero difference of norm at most  $rM$  and distance  $O(M^{-r})$ . As  $M \rightarrow \infty$  the norms of some such differences must tend to infinity, since rational independence excludes an exact relation. Thus  $\omega^*(\alpha) \geq r$ .  $\square$

**Proposition 6.2** (Quantitative bounds under logarithmic separation). *Suppose (6.1) holds for some  $s > 0$  and  $b_s > 0$ . Then there are  $c, C > 0$  such that*

$$(6.2) \quad cN^{r/(2r+1)}(\log(N+2))^{-2rs/(2r+1)} \leq W_{N,\varepsilon}(\alpha) \leq CN^{r/(2r+1)}(\log(N+2))^{2r^2s/(2r+1)}.$$

*Proof.* The packet bound (5.2) gives

$$N < B + b_s^{-2} B^{2r+1} (\log(2 + B))^{2s} \log(1/\kappa).$$

With  $B \leq r(2K)^{1/r}$  this implies  $N \leq C_0 K^{(2r+1)/r} (\log(2 + K))^{2s}$ . If  $K > N$ , the proposed lower bound is already true after reducing its constant. Otherwise  $\log(2 + K) \leq \log(2 + N)$ , and rearrangement proves the first inequality of (6.2).

For the upper inequality repeat the residue argument of Lemma 5.2. It produces  $q \leq Q^r$ ,  $\eta_\alpha(q) \leq Q^{-1}$  and  $H \leq rq^{1/r}$  with

$$\frac{b_s}{H^r (\log(2 + H))^s} \leq \frac{H}{qQ}.$$

Since  $q \leq Q^r$ , it follows for  $Q \geq 2$  that

$$(6.3) \quad q \geq c_0 \frac{Q^r}{(\log(Q+2))^{rs}}.$$

Indeed  $b_s q Q \leq H^{r+1} (\log(2 + H))^s \leq C_r q^{1+1/r} (\log(Q+2))^s$ , and raising the rearranged inequality to the  $r$ th power gives (6.3).

Choose an integer

$$Q = \left\lceil C_2 N^{1/(2r+1)} (\log(N+2))^{2rs/(2r+1)} \right\rceil.$$

For sufficiently large fixed  $C_2$ , (6.3) implies  $N\eta_\alpha(q)/q^2 \leq 1/100$  and  $q \geq 4$ . To see the constant choice explicitly, for large  $N$  one has  $\log(Q+2) \leq C_3 \log(N+2)$  with  $C_3$  fixed; thus the ratio is bounded by a constant times  $C_2^{-(2r+1)}$ . Enlarge the final constant for the finitely many initial horizons. Theorem 5.1 gives an exact machine with  $q \leq Q^r$  labels, proving the upper bound.  $\square$

*Completion of Theorem 1.1.* Apply Lemma 6.1 with  $s = 1 + \delta$  and then Proposition 6.2. This yields (1.4) on one full-measure set for all fixed  $\delta > 0$ . These statements concern a fixed alphabet before the horizon grows. None of their constants is asserted uniform in  $r$  or near a rational relation.  $\square$

**6.1. Rational dependencies without redundant exponents.** The number of listed rotations need not be the relevant arithmetic rank. The following result covers finite rational reparametrizations rather than assigning one exponent to every redundant letter.

**Corollary 6.3** (Finite rational extensions). *Suppose an alphabet contains  $I$  and rotations through angles  $\beta_1, \dots, \beta_d$ , where  $1, \beta_1, \dots, \beta_d$  are rationally independent and  $\omega^*(\beta) = d$ . Suppose every additional angle belongs to  $\mathbb{Q} + \sum_{j=1}^d \mathbb{Q}\beta_j$ . Then*

$$\lim_N \frac{\log W_{N,\varepsilon}}{\log N} = \frac{d}{2d+1}.$$

*The same assertion holds on a full-measure set of  $\beta$  with the logarithmic upper and lower powers of (1.4), replacing  $r$  by  $d$ . Reflection may be added. If all angles are rational, exact width is bounded independently of  $N$ .*

*Proof.* Restriction to the displayed  $d$ -angle subalphabet gives the lower bound. Choose one common denominator  $h$  and integers  $t_i, n_{ij}$  so that every angle is  $t_i/h + \sum_j n_{ij}\gamma_j$  with  $\gamma_j = \beta_j/h$ . Multiplication by  $h$  shows  $\|m \cdot \gamma\|_{\mathbb{R}/\mathbb{Z}} \geq h^{-1} \|m \cdot \beta\|_{\mathbb{R}/\mathbb{Z}}$ . Thus every separating power or logarithmic inequality for  $\beta$  holds for  $\gamma$  with a changed constant.

Take a simultaneous approximant  $p_j/q$  to  $\gamma$  from the proof above. A command's irrational part has residual angle at most  $2\pi(\sum_j |n_{ij}|)/(qQ)$ . The same polygon construction therefore works, after changing only fixed constants. Store in addition the rational phase  $c \in \mathbb{Z}/h\mathbb{Z}$ , updated by  $c \mapsto c + t_i$ . The decoder rotates the stored polygon vector by  $2\pi c/h$ . This uses  $hq$  labels, not an uncharged phase. Reflection sends  $c$  to  $-c$  and conjugates the polygon phase; the regular polygon and the construction are reflection-invariant. The exact expectation identity is unchanged. The finite multiplier  $h$  does not change a logarithmic exponent or the displayed logarithmic powers.

For a purely rational alphabet, choose a common period  $h$  and retain the seed identifier and the accumulated phase. This uses at most  $4h$  command labels for our four planar seeds, plus the held binary answer convention. No infinite-gap hypothesis is involved.  $\square$

## 7. EVERY IRRATIONAL ANGLE HAS CUBIC SCALES

We keep the two-letter alphabet  $\{I, R_{2\pi\alpha}\}$  and the planar resource and error conventions. No Diophantine lower bound is assumed in this section. The needed continued-fraction estimates are classical [3]; we include their short proof to specify the exact finite inequalities being used.

**Lemma 7.1** (Convergent separation). *Let  $p_n/q_n$  be the convergents of an irrational  $\alpha$ , ignoring the finitely many initial indices with repeated denominator. Then*

$$(7.1) \quad \frac{1}{q_{n+1} + q_n} < |q_n\alpha - p_n| < \frac{1}{q_{n+1}}, \quad \min_{1 \leq l < q_n} \|l\alpha\|_{\mathbb{R}/\mathbb{Z}} > \frac{1}{q_n + q_{n-1}} > \frac{1}{2q_n}.$$

*Proof.* The convergent recurrences imply  $p_n q_{n-1} - p_{n-1} q_n = \pm 1$  and alternating signs of  $e_n = q_n \alpha - p_n$ . If  $\xi$  is the next complete quotient, then

$$\alpha = \frac{p_n \xi + p_{n-1}}{q_n \xi + q_{n-1}}, \quad a_{n+1} < \xi < a_{n+1} + 1.$$

It follows that  $|e_n| = 1/(q_n \xi + q_{n-1})$ , proving the first pair.

For  $0 < l < q_n$  and an integer  $p$ , the determinant identity writes  $(p, l) = a(p_n, q_n) + b(p_{n-1}, q_{n-1})$  with integers  $a, b$ . Here  $b \neq 0$ ;  $a, b$  cannot both be positive, and cannot both be negative. If  $a = 0$

the error has modulus at least  $|e_{n-1}|$ . Otherwise they have opposite signs, so  $ae_n$  and  $be_{n-1}$  have the same sign and again  $|l\alpha - p| \geq |e_{n-1}|$ . Minimize over  $p$  and apply the first pair with index  $n - 1$ . This proves the remaining inequalities.  $\square$

**Theorem 7.2** (Universal cubic subsequences). *Set  $\kappa = \rho/\sqrt{2} - 2\varepsilon > 0$ ,  $C_\kappa = 8(1 + \log(1/\kappa))$ , and*

$$M_n = \lceil C_\kappa q_n^3 \rceil, \quad m_\kappa = \lceil 100(C_\kappa + 1) \rceil.$$

*For all sufficiently large  $n$ ,*

$$(7.2) \quad q_n/2 < W_{M_n, \varepsilon}(\alpha) \leq m_\kappa q_n.$$

*The upper bound is exact, uses common command rows and requires no regularity of the partial quotients.*

*Proof.* Use words of length  $B = q_n - 1$  whose number of initial active letters ranges uniformly over  $0, \dots, q_n - 1$ . Lemma 7.1 gives  $q_n$  distinct phases with separation greater than  $1/(2q_n)$ . If the proposed peak  $K$  were at most  $q_n/2$ , Corollary 4.3 and the packet budget would give

$$\left\lfloor \frac{M_n}{q_n - 1} \right\rfloor \frac{1}{4q_n^2} \leq \log(1/\kappa).$$

The left side is at least  $C_\kappa/4 - 1/(4q_n^2)$ , strictly greater than the right side. This proves the lower bound against all hidden-state machines.

For the upper bound use the polygon denominator  $Q_n = m_\kappa q_n$ . Distance to the nearest integer is subadditive, so

$$\|Q_n \alpha\|_{\mathbb{R}/\mathbb{Z}} \leq m_\kappa |q_n \alpha - p_n| < m_\kappa / q_{n+1} \leq m_\kappa / q_n.$$

Consequently  $Q_n^2 / [100 \|Q_n \alpha\|_{\mathbb{R}/\mathbb{Z}}] > m_\kappa q_n^3 / 100 \geq (C_\kappa + 1) q_n^3 \geq M_n$ . Equation (5.3) gives the exact upper construction. The constants have been chosen for transparency, not optimality.  $\square$

**Proposition 7.3** (Resonant long horizons). *For any irrational  $\alpha$  and integer  $q \geq 4$  with  $N_q = \lfloor q^2 / (100 \|q\alpha\|_{\mathbb{R}/\mathbb{Z}}) \rfloor \geq 1$ , one has  $W_{N_q, 0}(\alpha) \leq q$ . If  $\alpha$  is Liouville, there is a sequence  $N \rightarrow \infty$  on which  $\log W_{N, \varepsilon}(\alpha) / \log N \rightarrow 0$ .*

*Proof.* The first assertion is the finite enclosure implication (5.3). For a Liouville number choose arbitrarily large  $A$  and unbounded denominators  $q$  with  $0 < \|q\alpha\|_{\mathbb{R}/\mathbb{Z}} < q^{-A}$ . The first assertion then supplies horizons  $N_q \geq q^{A+2}/200$  for large  $q$ , with width at most  $q$ . The logarithmic ratio is at most  $1/(A+2) + o(1)$ . A diagonal sequence with  $A \rightarrow \infty$  proves the claim, since widths are at least two.  $\square$

*Proof of Theorem 1.2.* Equation (7.2) and  $M_n = \Theta(q_n^3)$  give the first assertion and a subsequence of logarithmic exponent  $1/3$ . Proposition 7.3 gives the zero lower limit for Liouville angles, and (5.4) gives the upper limit at most  $1/2$ .

It remains to verify unboundedness, which does not follow from a subsequence alone. Fix any proposed width  $K$ . The  $2K$  phases of counts  $0, \dots, 2K - 1$  are distinct for an irrational angle and have some positive minimum separation  $s_K$ . Independent words of length  $2K - 1$  imply  $\lfloor N/(2K - 1) \rfloor s_K^2 \leq \log(1/\kappa)$  for a width- $K$  machine. This fails for all sufficiently large  $N$ . Thus  $W_{N, \varepsilon} \rightarrow \infty$ .  $\square$

**Corollary 7.4** (An explicit fluctuating alphabet). *Let  $\alpha_L = \sum_{j=1}^{\infty} 10^{-j!}$ . For  $q_m = 10^{m!}$  and all large  $m$ , the horizon*

$$N_m = \lfloor q_m^{m+2} / 200 \rfloor$$

*admits an exact machine with at most  $q_m$  labels. The same fixed two-letter alphabet also has the cubic subsequences of Theorem 7.2; hence no single logarithmic width exponent exists. Adding reflection preserves these conclusions.*

*Proof.* The first  $m$  summands have denominator dividing  $q_m$ , and their remaining positive tail is less than  $2 \cdot 10^{-(m+1)!}$ . Thus  $0 < \|q_m \alpha_L\|_{\mathbb{R}/\mathbb{Z}} < 2q_m^{-m}$  for large  $m$ , proving the horizon bound by (5.3). The same tail estimates preclude rationality and show the Liouville property. The general cubic theorem applies. Reflection leaves the upper polygons invariant, while the rotation-only test words give the same lower bounds.  $\square$

These theorems describe different scales of one and the same experiment. A small label count on a long resonant horizon is not a constant-width simulator for all horizons, and it need not persist across the gaps between successive approximants. The exact finite optimum and the Liouville upper logarithmic limit remain separate quantitative questions. None of the proofs substitutes approximate output for the exact upper realizations.

## 8. ARITHMETIC, QUANTIZATION AND NUMERICAL SEMANTICS

Kronecker quasi-uniformity. Dick–Goda–Larcher–Pillichshammer–Suzuki [4], Theorem 3.9, characterize quasi-uniformity of the multidimensional sequence  $n\alpha \pmod{\mathbb{Z}^r}$  by the simultaneous bound  $\eta_\alpha(q) \geq cq^{-1/r}$ . Their Lemma 3.11 bounds ratios of successive best simultaneous denominators; Section 3.3 also contains the vector  $(2^{1/(r+1)}, \dots, 2^{r/(r+1)})$ . These are direct arithmetic antecedents, not new examples of this paper.

Our packet points instead have the form  $m \cdot \alpha \pmod{1}$ . The relevant separation is dual. The residue argument of Lemma 5.2, with an arbitrary nearest-integer numerator and  $\eta_\alpha(q)$  in place of  $Q^{-1}$ , proves directly that a dual bound with exponent  $r$  implies

$$\eta_\alpha(q) \geq br^{-r-1}q^{-1/r}.$$

Thus the cited quasi-uniformity theorem applies to the uniform badly approximable class used in the predecessor. Its denominator control supplies the arithmetic scales for a polygon upper bound. It supplies neither a compatible stochastic transition table nor a lower bound against discarded hidden history. The logarithmic separation of Lemma 6.1 is weaker than a uniform badly approximable inequality; it is proved by a summable tail estimate, not asserted to imply quasi-uniformity.

What is dynamic in the paired profiles. The geometry of nearest-center distortion and convex hull approximation is classical [5, 11]. A static  $k$ -center factorization does not specify how its encoder is calculated without retaining discarded inputs. Conversely, a convex codebook does not force arbitrary hidden states to possess coordinates in that codebook. The two implications in Section 3 avoid both identifications: the converse conditions on the actual state, and the upper theorem provides the same legal rows throughout the run. The packing–dilation balance in Corollary 3.7 is a conditional theorem on independently specified finite profiles, not a claimed equality of static and dynamic optima.

The circle program makes one of these profiles exactly finite, whereas the all-harmonic action-gap optimization of the predecessor remains infinite-dimensional. A finite word length can be exhaustively listed; an unbounded harmonic degree cannot be certified by a finite truncation without a tail theorem. No general action-gap algorithm follows from Proposition 3.1.

Branching programs and probability preservation. At fixed horizon our machine is a probabilistic ordered read-once layered program with arbitrary stochastic rows and bounded real output columns. We distinguish width from total size, uniform description and random-bit complexity. Fourier growth for regular, permutation and width-three branching programs concerns different hypotheses and objectives [9, 10, 6]. Circle-walk harmonic damping and its arithmetic behavior are also established subjects [2]. Our converse can use correlated letters inside independently sampled complete packets; it is not a theorem about average error under fair independent letters.

Preserving a strict cutpoint sign is weaker than preserving a numerical probability. The predecessor’s constant-width sign construction contracts the output amplitude with length and

hence does not contradict the present width growth. Here signal and tolerance are fixed, one query is selected after the word, and neither joint answers nor anytime correctness is required. Exact upper rows in this article are atomic real kernels, not finite-fair-bit algorithms. A row with three successors can still have costly or irrational coefficients.

Conclusions. The finite optimized word profile and the compatible enclosure profile retain quantitative information which qualitative gap data discard. They yield a minimal-type exponent and an almost-everywhere logarithmic estimate, and they exhibit fluctuating numerical width for every Liouville single angle. The reflected versions show that these conclusions survive a particular noncommuting finite extension, without asserting a classification of arbitrary noncommuting nongapped alphabets.

Exact finite widths, the Liouville upper logarithmic limit, optimal enclosure shapes and a general comparison between the two profiles remain distinct quantitative problems. The results here do not depend on a new external spectral-gap computation. The earlier expansion, calibration and representation theorems retain their original hypotheses in the unchanged supporting article.

# GENERAL THETA FOUNDATIONS I: ALPHABET DYNAMICS AND CALIBRATED NUMERICAL MEMORY

QIAN QI

**ABSTRACT.** We distinguish the geometry of a numerical experiment from the dynamics of its command alphabet. For a planar alphabet consisting of the identity and  $r$  rotations whose angles satisfy a dual badly approximable inequality, we prove that the minimum hidden stochastic width is  $\Theta(N^{r/(2r+1)})$ , including every fixed sufficiently small uniform error. Every finite-block optimized action gap is zero. Thus one circle action, one orbit space and one minimum orbit dimension support infinitely many distinct width exponents. The proof pairs a multivariate command-packet converse with an exact common-row polygon realization. For general orthogonal actions we optimize the command law, characterize finite-block expansion by the spectral radius of the uniform action average, and give a rational two-letter example with zero optimized one-step gap but positive two-step gap. We also turn the query-calibrated activation into a finite algebraic optimization, with a semidefinite upper certificate, explicit multiplicity examples and query-frame perturbation bounds. The resource throughout is nonuniform clocked atomic-row label width: tables and arithmetic are free, the horizon is fixed, and one terminal numerical query is answered.

## 1. INTRODUCTION

A finite numerical experiment prescribes probabilities, rather than only signs of probabilities relative to a threshold. Even when its linear response space has fixed dimension, a positive stochastic realization may need a growing number of persistent labels. Two features of the specification must be kept separate: the compact action generated by its commands, and the finite words that implement that action. The second feature is not determined by the first.

The experiment studied here has response

$$(1.1) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, A_w x \rangle}{2}, \quad A_w = A_{a_N} \cdots A_{a_1}.$$

The seed set is finite, the command alphabet is fixed, and exactly one coordinate query arrives after  $N$  commands. A simulator must satisfy the specification on every word. Its rows may vary with the epoch, and the simulator may be redesigned for each  $N$ . The minimum peak label count at binary total-variation error at most  $\varepsilon$  is denoted by  $W_{N,\varepsilon}$ .

For an expanding irreducible action, the earlier occupation and orbit-synthesis theorems give a width exponent equal to half the smallest nonzero orbit dimension. Their proofs are reproduced in the appendices. Expansion is sufficient, but neither a description of all alphabets nor a necessary condition for a growing width. Our first result addresses a class in which every finite-block norm-gap certificate vanishes.

**Theorem 1.1** (A nongapped alphabet hierarchy). *Let  $r \geq 1$  be fixed. Suppose  $\alpha \in \mathbb{R}^r$  and  $b_* > 0$  satisfy*

$$(1.2) \quad \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \geq b_* \|m\|_1^{-r} \quad \text{for every } m \in \mathbb{Z}^r \setminus \{0\}.$$

*Take the planar commands  $I, R_{2\pi\alpha_1}, \dots, R_{2\pi\alpha_r}$ , seeds  $\{\pm e_1, \pm e_2\}$ , and the two coordinate queries. For fixed  $0 < \rho \leq 1/10$  and  $0 \leq \varepsilon < \rho/(2\sqrt{2})$ ,*

$$(1.3) \quad W_{N,\varepsilon} = \Theta_{\alpha,r,\rho,\varepsilon}(N^{r/(2r+1)}).$$

*The lower bound allows arbitrary hidden stochastic states and time-dependent rows. An exact upper realization has common command rows and an  $N$ -dependent decoder. The same order holds after adjoining a reflection. Every finite-block optimized action gap of either alphabet is zero.*

The hypotheses have explicit examples in every  $r$ : put  $\xi = 2^{1/(r+1)}$  and  $\alpha_i = \xi^i$ . An algebraic-norm calculation proves (1.2) with  $b_* = (2/9)^r$ . The rotation matrices in this example have computable-real entries; algebraicity of the angles is not asserted to make those entries algebraic. The cases  $r = 1, 2, 3$  give exponents  $1/3, 2/5, 3/7$ . The connected effective action is the standard  $\text{SO}(2)$  action in all of them. Its minimum orbit dimension is always one. Section 6 proves the theorem, including every command in a packet and every persistent upper-state label.

A second distinction already occurs before the genuinely nongapped regime. Let  $V_a$  be the Koopman command operators on the complement of invariant functions. For a probability law  $p$ , write

$$g(p) = 1 - \|\sum_a p(a)V_a\|^2, \quad g_1^*(\mathcal{A}) = \max_{p \in \Delta(\mathcal{A})} g(p).$$

The optimized quantity depends only on the alphabet and action. Repeating this optimization over laws on actual length- $L$  words gives  $g_L^*$ . We prove that some  $g_L^* > 0$  if and only if the uniform one-step average has spectral radius less than one. This need not mean its norm is less than one. A two-letter rational  $\text{SO}(3)$  alphabet has  $g_1^* = 0$  but  $g_2^* > 0$ , and consequently linear numerical width. The proof of its positive block gap uses an explicitly identified qualitative algebraic spectral-gap theorem, not a numerical harmonic truncation.

The error tolerance is also part of the actual experiment. The canonical activation constant involves both an irreducible copy and the physical query basis. Section 4 gives an exact finite projection formulation, a semidefinite relaxation with a dual certificate, and a frame reconstruction problem with quantitative stability. It distinguishes these finite problems from infinite-dimensional gap positivity.

| Notation            | Meaning                                                      |
|---------------------|--------------------------------------------------------------|
| $W_{N,\varepsilon}$ | Peak available atomic labels; includes a held binary output. |
| $g_L^*, r_L$        | Optimized length- $L$ squared gap and complementary norm.    |
| $s_\lambda$         | Smallest orbit dimension in a nontrivial irreducible type.   |
| $c_\lambda$         | Seed activation divided by the norm of query reconstruction. |
| $b_*, r$            | Dual Diophantine constant and number of rotation angles.     |

The new assertions are the multi-angle nongapped hierarchy, the alphabet/block formulation and its worked separation, and the finite calibration and stability results. The single-angle packet idea, entropy occupation estimate, uniform orbit bound and minimum-orbit compiler are inherited ingredients, identified as such. Convex spectral optimization, commutant structure, Diophantine approximation and transformation-group geometry are classical tools. No priority claim for those tools is made. The statement is about label width, not uniform computational space, total branching-program size or an exact finite integer optimum.

## 2. THE EXPERIMENT AND ITS CHARGED STATE

Fix orthogonal matrices  $A_a \in O(\mathbb{R}^D)$  indexed by a finite alphabet  $\mathcal{A}$ , a nonempty finite set  $X$  of unit seeds,  $0 < \rho \leq 1/10$ , and a horizon  $N \geq 1$ . The target is (1.1).

**Definition 2.1** (Clocked atomic-row realization). A realization consists of finite sets  $S_0, \dots, S_N$ , initial rows  $E_x \in \Delta(S_0)$ , stochastic matrices  $T_{t,a} : S_t \rightarrow \Delta(S_{t+1})$ , and columns  $d_j : S_N \rightarrow [-1, 1]$ . Its mean output on  $(x, w, j)$  is

$$E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j.$$

It has error at most  $\varepsilon$  if this differs from  $\rho\langle e_j, A_w x \rangle$  by at most  $2\varepsilon$  for every triple. Its width is  $\max(2, |S_0|, \dots, |S_N|)$ . Available labels count, including unused padding. The factor two includes a charged held output after the final Bernoulli row.

The seed and query are atomic input symbols. Only the updated label persists: no seed, previous command, persistent random tape, protocol tag or acquisition history is free. A row may sample an arbitrary known real distribution. The epoch, horizon, row table, table construction and lookup, and real arithmetic are free. Common-row constructions below use the same  $T_a$  at every command epoch, but their final decoder may depend on  $N$ . They are not anytime simulators. A rational fair-bit implementation is a different resource, with sampler states and a self-paced interface; no equality with the atomic optimum is inferred.

Let  $H = \langle A_a \rangle$  and let  $R$  be the invariant span of  $HX$ . Unless specified otherwise, geometric applications assume  $H$  connected. Its nontrivial real isotypic subspaces in  $R$  are denoted by  $R_\lambda$ , with irreducible models  $E_\lambda$  of dimension  $d_\lambda$ . Orthogonal projections and adjoints refer to the physical Euclidean structure. An isometric intertwiner  $J : E_\lambda \rightarrow R_\lambda \subseteq \mathbb{R}^D$  is not an input to the machine.

**2.1. Proof-side conditional centroids.** A wordwise converse may choose a distribution on commands without changing the specification. If commands are fresh and independent under that test law, a unit orbit process  $Y_t$  and the actual register satisfy

$$(2.1) \quad Z_t = \mathbb{E}[Y_t | S_t], \quad q_t = \mathbb{E}\|Z_t\|^2, \quad v_t = \mathbb{E}\|Z_t\|^2, \quad Z_{t+1} = \mathbb{E}[A_a Z_t | S_{t+1}].$$

Indeed, conditional on  $(S_t, a)$  the future row uses no other past information. The conditional-expectation projection identity and Jensen's inequality give

$$(2.2) \quad q_{t+1} \leq q_t, \quad \Delta_t := \mathbb{E}\|A_a Z_t - Z_{t+1}\|^2 = v_t - v_{t+1}, \quad \sum_{t < N} \Delta_t \leq 1.$$

The same identities hold at boundaries of independent complete command words; their internal commands need not be independent. All internal updates are first integrated into their endpoint kernel. No identity requiring a fresh independent bit is invoked inside such a word.

**Lemma 2.2** (Terminal calibration). *For a fixed unit seed, any realization with error  $\varepsilon$  satisfies*

$$(2.3) \quad q_N \geq \kappa := \rho/\sqrt{D} - 2\varepsilon.$$

*More generally, for an isometric intertwiner  $J$  and a seed with  $a = \|J^*x\| > 0$ , tracking  $Y_t = J^*A_w x/a$  yields*

$$(2.4) \quad q_N \geq \rho a/B(J) - 2\varepsilon, \quad B(J) = \|J^*\|_{\ell_\infty^D \rightarrow \ell_2^{d_\lambda}}.$$

*Proof.* Let  $d = (d_1, \dots, d_D)$ . Wordwise coordinate error bounds the norm of the difference between its mean and the target by  $2\varepsilon\sqrt{D}$ . Thus  $\mathbb{E}\langle Y_N, d(S_N) \rangle \geq \rho - 2\varepsilon\sqrt{D}$ , whereas its absolute value is at most  $\sqrt{D}q_N$ . For the second assertion apply  $J^*$  before pairing with the normalized constituent orbit. The error is at most  $2\varepsilon B(J)$  and  $\|J^*d(s)\| \leq B(J)$ . This proves (2.4). The pairings are analytical devices; only one query is answered.  $\square$

For fixed sizes the optimum error is attained: parameters range over a finite product of compact simplices and intervals, and the objective is a finite maximum of continuous functions. Bounds below therefore concern actual optimal final error, irrespective of cancellation between intermediate errors.

## 3. CANONICAL ALPHABET AND BLOCK GAPS

Let  $E$  be a nontrivial orthogonal representation of the effective group  $H$ . On  $L^2(\mathbb{S}(E))$  write  $V_a f(u) = f(A_a^{-1}u)$  and let  $\Pi$  be Haar averaging. All operators below are restricted to  $\mathcal{H} = (I - \Pi)L^2(\mathbb{S}(E))$ , which each  $V_a$  preserves. The complexification is used for adjoints and spectra. Define

$$(3.1) \quad r_1(\mathcal{A}) = \min_{p \in \Delta(\mathcal{A})} \|P(p)\|, \quad P(p) = \sum_a p(a)V_a, \quad g_1^* = 1 - r_1^2.$$

Equivalent orthogonal actions conjugate these operators. Adding a redundant compact presenting factor does not change them. Repeating a letter does not change the set of admissible averages, although it changes the particular uniform law.

**Proposition 3.1** (Optimization, full support and simultaneous laws). *The minimum in (3.1) is attained. The function  $g(p) = 1 - \|P(p)\|^2$  is concave and 2-Lipschitz in  $\ell_1$ . Its supremum on full-support laws equals  $g_1^*$ . Every full-support law has positive gap if and only if  $g_1^* > 0$ . If  $m = |\mathcal{A}|$  and  $u$  is uniform, then*

$$(3.2) \quad g(u) \geq g_1^*/m.$$

*More generally,  $q(a) \geq \tau p(a)$  for all letters implies  $g(q) \geq \tau g(p)$ . For finitely many represented types, individual positive optimized gaps can be certified by one common full-support law.*

*Proof.* Unitary norms give  $\|P(p) - P(q)\| \leq \|p - q\|_1$  and  $\|P(p)\| \leq 1$ . Continuity and compactness give attainment, and the square of a norm is convex. Squaring the preceding inequality gives the stated Lipschitz bound for gaps. Approximation of a maximizing law by its mixtures with the uniform law proves the supremum assertion, not attainment by a full-support optimizer.

If  $q = \tau p + (1 - \tau)p'$  and  $f \in \mathcal{H}$ , convexity of the squared norm yields

$$\|P(q)f\|^2 \leq \tau \|P(p)f\|^2 + (1 - \tau) \|P(p')f\|^2 \leq (1 - \tau g(p)) \|f\|^2.$$

This proves domination. Uniform  $u$  dominates  $p/m$  for every  $p$ . Any full-support law dominates a positive multiple of a maximizing law. Finally a mixture  $\sum_i w_i p_i$  dominates  $w_i p_i$  for each type's chosen law; a further positive uniform mixture gives full support. Alternatively (3.2) applies to all types at once. Optimizers need not be unique.  $\square$

Laziness can be priced precisely: if identity is already an allowed letter, adding it with weight  $\eta < 1$  loses at most the factor  $1 - \eta$  in this certificate. If it is not a letter, silently inserting idle steps changes the word interface. Nor does zero one-step gap imply zero gap after such a modification.

**3.1. A dual problem and the limit of finite truncation.** For unit  $f \in \mathcal{H}$ , let  $Q(f)$  be the real Gram matrix

$$Q(f)_{ab} = \operatorname{Re}\langle V_a f, V_b f \rangle, \quad \mathcal{C} = \overline{\operatorname{conv}}\{Q(f) : \|f\| = 1\}.$$

It is a compact convex subset of real positive semidefinite  $m$ -by- $m$  matrices with diagonal one.

**Proposition 3.2** (Finite-dimensional Gram dual). *One has*

$$(3.3) \quad r_1^2 = \min_{p \in \Delta_m} \max_{Q \in \mathcal{C}} p^T Q p = \max_{Q \in \mathcal{C}} \min_{p \in \Delta_m} p^T Q p.$$

*If  $r_{1,L}$  is the same norm minimum restricted to spherical harmonics of degrees at most  $L$ , then  $r_{1,L} \uparrow r_1$ . These finite problems are convex semidefinite programs when their blocks are supplied. They give upper bounds on  $g_1^*$ , not finite certificates of positive full gap without a tail estimate.*

*Proof.* For fixed  $p$ , the squared norm is  $\sup_f p^T Q(f) p$ . Taking the closed convex hull does not change the supremum. The expression is convex in  $p$  and affine in  $Q$ ; the compact convex minimax theorem proves (3.3). This is the usual convex spectral-design mechanism, not a new minimax principle; compare the finite-chain optimization in [11].

The harmonic spaces are invariant under orthogonal substitutions and Haar averaging. Their finite orthogonal sums increase densely. Consequently the truncated norms increase pointwise to the full norm. Take a subsequence of truncated minimizing laws converging to  $p_*$ . For every fixed  $L_0$ , continuity on its finite blocks gives  $\|P(p_*)\|_{\leq L_0} \leq \lim_L r_{1,L}$ . Taking the supremum over  $L_0$  gives  $r_1 \leq \lim_L r_{1,L}$ ; the reverse inequality is immediate. The block norm constraints are

$$\begin{pmatrix} tI & P_\ell(p) \\ P_\ell(p)^* & tI \end{pmatrix} \succeq 0 \quad (\ell \leq L),$$

with invariant subspaces removed. They describe a finite SDP. Convergence alone supplies no effective error bound for the omitted degrees. The set  $\mathcal{C}$  is finite-dimensional but is specified by all unit vectors in an infinite-dimensional space; its dual is not an effective positivity algorithm.  $\square$

**3.2. The block invariant.** For  $L \geq 1$ , give every word  $w \in \mathcal{A}^L$  its actual operator  $V_w$  and put

$$(3.4) \quad r_L = \min_{\pi \in \Delta(\mathcal{A}^L)} \left\| \sum_w \pi(w) V_w \right\|, \quad g_L^* = 1 - r_L^2.$$

A block is  $L$  ordinary inputs. This definition supplies a test law, not a larger free input symbol or an extra runtime register.

**Theorem 3.3** (Finite-block expansion). *Let  $M = m^{-1} \sum_a V_a$  on  $\mathcal{H}$ . The following are equivalent:*

- (1)  $g_L^* > 0$  for some finite  $L$ ;
- (2)  $\|M^L\| < 1$  for some finite  $L$ ;
- (3) the spectral radius of  $M$  is less than one.

*The equivalence remains true with  $M$  replaced by the average under any fixed full-support law. Also  $r_{L+L'} \leq r_L r_{L'}$ . For finitely many types with positive finite-block gaps, a common length and a common full-support word law work for all of them.*

*Proof.* The uniform product law assigns  $m^{-L}$  to every word and hence dominates  $m^{-L} \pi$  for any law  $\pi$ . Proposition 3.1, applied to word operators, gives

$$(3.5) \quad 1 - \|M^L\|^2 \geq m^{-L} g_L^*.$$

A fixed full-support law gives the same argument with the smallest product mass in place of  $m^{-L}$ . Thus (1) and (2) are equivalent. The spectral-radius formula  $\text{spr}(M) = \lim_n \|M^n\|^{1/n}$  gives (2)  $\Leftrightarrow$  (3). Concatenating independently chosen word laws proves submultiplicativity. A common multiple of the finitely many good lengths admits a positive gap for every type by repeating each type's good law; a full-support common word law dominates each one. All invariant complements refer to the original effective action.  $\square$

This equivalence identifies a genuine difference between norm and spectral radius of a nonnormal action average. It is not a claim that either can be certified by finitely many unaccompanied harmonic calculations. The next sections make the finite numerical calibration explicit, then apply this distinction to a rational alphabet.

#### 4. FINITE OPTIMIZATION OF THE ERROR CALIBRATION

Fix a nontrivial isotypic subspace  $R_\lambda$  of the reachable space and its orthogonal projection  $S_\lambda$ . All norms in this section use the actual coordinate queries of (1.1), not a freely rotated query

basis. Define

$$(4.1) \quad a_\lambda = \max_{x \in X, J} \|J^* x\|, \quad c_\lambda = \max_{x \in X, J} \frac{\|J^* x\|}{B(J)}, \quad J^* J = I,$$

where  $J : E_\lambda \rightarrow R_\lambda$  ranges over isometric intertwiners. This is the canonical isotypic convention: a displayed splitting into equivalent copies is not canonical.

**Theorem 4.1** (Projection formulation and algebraic evaluation). *Let  $d = d_\lambda$  and let  $\mathcal{P}_\lambda$  consist of the real matrices satisfying*

$$(4.2) \quad P = P^T = P^2, \quad \text{tr } P = d, \quad P = S_\lambda P S_\lambda, \quad P A_a = A_a P \quad (a \in \mathcal{A}).$$

Then

$$(4.3) \quad c_\lambda^2 = \max_{x \in X, P \in \mathcal{P}_\lambda} \frac{x^T P x}{\max_{\sigma \in \{-1, 1\}^D} \sigma^T P \sigma}, \quad \frac{a_\lambda}{\sqrt{D}} \leq c_\lambda \leq \frac{a_\lambda}{\sqrt{d}}.$$

*If the finite matrices, seeds and the certified isotypic projection are real algebraic, this number and an optimizing projection are real algebraic and can be obtained by a finite quantifier-elimination procedure.*

*Proof.* Norm duality and the extreme points of a cube give

$$(4.4) \quad B(J) = \max_{\|u\|=1} \|Ju\|_1 = \max_{\sigma \in \{-1, 1\}^D} \|J^* \sigma\|.$$

The projection  $P = JJ^*$  satisfies (4.2). Conversely any such projection has an invariant image inside one isotypic component. Its real dimension  $d$  forces that image to be one irreducible copy, so an isometric intertwiner onto it exists. The value of both numerator and denominator depends only on  $P$ , proving the identity. Averaging  $\sigma^T P \sigma$  over independent signs gives  $\text{tr } P = d$ , whereas  $\sigma^T P \sigma \leq \|\sigma\|^2 = D$ . Taking maxima yields the two inequalities.

The set of projections is compact and nonempty; the denominator is at least  $d$ . For any proposed squared value  $t$ , feasibility is the finite disjunction over seeds of (4.2) and

$$(4.5) \quad x^T P x \geq t \sigma^T P \sigma \quad \text{for every } \sigma \in \{-1, 1\}^D.$$

These are polynomial conditions of degree at most two in  $(t, P)$ . Real algebraic input is represented by defining polynomials and isolating intervals. Quantifier elimination over real closed fields, for example cylindrical algebraic decomposition [8], determines the compact feasible interval of  $t$ , its endpoint and a witness. Compact semialgebraic optimization over algebraic data has an algebraic endpoint and an algebraic witness. This is finite decidability, not a polynomial-time claim. There are exponentially many sign constraints. The certified projection is part of the input; no algorithm for discovering a compact-group spectral gap is hidden in this calculation.  $\square$

**4.1. The multiplicity models and a semidefinite certificate.** The real commutant of an isotypic component is a matrix algebra over  $\mathbb{F} = \mathbb{R}, \mathbb{C}$  or the quaternions. Its invariant real orthogonal projections of rank  $d$  correspond to rank-one Hermitian projections over  $\mathbb{F}$ . This follows by identifying the isotypic component with a multiplicity space tensored over the irreducible division-algebra commutant: invariant submodules correspond to  $\mathbb{F}$ -linear multiplicity subspaces, and adjoints correspond to Hermitian adjoints. In particular the rank constraint is essential in every commutant type. It is not replaced by a trace condition alone.

For a matrix  $M$ , write

$$\mathcal{E}_\lambda(M) = \int_H h S_\lambda M S_\lambda h^T dm_H(h).$$

This is the orthogonal projection onto the self-adjoint commutant supported on  $R_\lambda$ . With algebraic command matrices it can equivalently be computed as the orthogonal projection onto the solution

of the finite linear commutation equations. The integral explains its positivity; an integration oracle is unnecessary for that finite linear problem.

**Proposition 4.2** (A primal–dual upper certificate). *For each seed  $x$ , let  $v_x$  be the optimum of*

$$(4.6) \quad \begin{aligned} & \text{maximize } \text{tr}(xx^T Q), \\ & \text{subject to } Q \succeq 0, \quad Q = S_\lambda Q S_\lambda, \quad [Q, A_a] = 0, \quad \sigma^T Q \sigma \leq 1 \quad (\sigma \in \{-1, 1\}^D). \end{aligned}$$

*Then  $c_\lambda^2 \leq \max_x v_x$ . The dual for fixed  $x$  is*

$$(4.7) \quad \min_{y_\sigma \geq 0} \sum_\sigma y_\sigma, \quad \sum_\sigma y_\sigma \mathcal{E}_\lambda(\sigma \sigma^T) - \mathcal{E}_\lambda(xx^T) \succeq 0 \quad \text{on } R_\lambda.$$

*Both optima are attained and equal. An optimal nonzero  $Q$  of real rank  $d$  certifies equality with the corresponding projection optimization. Higher-rank solutions are only upper bounds.*

*Proof.* For an admissible  $P$ , set  $Q = P / \max_\sigma \sigma^T P \sigma$ . This is feasible and has objective equal to (4.3). The dual follows from the trace pairing in the self-adjoint commutant and positivity of  $Q$ . The feasible set is bounded: averaging its sign inequalities gives  $\text{tr } Q \leq 1$ . A sufficiently small positive multiple of  $S_\lambda$  is strictly feasible relative to the supported commutant. Taking all dual sign weights equal and large makes the dual constraint positive definite on  $R_\lambda$ , because the sign sum is a positive multiple of the identity. Finite-dimensional semidefinite strong duality gives equality and attainment. Finally a positive commuting matrix of rank  $d$  has one irreducible image; on that image its self-adjoint restriction is scalar. Hence  $Q = tP$ . Scaling to a saturated sign constraint recovers the original ratio. This last argument does not apply to higher commutant rank.  $\square$

**Proposition 4.3** (Computed calibrations). *For a multiplicity-one nontrivial representation filling the physical space of dimension  $D$ , with unit seeds,  $c = 1/\sqrt{D}$ . Thus the standard spherical, traceless complex Hermitian projective, and standard block  $\mathbb{R}^3 \oplus \mathbb{R}^2$  examples have respectively*

$$c = 1/\sqrt{D}, \quad c = 1/\sqrt{q^2 - 1}, \quad c_3 = 1/\sqrt{3}, \quad c_2 = 1/\sqrt{2}$$

*for unit coordinate seeds in their indicated blocks.*

*For  $m$  equivalent real-type copies in orthogonal physical coordinate blocks  $(\mathbb{R}^d)^m$ , assume the reachable isotypic space is the whole block space. Writing a seed as  $x = (x_1, \dots, x_m)$ , one has*

$$(4.8) \quad c = \frac{1}{\sqrt{d}} \max_{x \in X, i} \|x_i\|.$$

*For  $d = 3, m = 2$  and the two seeds  $(e_1, e_1)/\sqrt{2}$  and  $(e_1, -e_1)/\sqrt{2}$ , Euclidean activation is  $a = 1$  but query calibration is  $c = 1/\sqrt{6}$ .*

*Proof.* In multiplicity one the sole copy projection is  $I$ , and (4.4) gives  $B = \sqrt{D}$ . For a coordinate block replace  $I$  by its block projection. In the real-type multiplicity model, every isometric intertwiner is, up to an orthogonal change in the model,  $Ju = (a_1 u, \dots, a_m u)$  with  $\sum_i a_i^2 = 1$ . Thus

$$B(J) = \sqrt{d} \sum_i |a_i|, \quad \|J^* x\| = \left\| \sum_i a_i x_i \right\| \leq \sum_i |a_i| \max_i \|x_i\|.$$

Taking one nonzero  $a_i$  attains the resulting bound. The two displayed seeds activate the full two-copy space, and each block has norm  $1/\sqrt{2}$ ; a diagonal copy attains  $a = 1$ .  $\square$

The last example admits a short dual certificate as well. For the positive diagonal seed use the sign vector  $\sigma = (1, 1, 1, 1, 1, 1)$  and dual weight  $1/6$ . Twirling under the diagonal  $\text{SO}(3)$  action gives  $\mathcal{E}(xx^T) = \mathcal{E}(\sigma \sigma^T)/6$ . A diagonal-copy projection scaled by  $1/6$  is a matching feasible primal point. For the other seed change the signs of the last three coordinates. This certifies the value without a nonconvex numerical search.

**4.2. Physical query frames.** Let  $F : \mathbb{R}^D \rightarrow \mathbb{R}^m$  have rows of Euclidean norm at most one, and replace the coordinate means by  $\rho F A_w x$ . For a copy  $J$  that can be reconstructed from these queries, define

$$(4.9) \quad \beta_F(J) = \min_{LF=J^*} \|L\|_{\ell_\infty^m \rightarrow \ell_2^d}, \quad c_{\lambda,F} = \max_{x,J} \|J^* x\| / \beta_F(J).$$

The minimum is finite exactly when  $\ker F \subseteq \ker J^*$ . Maxima range only over such copies. If there is none, no positive calibration is inferred. Full column rank is a sufficient condition.

**Theorem 4.4** (Frame reconstruction and stability). *For fixed  $J$ , (4.9) is the finite second-order cone problem*

$$\min t \quad \text{subject to } LF = J^*, \quad \|L\sigma\| \leq t \quad (\sigma \in \{-1, 1\}^m).$$

*Its minimum is attained, and terminal calibration becomes  $q_N \geq \rho c_{\lambda,F} - 2\varepsilon$ . Duplicating a query does not change  $\beta_F$  or  $c_{\lambda,F}$ . Adding query rows can only increase the calibrated activation; deleting rows can decrease it or destroy reconstructibility.*

*For full-column-rank frames  $F, F'$  with the same number of rows, set  $\delta = \|F' - F\|_{2 \rightarrow 2}$ . With the same seed set,*

$$(4.10) \quad \frac{c_{\lambda,F}}{1 + \delta\sqrt{m}/\sigma_{\min}(F')} \leq c_{\lambda,F'} \leq (1 + \delta\sqrt{m}/\sigma_{\min}(F))c_{\lambda,F}.$$

*If finite seed sets have Hausdorff distance at most  $h$ , their calibrated activations for fixed  $F$  differ by at most  $h \max_j \|F_j\|$ .*

*Proof.* The sign formula for the operator norm gives the cone constraints. A bounded norm bounds every column of  $L$ , so minimizing sequences have convergent subsequences. Feasibility of  $LF = J^*$  is precisely the stated kernel condition. Applying  $L$  to the vector of decoder means reproduces the target constituent; its norm is at most  $\beta_F$  and its error at most  $2\varepsilon\beta_F$ . The proof of Lemma 2.2 then applies.

An added query can be ignored. Conversely, if a row is duplicated, sum the columns of  $L$  assigned to its duplicates. The new reconstruction norm cannot exceed the old one, since giving equal signs to those duplicate entries is a restriction of the old cube. These two inequalities prove equality for duplication.

Write  $\Delta = F' - F$  and use the Moore–Penrose left inverse  $F'^+$ . If  $LF = J^*$ , then

$$L' = L - L\Delta F'^+ \quad \text{satisfies} \quad L'F' = J^*.$$

Furthermore,

$$\|\Delta F'^+\|_{\infty \rightarrow \infty} \leq \delta\sqrt{m}/\sigma_{\min}(F'),$$

after bounding each output coordinate by its Euclidean norm. Thus  $\beta_{F'}(J) \leq \beta_F(J)(1 + \delta\sqrt{m}/\sigma_{\min}(F'))$ . Swap the frames for the reverse comparison, take ratios and maxima, and obtain (4.10). Finally  $\|J^*(x - x')\| \leq h$ . Since  $J^*Ju = u$ ,  $1 \leq \beta_F(J)\|FJu\|_\infty \leq \beta_F(J) \max_j \|F_j\|$  for unit  $u$ . This proves the seed bound. No uniform stability is implied as a query frame loses rank.  $\square$

These computations concern the sufficient terminal correlation used in a width converse. They do not assert that  $\rho c/2$  is the exact critical error of the whole experiment. In particular, the algebraic calibration procedure is not an algorithm for deciding infinite-dimensional expansion.

## 5. A BLOCK-EXPANDED WIDTH THEOREM AND A RATIONAL EXAMPLE

For connected  $H$ , let  $s_\lambda = \min_{\|u\|=1} \dim(Hu)$  in each active nontrivial type, and put  $\sigma_X = \max_\lambda s_\lambda$ . Here activation and reachability use the entire invariant seed span, not an arbitrary displayed decomposition into copies.

**Theorem 5.1** (Dominant finite-block expansion). *Suppose a type  $\lambda$  with  $s_\lambda = \sigma_X$  has  $g_L^* > 0$  for a fixed finite  $L$ . If  $R$  has dimension  $D_R$ ,  $0 < \rho \leq \min(1/10, 1/(8D_R))$ , and  $0 \leq \varepsilon < \rho c_\lambda/2$ , then*

$$(5.1) \quad W_{N,\varepsilon} = \Theta(N^{\sigma_X/2}).$$

*The constants may depend on the fixed action, alphabet, block length, seeds, signal and error. Other active types need not have any block gap. The exact upper construction has common command rows and a horizon-dependent decoder.*

*Proof.* Choose a maximizing seed and copy in (4.1), and choose a positive-gap length- $L$  word law. Feed independent complete words with this law, followed by any fixed remainder of length less than  $L$ . The uncompressed constituent orbit stays of norm one. Compressing all intermediate computation gives a common stochastic endpoint row for each starting state and word. Conditional centroids at block boundaries satisfy (2.1)–(2.2); deterministic remaining commands cannot increase their mean norm. Terminal calibration therefore gives  $q_t \geq \kappa = \rho c_\lambda - 2\varepsilon > 0$  at every block boundary.

The uniform orbit estimate of Theorem A.1 and the occupation theorem in Appendix B, now in dimension  $d_\lambda$ , imply, at peak width  $K$ ,

$$(5.2) \quad \lfloor N/L \rfloor g_L^* \leq B_{d_\lambda, A_\lambda, s_\lambda} \kappa^{-3-2/s_\lambda} K^{2/s_\lambda}.$$

Sphere and Lebesgue action norms agree by polar coordinates: both averages act trivially on the radial factor and identically on  $L^2$  of the sphere. Thus no full presenting-group gap is substituted for the defined action gap. This proves the lower order.

For completeness the exact upper bound prices all branches. Split  $R$  orthogonally into irreducible copies of dimensions  $d_i$ , including trivial copies. Choose branch  $i$  initially with probability  $w_i = d_i/D_R$  and store its identifier in a disjoint label set. In that branch synthesize the mean  $(\rho/w_i)A_w\pi_i x$ . The component seed has norm at most one, and  $\rho/w_i \leq 1/(8d_i)$ . The construction in Theorem C.2, whose initialization also accepts vectors in the unit ball, gives  $O(N^{s_i/2})$  labels. A trivial copy needs a fixed two-label mixture to retain its initial scalar; its commands can be identities. The weighted sum of all branch outputs is exactly  $\rho A_w x$ . Total width is the sum of the branch widths, hence  $O(N^{\sigma_X/2})$ . Only one final query is answered, and its row is selected from the branch carried by the label. This proves the matching upper bound and prices the selector.  $\square$

The full group norm-gap sufficient theorem and the earlier one-step dominant-action theorem are contained in this statement, not withdrawn. Its hypothesis is still sufficient rather than necessary. Section 6 treats a family outside every finite-block expansion certificate.

**Theorem 5.2** (A rational alphabet whose first useful block has length two). *Let*

$$a = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 3/5 & -4/5 \\ 0 & 4/5 & 3/5 \end{pmatrix}, \quad b = \begin{pmatrix} 3/5 & -4/5 & 0 \\ 4/5 & 3/5 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathcal{A} = \{a, ab\}.$$

*For the standard  $\text{SO}(3)$  action on  $\mathbb{R}^3$ ,*

$$g_1^*(\mathcal{A}) = 0, \quad g_2^*(\mathcal{A}) > 0.$$

*The second inequality uses the algebraic spectral-gap theorem [2, Theorem 1.2]; it is a qualitative external certificate. With unit coordinate seeds,  $0 < \rho \leq 1/24$  and  $\varepsilon < \rho/(2\sqrt{3})$ , the numerical width is  $\Theta(N)$ .*

*Proof.* The common angle is irrational relative to  $2\pi$ . Otherwise  $2\cos\theta = 6/5$  would be a rational algebraic integer, hence an integer. Powers of  $a$  and  $b$  therefore contain the full rotations about their respective axes in their closures. Their infinitesimal rotations generate  $\mathfrak{so}(3)$ , so the closure is  $\text{SO}(3)$ . The given two-letter alphabet generates the same closed group since  $a^{-1}(ab) = b$ .

For any probability  $p$ , its average is  $V_a((1-p)I + pV_b)$ . There is a nonconstant mean-zero function fixed by  $V_b$ , for example the third coordinate on the sphere. This average preserves its norm. Every average is a contraction, so every one-step norm is exactly one.

Put  $c = a^{-1}ba$ . It rotates about an axis different from that of  $b$ , and  $b, c$  again generate a dense subgroup of  $\text{SO}(3)$ . They have rational matrices. For the symmetric average

$$Q = (V_b + V_{b^{-1}} + V_c + V_{c^{-1}})/4$$

the cited theorem, applied to the compact connected simple group  $\text{SO}(3)$ , gives a spectral gap. In particular there is  $\delta > 0$  with  $\langle (I - Q)f, f \rangle \geq \delta \|f\|^2$  on the mean-zero spherical subspace. The spherical action is a quotient of the regular group action; all entries of the adjoint matrices are algebraic. This is the sole deep input.

The uniform two-step average equals

$$V_{a^2} B, \quad B = (I + V_c)(I + V_b)/4.$$

For its four unitary summands  $U_1 = I, U_2 = V_b, U_3 = V_c, U_4 = V_{cb}$ , the variance identity gives

$$\begin{aligned} \|f\|^2 - \|Bf\|^2 &= \frac{1}{16} \sum_{i < j} \|U_i f - U_j f\|^2 \\ &\geq \frac{\|f - V_b f\|^2 + \|f - V_c f\|^2}{16} = \frac{1}{4} \langle (I - Q)f, f \rangle. \end{aligned}$$

Thus  $g_2^* \geq \delta/4 > 0$ . The minimum orbit dimension is two and Proposition 4.3 gives  $c = 1/\sqrt{3}$ . Apply Theorem 5.1. Finite matrix checks establish the displayed identities, not the external infinite-dimensional value of  $\delta$ .  $\square$

## 6. SHARP WIDTHS WITHOUT ANY FINITE-BLOCK GAP

We prove Theorem 1.1. Throughout this section  $r, \alpha, b_*, \rho, \varepsilon$  are fixed as in that theorem. Distances on  $\mathbb{R}/\mathbb{Z}$  use the shorter circular distance in  $[0, 1/2]$ , and logarithms are natural. We retain the entire wordwise specification; command laws appear only in the converse.

### 6.1. A packet can only lose conditional amplitude.

**Lemma 6.1** (Endpoint quantization of a fresh packet). *Let a complete random command word  $W$  be independent of the past and of the old register's private randomness. Its net orthogonal action is  $U_W$ . If the register has at most  $k$  labels at its endpoint, and the product distribution obeys*

$$(6.1) \quad \sup_{\|u\|=1, v_1, \dots, v_k \in \mathbb{S}^1} \mathbb{E} \max_j \langle v_j, U_W u \rangle \leq 1 - \gamma,$$

*then the conditional-mean norms at the two boundaries satisfy  $q' \leq (1 - \gamma)q$ .*

*Proof.* Let  $z_s = \mathbb{E}[Y \mid S = s]$  before the word. Integrate all internal rows and randomness into a stochastic endpoint kernel  $T(j \mid s, W)$ . Independence of the complete word and the update rule give

$$z'_j = \mathbb{E}[U_W z_s \mid S' = j].$$

Choose  $v_j = z'_j / \|z'_j\|$  when  $z'_j \neq 0$ , and any unit direction otherwise. Then

$$\begin{aligned} q' &= \sum_s \mathbb{P}(S = s) \mathbb{E}_W \sum_j T(j \mid s, W) \langle v_j, U_W z_s \rangle \\ &\leq \sum_s \mathbb{P}(S = s) \|z_s\| \sup_{\|u\|=1} \mathbb{E}_W \max_j \langle v_j, U_W u \rangle \leq (1 - \gamma)q. \end{aligned}$$

No condition is imposed on the number of intermediate states. The maximizing assignment in the second line need not be executable; allowing it only increases an upper bound on surviving amplitude. Commands inside  $W$  may be correlated.  $\square$

For an integer  $k \geq 1$ , put

$$(6.2) \quad L = \lceil (2k)^{1/r} \rceil, \quad B = r(L-1), \quad s = b_* B^{-r}.$$

A packet has  $r$  segments, each of length  $L-1$ . In segment  $i$  first give  $J_i$  copies of rotation  $i$ , then  $L-1-J_i$  idle letters, where the  $J_i$  are independent uniform variables in  $\{0, \dots, L-1\}$ . Thus there are exactly  $B$  actual commands and  $L^r \geq 2k$  equiprobable products.

**Lemma 6.2** (Separated multivariate packets). *The products in this packet have pairwise circular angular distance at least  $s$ . Condition (6.1) holds with  $\gamma = s^2$ .*

*Proof.* A difference of distinct count vectors is nonzero with  $\ell_1$  norm at most  $B$ . Inequality (1.2) therefore gives the separation. A circular open cap of radius  $s/2$  around one decoder direction contains at most one product point, even after an arbitrary common rotation by  $u$ . At most  $k$  of the  $L^r$  points lie in the union of the  $k$  caps. At least half the points have distance at least  $s/2$  from every decoder direction. For  $0 \leq d \leq 1/2$ ,  $1 - \cos(2\pi d) = 2 \sin^2(\pi d) \geq 8d^2$ . On that half the scalar-product loss is at least  $2s^2$ . Its average is at least  $s^2$ , as claimed. Boundary points satisfy the same weak inequality.  $\square$

**Proposition 6.3** (Finite packet and occupation bounds). *Let  $\kappa = \rho/\sqrt{2} - 2\varepsilon > 0$ . For a simulator of peak width  $K$ , define  $B$  by (6.2) with  $k = K$ . Then*

$$(6.3) \quad \lfloor N/B \rfloor b_*^2 B^{-2r} \leq \log(1/\kappa), \quad N < B + b_*^{-2} B^{2r+1} \log(1/\kappa).$$

*Consequently  $K \geq cN^{r/(2r+1)}$  for a fixed positive  $c$ . More generally, if  $B$  is defined from a proposed small width  $k$ , any available profile satisfies*

$$(6.4) \quad \#\{1 \leq t \leq N : K_t \leq k\} \leq B - 1 + b_*^{-2} B^{2r+1} \log(1/\kappa),$$

*with no bound on other widths.*

*Proof.* Feed independent packets up to time  $B \lfloor N/B \rfloor$  and idle letters thereafter. The same realization must pass this law because its requirement is wordwise. Lemmas 6.1 and 6.2 give  $q_N \leq (1-s^2)^{\lfloor N/B \rfloor}$ . Terminal calibration gives  $q_N \geq \kappa$ . Taking logarithms and using  $-\log(1-s^2) \geq s^2$  proves both inequalities. Since  $B = r(\lceil (2K)^{1/r} \rceil - 1) \leq r(2K)^{1/r}$ , the second inequality gives the stated lower power, after enlarging constants for finitely many small  $N$ .

For the profile statement discard small-width endpoints before  $B$ . Among the rest, greedily select the earliest available endpoint and then the next at least  $B$  later. At most  $B$  selected-or-discarded integer endpoints are accounted for by each choice. The chosen length- $B$  intervals are disjoint. Put an independent packet in each and deterministic idle commands in all gaps. Only the chosen endpoints need have at most  $k$  labels. Repeating the loss argument bounds the number of chosen intervals by  $s^{-2} \log(1/\kappa)$ . Adding the at most  $B-1$  initial endpoints proves (6.4). The test law is selected from available layer sizes, not by inspecting a machine's private state.  $\square$

**6.2. Simultaneous denominators at every scale.** The following elementary argument records the arithmetic needed for an upper construction at every horizon, not merely on a subsequence.

**Lemma 6.4** (Comparable simultaneous denominators). *For each integer  $Q \geq 2$ , there are integers  $p_1, \dots, p_r, q$  such that*

$$(6.5) \quad c_* Q^r \leq q \leq Q^r, \quad \max_i |q\alpha_i - p_i| \leq Q^{-1}, \quad c_* = (b_*/r^{r+1})^r.$$

*Proof.* Place the  $Q^r + 1$  vectors  $j\alpha \bmod \mathbb{Z}^r$ ,  $0 \leq j \leq Q^r$ , in  $Q^r$  equal boxes. Two lie in the same box; subtraction gives  $1 \leq q \leq Q^r$  and the stated errors. This is the usual simultaneous Dirichlet pigeonhole argument.

Put  $M = \lfloor q^{1/r} \rfloor$ . The  $(M+1)^r > q$  integer vectors in  $\{0, \dots, M\}^r$  cannot have distinct values of  $m \cdot p \bmod q$ . Their difference gives a nonzero  $m$  with  $H = \|m\|_1 \leq rM$  and  $q \mid m \cdot p$ . Hence

$$b_* H^{-r} \leq \|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} \leq \frac{H}{qQ}.$$

It follows that  $b_* qQ \leq H^{r+1} \leq r^{r+1} q^{(r+1)/r}$ , which rearranges to the lower bound on  $q$ . No unexplained transference constant is used.  $\square$

**Proposition 6.5** (Exact common-row upper realization). *For every  $N \geq 1$  there is an exact realization using  $O(N^{r/(2r+1)})$  labels, with common command rows and an  $N$ -dependent decoder. It uses the original  $r+1$  letters; a reflection may also be included at the same cost.*

*Proof.* Choose an integer  $Q$  so that  $c_* Q^r \geq 4$  and

$$\frac{4\pi^2 N}{c_*^2 Q^{2r+1}} \leq \log 2.$$

It can be chosen  $O(N^{1/(2r+1)})$ , with a constant depending only on the fixed data. Take  $q, p_i$  from Lemma 6.4. Let  $P$  be the regular  $q$ -gon with vertices  $u_j = (\cos(2\pi j/q), \sin(2\pi j/q))$ . Write  $\delta_i = 2\pi(\alpha_i - p_i/q)$ , so  $|\delta_i| \leq 2\pi/(qQ) \leq \pi/q$ . The rotated vertices lie in  $\Lambda_i P$ , where

$$(6.6) \quad \Lambda_i = \frac{\cos(\pi/q - |\delta_i|)}{\cos(\pi/q)}, \quad \log \Lambda_i \leq |\delta_i| \tan(\pi/q) \leq \frac{4\pi^2}{q^2 Q}.$$

The first identity follows by intersecting the ray to a rotated vertex with the chord between the adjacent polygon vertices. The logarithmic inequality follows by integrating the derivative of  $\log \cos(\pi/q - t)$ , and  $\tan(\pi/q) \leq 2\pi/q$  for  $q \geq 4$ .

Put  $\Lambda = \max(1, \Lambda_1, \dots, \Lambda_r)$ . Then  $\Lambda^N \leq 2$ , and  $\Lambda^{-1} R_{2\pi\alpha_i} P \subseteq P$ . The same containment holds for the identity and for reflection in the first coordinate axis, since the latter preserves  $P$ . For each label  $u_j$  and command choose convex coordinates in  $P$  of its image divided by  $\Lambda$  as the stochastic row. These choices are made once and do not depend on the epoch. Initially represent  $x/2$  as a mixture of the vertices; this is possible since  $P$  contains the radius- $\cos(\pi/q)$  disk. At epoch  $t$  interpret label  $j$  as  $2\Lambda^t u_j$ . Induction using the common rows gives mean  $A_w x$ . The final decoder is

$$d_\ell(j) = 2\rho \Lambda^N \langle e_\ell, u_j \rangle,$$

whose modulus is at most  $4\rho \leq 2/5$ . Every conditional response is therefore exact. At most three successors per row suffice by planar Carathéodory; the vector interpretation is a description of fixed rows, not an extra real register. Finally  $q \leq Q^r = O(N^{r/(2r+1)})$ . Every partial command step uses the same  $q$  labels.  $\square$

### 6.3. Vanishing gaps and explicit angles.

**Proposition 6.6** (All block gaps vanish). *For any finite family of planar rotations generating a dense subgroup of  $\text{SO}(2)$ , all optimized finite-block gaps on its circle action are zero. This remains true after adjoining the reflection above when the effective group is  $O(2)$ .*

*Proof.* Simultaneous Dirichlet approximation gives integers  $n_j \rightarrow \infty$  for which all  $n_j \alpha_i$  approach integers. For an irrational generating family the denominators cannot remain bounded. On the mean-zero Fourier mode  $e^{in_j \theta}$  every fixed rotation word then has eigenvalue approaching one. Every average on any fixed finite word set has norm one, so no law has positive gap. For the reflected alphabet use the normalized real function  $\cos(n_j \theta)$ . Reflection fixes it; rotations and any fixed words move it by a norm tending to zero. The same conclusion follows. The constants are invariant functions only at frequency zero because the effective actions are respectively  $\text{SO}(2)$  and  $O(2)$ .  $\square$

**Proposition 6.7** (An explicit family in every alphabet size). *Let  $\xi = 2^{1/(r+1)}$  and  $\alpha_i = \xi^i$ ,  $1 \leq i \leq r$ . Then (1.2) holds with  $b_* = (2/9)^r$ .*

*Proof.* For nonzero  $m$  let  $H = \|m\|_1 \geq 1$  and choose  $m_0 \in \mathbb{Z}$  nearest to  $-\sum_i m_i \xi^i$ . The polynomial  $P(T) = m_0 + \sum_i m_i T^i$  is nonzero of degree at most  $r$ . Since  $T^{r+1} - 2$  is Eisenstein,  $P(\xi) \neq 0$ . It is an algebraic integer of nonzero integer norm. All conjugates of  $\xi$  have the same modulus and  $|\xi^i| < 2$ , so  $|m_0| \leq 2H + 1/2 \leq 5H/2$ . Each of the other  $r$  conjugates of  $P(\xi)$  has modulus at most  $9H/2$ . The product of all  $r+1$  moduli is at least one. Therefore

$$\|m \cdot \alpha\|_{\mathbb{R}/\mathbb{Z}} = |P(\xi)| \geq (2/9)^r H^{-r}.$$

The norm argument is classical algebraic Diophantine separation; its role here is to supply explicit input data for the memory theorem.  $\square$

*Proof of Theorem 1.1.* Propositions 6.3 and 6.5 give the matching powers. Adding reflection retains the upper construction and the converse applies to its rotation-only subalphabet. Proposition 6.6 proves the gap assertion. The effective groups are the full indicated circle and orthogonal circle actions, since (1.2) makes each angle irrational. Proposition 6.7 supplies the announced examples.  $\square$

At any one internal cut the exact separate positive minimum is still three. Indeed all actual residuals depend affinely on a planar vector, and the idle-prefix images of the four seeds give affine dimension two. Hence at least three normalized states are required. For the reverse bound choose an equilateral triangle of circumradius  $2\rho \leq 1/5$ . It contains the radius- $\rho$  disk. Its three vertices define legal complete future continuations, since every future command is orthogonal and every final coordinate remains bounded by one. Their convex coordinates factor every actual residual at that cut. One can embed this factorization in a complete machine by retaining the full past before that cut and the chosen vertex plus the full remaining word thereafter. Other cuts are unrestricted in this separate-minimum assertion. Thus all exponents above measure causal compatibility beyond the same static value three.

## 7. FINITE COMPONENTS AND OBSERVABLE QUOTIENTS

Connectedness is not harmless bookkeeping. If  $H$  is a compact matrix group, its identity component  $H^0$  has finite index, and other components can permute its isotypic subspaces. An uncharged component label would therefore change the realization problem.

**Proposition 7.1** (A paid finite-component compiler). *Choose representatives  $r_c$  of the finite quotient  $H/H^0$ , with  $r_e = I$ , and write*

$$(7.1) \quad A_a r_c = r_{c'} h_{a,c}, \quad h_{a,c} \in H^0.$$

*Suppose the finite connected-component alphabet  $\{h_{a,c}\}$  has an exact common-row vector realization of width  $K_N$  for the required seeds and signal, whose terminal represented vectors have norm at most one. Then the original alphabet has an exact realization of width at most  $\max(2, [H : H^0] K_N)$ . The terminal decoder may depend on  $N$ . If  $H$  itself is finite, the exact width is at most  $\max(2, |HX|)$  at every horizon.*

*Proof.* Use labels  $(c, s)$ . Given letter  $a$  and label  $(c, s)$ , update  $c$  to the uniquely determined  $c'$  in (7.1), and use the connected compiler's row for  $h_{a,c}$  on  $s$ . The row depends only on the actual stored pair and the input. Inductively, if  $A_w = r_c h_w$ , the represented internal vector has mean  $\rho h_w x$ . At the final query use  $\langle e_j, r_c v_s \rangle$ . Its modulus is at most one and its overall mean is  $\rho \langle e_j, A_w x \rangle$ . The component identity is part of every label. No fixed choice of  $H^0$  isotypic coordinates is assumed preserved by all components.

For finite  $H$ , retain the actual point in the finite orbit union  $HX$ , update it by the command permutation, and sample the prescribed bounded terminal row. This gives the stated bound. It is an upper bound, not a claim that every orbit point is a necessary label.  $\square$

The minimum-orbit construction in Appendix C, followed by the paid branch construction in Theorem 5.1, supplies such vector compilers at the stated small signal even without expansion. A matching lower bound for an arbitrary finite extension requires information about actual return words and the action on the activated subspaces; it does not follow solely from the index. The reflection extension in Theorem 1.1 is a matched nongapped example: its upper polygon is reflection-invariant, while restriction to rotation words gives the full lower order.

**Proposition 7.2** (Metric orbit quotients do not specify numerical memory). *The metric quotients of the standard actions  $\mathrm{SO}(d) \curvearrowright \mathbb{R}^d$ ,  $d \geq 2$ , are all the half-line. Their minimum nonzero orbit dimensions are  $d - 1$ . The same half-line is the metric quotient of the finite reflection action  $\{\pm 1\} \curvearrowright \mathbb{R}$ . Moreover there are numerical alphabets with the identical effective standard  $\mathrm{SO}(2)$  action, identical seeds and queries, and identical orbit geometry, but infinitely many distinct sharp width exponents.*

*Proof.* Two standard orthogonal orbits are spheres of radii  $r, s$ ; their distance is  $|r - s|$ . The reflection quotient has the same distance between the absolute values. Orbit dimensions in the standard connected actions are those of the spheres. Thus metric quotient-equivalence alone cannot preserve the minimum orbit dimension. The last assertion is Theorem 1.1 with the explicit angle families of Proposition 6.7: all act on the same plane and their exponents  $r/(2r + 1)$  are distinct.  $\square$

An ambient linear isometry taking every orbit onto an orbit does preserve the dimensions of those orbit submanifolds. To preserve the numerical experiment it must additionally intertwine the actual command letters and transform the seeds and queries. An isometry of the quotient, or a polar section with its finite Weyl group, need not do this. These are distinct equivalence relations, not competing proofs of the same invariant.

## 8. CLASSICAL BOUNDARIES AND SCOPE

**8.1. Transformation groups.** Gorodski–Lythchak [12, Section 1 and Proposition 1.1] distinguish metric quotient-equivalence from ambient orbit-equivalence and study reductions, boundary, cohomogeneity and copolarity. Their Proposition 1.1 imposes a no-boundary hypothesis when recovering the ambient dimension. The half-line example in Proposition 7.2 has boundary and makes no contrary assertion. Their principal-isotropy reductions and polar examples identify quotient metric spaces; they do not provide command intertwiners preserving specified numerical words. The full alphabet is additional dynamic data.

The sphere-orbifold classification in [13, Theorem 1.1] concerns the geometry of the quotient, not the wordwise positive width of a chosen generating set. Gorodski–Thorbergsson [14, Theorems 1.1 and 1.2] classify variationally complete and irreducible taut representations through orbit equivalence and osculating-space structure. Those results can identify useful orbit types in their classes; neither tautness nor polarity supplies a gap for a given alphabet. Our uniform orbital small-ball estimate is an inherited compact differential-chart argument. It is not presented as a replacement for the slice theorem or a new classification of compact representations. The algebraic evaluation of selected adjoint and exterior-power minima in the supporting manuscript remains intact; no general highest-weight classification is asserted here.

The support-net compiler uses the extrinsic convex hull of an orbit and quadratic loss at a support maximum. These are standard convex and Riemannian geometric facts [7, 10, 9]. Its role is to make one legal set of transition rows serve every layer. The nongapped hierarchy is more

sharply alphabet-dependent: even preserving the full orbit foliation in the same ambient plane does not preserve its width exponent.

**8.2. Spectral design, circle walks and branching programs.** Boyd–Diaconis–Xiao [11, Sections 2–4] formulate finite reversible Markov-chain design as convex spectral-norm minimization with semidefinite duality. Proposition 3.2 uses that classical convex structure, but its admissible operators act on an infinite spherical harmonic sum. Its truncated programs have the opposite certification direction from an upper tail estimate. We do not infer a positive infinite gap from a finite SDP.

The algebraic expansion theorem of Benoist–de Saxcé [2, Theorem 1.2 and Definition 2.1] is an external qualitative input. In Theorem 5.2 it is used only for the symmetric average of the explicitly verified dense generators  $b, c$ . Our four-word variance estimate then supplies the stated two-step norm loss. This separation avoids treating the norm of a nonnormal one-step average as its spectral radius.

Berkes–Borda [15] analyze circle random walks using Fourier multipliers and Diophantine data. The simultaneous pigeonhole argument and the algebraic-norm separation in Section 6 are elementary arithmetic tools. The additional assertion here concerns loss forced by compression into an arbitrary hidden register and a matching exact positive realization. Its test packets are independent as complete words, not independent-letter samples inside a packet. The  $r = 1$  mechanism and the general conditional-centroid packet inequality are inherited from the earlier rotation development; the multivariate separation, every-scale denominator argument and their matched  $r/(2r + 1)$  law are the extension proved here.

The clocked model is a nonuniform probabilistic ordered read-once layered program with real terminal columns. Regular and permutation branching-program Fourier bounds, such as [5, 6, 3], concern their stated transition assumptions and pseudorandomness or Fourier growth. This paper does not claim those objectives or count total program size. A Bernoulli row converts one bounded column into randomized Boolean acceptance, but preserving a cutpoint sign is weaker than preserving its numerical value. The constant-width attenuated sign simulator, the version-pinned quantum-automata comparison and the projective examples remain in the unaltered supporting manuscript; they are not new claims of this revision.

**8.3. Resource ledger in the theorem.** For a common-row upper realization with  $K$  labels there are  $|\mathcal{A}|K$  command rows, in addition to the seed and decoder rows. A bound of  $d + 1$  successors per row does not bound the complexity of constructing their weights or storing their real values. For a general clocked machine there can instead be  $|\mathcal{A}| \sum_{t < N} K_t$  distinct command rows. None of these descriptions is charged as persistent label width.

The largest toral widths in Theorem 1.1 correspond to  $\frac{r}{2r+1} \log_2 N + O(1)$  label bits, not polynomially many bits. Exact irrational stochastic rows are not finite random-bit algorithms. Output error, calibration, alphabet size and representation dimension are fixed before  $N$  grows. A simultaneous channel of all coordinate answers, repeated queries, an anytime decoder and adaptive experimental design are different tasks.

**8.4. Conclusions.** The alphabet can be expanding only after a finite word block, or nongapped at every finite block while still forcing a sharp growing width. Optimizing the proof law makes this distinction canonical. The explicit nongapped hierarchy shows why a representation exponent cannot classify all alphabets, and supplies matching laws in a substantial excluded family rather than merely restating the exclusion.

The numerical calibration is now a finite algebraic problem with certified convex upper bounds and quantitative frame stability. This does not make spectral-gap positivity decidable. The general dominant-nongapped problem beyond the dual badly approximable planar families, sharp finite integer widths, uniform varying-signal laws and optimal table or fair-bit costs remain distinct

questions. The optional arithmetic LPS application in the preserved manuscript retains its original explicitly stated external dependency and its original-page audit limitation. Neither these results nor their reproducible builds assert an independent priority certification or an editorial outcome.

#### APPENDIX A. THE SMALLEST ORBIT CONTROLS UNIFORM CONCENTRATION

In this section  $G$  is a compact connected Lie group,  $U : G \rightarrow O(V)$ , and  $V^G = \{0\}$ . Put

$$(A.1) \quad s(U) = \min_{u \in \mathbb{S}(V)} \dim(Gu).$$

The minimum is over *all* directions. It can be smaller than the dimension of a generic orbit. Since  $G$  is connected,  $s(U) \geq 1$ .

**Theorem A.1** (Uniform concentration across orbit types). *There is a finite constant  $A_U \geq 1$  such that*

$$(A.2) \quad \sup_{u, v \in \mathbb{S}(V)} m_G\{g : \|U_g u - v\| \leq r\} \leq A_U r^{s(U)} \quad (0 < r \leq 1).$$

*This exponent is optimal among uniform power upper bounds: for a unit  $u_0$  with  $\dim(Gu_0) = s(U)$  there are  $c, r_0 > 0$  such that*

$$(A.3) \quad m_G\{g : \|U_g u_0 - u_0\| \leq r\} \geq c r^{s(U)} \quad (0 < r < r_0).$$

*No regular-orbit, constant-stabilizer, or simple-spectrum hypothesis is needed in (A.2).*

*Proof.* Write  $m = \dim G$ ,  $s = s(U)$  and let  $\mathfrak{g}$  be the Lie algebra. For  $u \in \mathbb{S}(V)$  the differential

$$A_u : \mathfrak{g} \longrightarrow V, \quad X \longmapsto dU(X)u$$

has rank  $\dim(Gu) \geq s$ . Its  $s$ th singular value is continuous in  $u$  and is strictly positive on the compact sphere. Its minimum is therefore positive. We give a chart argument that also records why variation of the stabilizer causes no loss in the exponent.

Fix  $(g_0, u_0) \in G \times \mathbb{S}(V)$ . In a smooth coordinate chart  $g = \psi(z, w)$ , where  $z \in \mathbb{R}^s$  and  $w \in \mathbb{R}^{m-s}$ , select  $s$  coordinate directions and a linear projection  $L : V \rightarrow \mathbb{R}^s$  for which

$$D_z[LU_{\psi(z, w)}u]_{(g_0, u_0)} = M$$

is invertible. This is possible by the rank bound. By shrinking to a product of bounded open rectangles  $Z \times W$  and a neighborhood  $J$  of  $u_0$ , arrange

$$\|D_z[LU_{\psi(z, w)}u] - M\|_{\text{op}} \leq \frac{1}{2}\sigma_{\min}(M) \quad (z, w, u) \in Z \times W \times J.$$

Take  $Z$  convex. For fixed  $(w, u)$ , integration along the segment from  $z$  to  $z'$  gives

$$(A.4) \quad \|LU_{\psi(z, w)}u - LU_{\psi(z', w)}u\| \geq \frac{1}{2}\sigma_{\min}(M)\|z - z'\|.$$

If both points lie in the inverse image of the radius- $r$  ball around  $v$ , their projected distance is at most  $2\|L\|r$ . This inverse image, on the fixed  $w$  slice, consequently has diameter at most  $4\|L\|r/\sigma_{\min}(M)$ , and hence  $s$ -dimensional Lebesgue measure at most a constant times  $r^s$ . Haar measure has a bounded smooth density in the chosen relatively compact chart. Integration in the remaining  $m - s$  coordinates yields the same bound there.

Choose finitely many of these product neighborhoods covering  $G \times \mathbb{S}(V)$ . For each fixed  $u$ , those whose  $J$  contains  $u$  cover  $G$ ; summing the preceding bounds proves (A.2). All constants are independent of the center  $v$ . An empty inverse image contributes zero. This use of a finite cover, rather than a separate density estimate on every orbit, is what controls neighborhoods of singular orbit types.

For the converse,  $Gu_0 \simeq G/G_{u_0}$  is a compact smooth embedded  $s$ -dimensional submanifold. The pushforward of Haar probability is its normalized invariant Riemannian volume: the induced metric is  $G$ -invariant and the invariant probability on this homogeneous space is unique. A smooth

local graph at  $u_0$  has volume comparable to  $r^s$  in a small ambient ball. This proves (A.3). If a uniform estimate with exponent  $s' > s$  held, comparison at  $u_0$  as  $r \downarrow 0$  would contradict it.  $\square$

The rank computation in (A.1) is intrinsic to the representation. For example, given algebraic skew matrices  $B_1, \dots, B_m$  spanning its infinitesimal action, the condition  $s(U) \leq r$  is the existence of a real vector  $u$  with  $\sum u_i^2 = 1$  and all  $(r+1)$ -minors of  $[B_1 u \cdots B_m u]$  zero. Thus it is an explicit real-algebraic decision problem for fully specified algebraic data; quantifier elimination applies [8]. This is not a test for a spectral gap, and no efficient algorithm in a succinct representation is asserted.

**Corollary A.2** (Intrinsic occupation exponent). *Suppose the representation satisfies (B.2). In the setting of Lemma 2.2,  $q_N \geq \kappa > 0$  implies*

$$(A.5) \quad \sum_{\substack{0 \leq t \leq N \\ \bar{K}_t \leq k}} g_t \leq 2048 D (16 A_U)^{2/s(U)} \kappa^{-3-2/s(U)} k^{2/s(U)}.$$

*The estimate allows arbitrary hidden continuations and imposes no bound on the other cuts.*

*Proof.* Apply Theorem B.5 with the uniform estimate (A.2). In particular the conditional means may change orbit type at every step; their directions still satisfy the same estimate.  $\square$

## APPENDIX B. AN ORBITAL ENTROPY OCCUPATION THEOREM

Lebesgue measure is used on  $V = \mathbb{R}^D$  and normalized Haar measure on  $G$ . For a function on  $V$ , set

$$(B.1) \quad \mathcal{U}_a f(z) = f(U_a^{-1} z), \quad P_t = \sum_a p_t(a) \mathcal{U}_a, \quad \Pi f(z) = \int_G f(U_g^{-1} z) dm_G(g).$$

Thus  $\mathcal{U}_a^* = \mathcal{U}_{a^{-1}}$ ,  $\Pi$  is an orthogonal projection, and  $P_t \Pi = \Pi P_t = \Pi$ . The probability law  $p_t$  need not be symmetric. Its required squared norm gap is

$$(B.2) \quad \|P_t f\|_2^2 \leq \|\Pi f\|_2^2 + (1 - g_t) \|f - \Pi f\|_2^2, \quad 0 \leq g_t \leq 1.$$

Invariance in this formula means  $G$ -invariance, not necessarily radial symmetry. In a reducible representation invariant functions can carry many parameters.

**Lemma B.1** (Transfer of a group norm gap). *If right convolution  $R_{p_t} F(g) = \sum_a p_t(a) F(ga)$  on  $L^2(G)$  has mean-zero norm at most  $\sqrt{1 - g_t}$ , then (B.2) holds in every orthogonal representation on  $V$ .*

*Proof.* For each  $z$  apply the group inequality to  $F_z(g) = f(U_g^{-1} z)$ . Its mean is  $\Pi f(z)$  and  $R_{p_t} F_z(g) = P_t f(U_g^{-1} z)$ . Integrate the resulting inequality in  $z$ . Orthogonal changes of variables and Fubini identify the three integrals with those in (B.2). First take bounded compactly supported  $f$  and then use density. This proof does not replace the full group gap by a gap in the defining representation.  $\square$

**B.1. The conditional-mean cost.** Let  $G_D$  be a standard independent real Gaussian vector and let  $\gamma_\tau$  be the density of  $\tau G_D$ .

**Lemma B.2** (A one-sided Gaussian coupling inequality). *For bounded  $X$  and a finite-valued variable  $J$ , put  $M = \mathbb{E}[X \mid J]$ . For every  $\tau > 0$ ,*

$$(B.3) \quad h(X + \tau G_D) - h(M + \tau G_D) \leq \frac{\mathbb{E}\|X - M\|^2}{2\tau^2}.$$

*Proof.* Write  $f = \text{Law}(M) * \gamma_\tau$ . Differentiation of the Gaussian mixture and the conditional covariance identity give

$$(B.4) \quad \nabla^2 \log f(y) = -\tau^{-2}I + \tau^{-4} \text{Cov}(M \mid M + \tau G_D = y) \succeq -\tau^{-2}I.$$

Hence  $\phi(x) = -\mathbb{E} \log f(x + \tau G_D)$  has Hessian at most  $\tau^{-2}I$ . Taylor's inequality at  $M$  yields  $\phi(X) \leq \phi(M) + \langle \nabla \phi(M), X - M \rangle + \|X - M\|^2 / (2\tau^2)$ . The conditional expectation of the linear term given  $J$  is zero. If  $g = \text{Law}(X) * \gamma_\tau$ , nonnegativity of  $D(g \parallel f)$  gives  $h(g) \leq -\int g \log f = \mathbb{E} \phi(X)$ , whereas  $\mathbb{E} \phi(M) = h(f)$ . Boundedness of  $X, M$  provides Gaussian bounds with finite second moments and justifies differentiation and integration. These identities prove (B.3).  $\square$

This elementary consequence of Gaussian posterior identities is used as an estimate, not as a claim of priority over the Gaussian estimation literature [1, 4]. The estimate is one-sided and can have a negative left side. Here  $J$  can be a finite register with no Gaussian observation model; the smoothing noise is added after conditioning.

**Lemma B.3** (Entropy production away from invariant functions). *For any bounded-support Gaussian mixture density  $f$ ,*

$$(B.5) \quad h(P_t f) - h(f) \geq g_t \|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq 0.$$

*Proof.* Put  $f_a = \mathcal{U}_a f$  and  $h = P_t f$ . Orthogonality preserves entropy, so  $h(h) - h(f) = \sum_a p_t(a) D(f_a \parallel h)$ . For probability densities  $u, v$ ,  $D(u \parallel v) \geq \|\sqrt{u} - \sqrt{v}\|_2^2$ ; it follows, for example, from  $-\log x \geq 2(1 - \sqrt{x})$  and integration. The mean is the least-squares minimizer, and thus

$$\sum_a p_t(a) \|\sqrt{f_a} - \sqrt{h}\|_2^2 \geq \sum_a p_t(a) \|\sqrt{f_a} - P_t \sqrt{f}\|_2^2 = 1 - \|P_t \sqrt{f}\|_2^2.$$

Apply (B.2) and  $\|\sqrt{f}\|_2 = 1$ .  $\square$

No logarithmic Sobolev inequality or point-mass mixing assertion is used in this step.

**B.2. Sparsity away from invariant densities.** Suppose that the representation obeys the uniform orbital bound

$$(B.6) \quad m_G\{g : \|U_g u - v\| \leq r\} \leq A r^s \quad (u, v \in \mathbb{S}(V), \ 0 < r \leq 1),$$

where  $A \geq 1$  and  $s > 0$ . In particular the representation has no nonzero fixed vector. It is essential that  $u$  range over all possible centroid directions, not merely the initial seed orbit.

**Lemma B.4** (Finite centroids cannot be almost invariant). *Suppose  $Z$  has at most  $k$  values in the unit ball and  $\mathbb{E}\|Z\| \geq \kappa$ , where  $0 < \kappa \leq 1$ . Set*

$$(B.7) \quad r = \left( \frac{\kappa}{16Ak} \right)^{1/s}, \quad \tau = \frac{\kappa r}{8\sqrt{2D}}, \quad f = \text{Law}(Z) * \gamma_\tau.$$

*Then  $\|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq \kappa/16$ .*

*Proof.* Atoms of norm at least  $\kappa/2$  have total mass at least  $\kappa/2$ . Let  $\Omega$  be the union of radius- $r$  caps around their directions, and let  $C_\Omega$  be its cone. By Markov's inequality,  $\mathbb{P}(\|G_D\| \leq \sqrt{2D}) \geq 1/2$ . On this event, perturbing a high-norm atom by  $\tau G_D$  changes its direction by at most  $4\tau\sqrt{2D}/\kappa = r/2$ . Therefore  $\int_{C_\Omega} f \geq \kappa/4$ .

For any  $G$ -invariant  $u \in L^2(V)$ , Haar averaging and (B.6) give

$$\int_{C_\Omega} |u(z)|^2 dz = \int |u(z)|^2 \int_G \mathbf{1}_{C_\Omega}(U_g z) dm_G(g) dz \leq k A r^s \|u\|_2^2.$$

The point  $z = 0$  is Lebesgue-null. Taking  $u = \Pi \sqrt{f}$ , whose norm is at most one, bounds this integral by  $\kappa/16$ . The reverse triangle inequality in  $L^2(C_\Omega)$  now gives a norm difference at least  $\sqrt{\kappa/4} - \sqrt{\kappa/16} = \sqrt{\kappa}/4$ . Repeated directions and zero centroids cause no change.  $\square$

**Theorem B.5** (Orbital occupation budget). *Under (B.2) and (B.6), let a finite hidden register track a unit-vector command process as in (2.1). If  $q_N \geq \kappa > 0$ , then, for every  $k \geq 1$ ,*

$$(B.8) \quad \sum_{\substack{0 \leq t < N \\ K_t \leq k}} g_t \leq B_{D,A,s} \kappa^{-3-2/s} k^{2/s}, \quad B_{D,A,s} = 2048D(16A)^{2/s}.$$

*The same inequality holds with  $K_t$  replaced by the number of positive-probability labels under the chosen test law. No bound is imposed on the other epochs.*

*Proof.* Fix  $k$  and the single scale (B.7) for the entire run. Write  $f_t = \text{Law}(Z_t) * \gamma_\tau$ . Isotropy of the Gaussian makes the density of  $U_a Z_t + \tau G_D$  equal to  $P_t f_t$ . By Lemmas B.2 and B.3,

$$h(f_{t+1}) - h(f_t) \geq g_t \|\sqrt{f_t} - \Pi \sqrt{f_t}\|_2^2 - \frac{\Delta_t}{2\tau^2}.$$

At an epoch with at most  $k$  labels, Lemma B.4 bounds the norm term below by  $\kappa/16$ . Elsewhere it is nonnegative. The initial density is a translate of  $\gamma_\tau$ ; the terminal second moment is at most  $1 + D\tau^2$ . The Gaussian maximum-entropy bound and (2.2) yield

$$\frac{\kappa}{16} \sum_{K_t \leq k} g_t \leq \frac{D}{2} \log \left( 1 + \frac{1}{D\tau^2} \right) + \frac{1}{2\tau^2} \leq \frac{1}{\tau^2}.$$

Substitute (B.7). The same Gaussian scale is retained through all epochs; no repeated mixing-time charge is incurred.  $\square$

**Corollary B.6** (Actual terminal error). *For a constant gap  $g > 0$ , let  $\mathcal{E}_N(\mathbf{K})$  be the minimum actual wordwise binary-TV error over a prescribed available profile, and put  $K = \max_t K_t$ . Then*

$$(B.9) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{D}} - \left( \frac{B_{D,A,s} K^{2/s}}{gN} \right)^{1/(3+2/s)} \right]_+.$$

*In particular,  $K = o(N^{s/2})$  implies  $\liminf \mathcal{E}_N \geq \rho/(2\sqrt{D})$ .*

*Proof.* If the actual error is below the calibration threshold, combine (2.3) with (B.8) and solve for it. Otherwise the displayed lower bound already holds. Attainment or a minimizing sequence gives the same conclusion for the optimum.  $\square$

Local simulation errors may cancel. Nothing in this corollary sums such errors or rules out cancellation; its objective is the actual final law.

## APPENDIX C. EXACT SYNTHESIS FROM A MINIMAL ORBIT

Assume in this section that  $V$  is a nontrivial real irreducible orthogonal representation, of dimension  $d$ . Choose a unit vector  $v_0$  with orbit dimension  $s = s(U)$ , and set

$$\mathcal{O} = Gv_0, \quad C = \text{conv } \mathcal{O}.$$

The orbit may be a singular orbit in the unit sphere. As a homogeneous space in its own right it is nevertheless a smooth compact manifold.

**Lemma C.1** (Inradius and quadratic support approximation). *One has  $d^{-1}\mathbb{B}(V) \subseteq C \subseteq \mathbb{B}(V)$ . There are  $c, C_0, h_0 > 0$ , depending on  $U$  and  $v_0$ , such that for  $0 < h \leq h_0$  a set  $\mathcal{V}_h \subset \mathcal{O}$  with  $|\mathcal{V}_h| \leq C_0 h^{-s}$  satisfies*

$$(C.1) \quad (1 - ch^2)C \subseteq \text{conv } \mathcal{V}_h \subseteq C \quad \text{whenever } ch^2 < 1.$$

*Proof.* The mean of  $U_g v_0$  is an invariant vector and is zero. Its covariance is  $I/d$ : the covariance is self-adjoint and commutes with the representation, so its eigenspaces are invariant; irreducibility and trace one give the claim. This is the real Schur orthogonality calculation, for example [7, Lemma 5]. For unit  $H$ , let  $f(g) = \langle H, U_g v_0 \rangle$  and  $M = \max_g f(g)$ . Since  $-1 \leq f \leq M$ ,

$$0 \leq \mathbb{E}[(M - f)(f + 1)] = M - \mathbb{E}f^2 = M - 1/d.$$

Every support function of  $C$  is thus at least  $1/d$ , which proves the inradius statement.

Equip  $\mathcal{O}$  with its induced Riemannian metric. Finitely many bounded smooth coordinate patches, with their inverses uniformly Lipschitz on smaller patches, give an intrinsic  $h$ -net with at most  $C_0 h^{-s}$  points. At a maximizer  $y$  of  $z \mapsto \langle H, z \rangle$  on  $\mathcal{O}$ , its tangential first derivative is zero. The second fundamental form of the compact embedded orbit is bounded. Along a unit-speed minimizing geodesic of length at most  $h$ , Taylor's formula therefore gives

$$\langle H, y \rangle - \langle H, v \rangle \leq L \|H\| h^2$$

for a nearby net point  $v$ , with  $L$  independent of  $H, y$ . The inradius bound gives  $\|H\| \leq d h_C(H)$ . Hence  $h_{\text{conv } \nu_h}(H) \geq (1 - L d h^2) h_C(H)$  for every  $H$ . Taking  $c \geq L d$ , and using the support-function criterion, proves (C.1).  $\square$

The covering exponent  $s$  and quadratic loss at a support maximum are geometric facts, not new quantization exponents. What is needed for realization is an enclosure compatible with *every command* and *every layer*; the following construction supplies it.

**Theorem C.2** (A minimal-orbit positive realization). *For any finite command alphabet, any finite unit seed set, and  $0 < \rho \leq 1/(8d)$ , the experiment (1.1) has an exact realization with at most  $C_U N^{s(U)/2}$  available labels, for  $N \geq 1$ . All command matrices can be chosen independent of the epoch; the final decoder may depend on  $N$ . Each row has at most  $d + 1$  successors. If the seeds belong to  $C \cap \mathbb{S}(V)$ , the amplitude range improves to  $0 < \rho \leq 1/10$ .*

*Proof.* Choose

$$h_N = \min\{h_0, (8cN)^{-1/2}\}, \quad \eta = 1 - c h_N^2 \geq 1 - 1/(8N), \quad a_t = \eta^{-t}/4.$$

Let  $v_1, \dots, v_M$  be the net points. The represented vector of a label  $i$  at layer  $t$  is  $a_t v_i$ . These vectors describe the fixed rows; they are not stored as real-valued runtime data.

The polytope  $\text{conv}\{v_i\}$  contains  $\eta C$  and hence a ball of radius  $\eta/d$ . For a unit seed  $x$ ,  $4\rho x \in \eta C$  if  $\rho \leq 1/(8d)$ , because  $4\rho \leq 1/(2d) < \eta/d$ . Choose its convex coordinates as the initial distribution. More generally, if  $x \in C$  and  $4\rho \leq 2/5 < \eta$ , the same initialization is valid. For each command  $a$  and label  $i$ , invariance of  $C$  gives

$$\eta U_a v_i \in \eta C \subseteq \text{conv}\{v_j\}.$$

Choose any convex coordinates of this point for the row  $T_a(i, \cdot)$ . They do not depend on  $t$ . Since  $a_{t+1}\eta = a_t$ , conditional expectation updates the represented vector by exactly  $U_a$ . Induction gives mean  $\rho U_w x$  after each complete prefix.

Use the terminal column  $d_j(i) = a_N \langle e_j, v_i \rangle$ . Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $|d_j(i)| \leq 2/7 < 1$ . This proves every numerical conditional law exactly. Carathéodory's theorem gives  $d + 1$  successors. Finally  $M \leq C_0 h_N^{-s} \leq C_U N^{s/2}$ , with the fixed two-state output cut absorbed into the constant. Neither convex feasibility nor row lookup is priced as computation in this model.  $\square$

**Corollary C.3** (The irreducible width law). *Suppose a probability law on the finite command alphabet has a full mean-zero group norm gap. For a nontrivial real irreducible  $V$ , any nonempty finite unit seed set, fixed  $0 < \rho \leq 1/(8d)$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{d})$ ,*

$$(C.2) \quad W_{N,\varepsilon} = \Theta_{U,p,\rho,\varepsilon}(N^{s(U)/2}).$$

*The same order holds for exact vector-state realizations and for fixed-length realizations with common command rows. For seeds on a minimal orbit the amplitude range is  $0 < \rho \leq 1/10$ .*

*Proof.* A full group norm gap transfers to (B.2) with a fixed  $g > 0$ . Apply Corollary A.2 at the peak  $k$ , using  $\kappa = \rho/\sqrt{d} - 2\varepsilon > 0$ . It gives  $gN \leq B\kappa^{-3-2/s}k^{2/s}$  and therefore the lower order. The exact machine in Theorem C.2 is an upper bound for every allowed error, is vector-valued in its representation, and has common command rows. These subclasses lie inside the unrestricted clocked class, so the lower bound applies to them too. The last assertion uses the stronger initialization in that theorem.  $\square$

# GENERAL THETA FOUNDATIONS I: INTRINSIC ACTION GAPS AND NUMERICAL MEMORY

QIAN QI

**ABSTRACT.** We study the nonuniform clocked atomic-row label width of numerical experiments generated by a finite orthogonal command alphabet. We formulate expansion on the effective action rather than on a presenting group, and remove the dependence of calibration on a choice of irreducible copies. A commutant covariance formula computes an intrinsic isotypic activation magnitude; an optimized query norm gives a canonical error threshold. For arbitrary finite seeds, let  $R$  be their invariant span and let  $\sigma$  be the largest minimum unit-orbit dimension among its nontrivial irreducible types. If one type attaining  $\sigma$  has a positive action gap, then at the stated fixed signal and error the minimum hidden width is  $\Theta(N^{\sigma/2})$ . No expansion is required on the other types. We exhibit a faithful rational alphabet with an effective circle factor, no full group norm gap, and linear numerical width. We compute the minimum-orbit invariant for all compact simple adjoint representations and for classical defining and second exterior power modules, including their minimizing stabilizers. The lower bound retains the actual hidden register; the upper construction prices its branch labels and realizes every numerical response exactly. Epoch, horizon-specific design, tables, arithmetic and exact atomic sampling remain uncharged; this is not a uniform-space theorem.

## 1. INTRODUCTION

A numerical command experiment asks a finite register to retain enough information to answer one selected observable after a word of known length. The number of labels at a single cut is a static positive factorization problem. Using small factorizations at every cut requires one compatible chain of stochastic updates, and is a different problem. For orthogonal command dynamics, orbit geometry and a conditional-mean entropy budget quantify this difference.

The hypothesis should be a property of the experiment. A presentation by a group with an unused compact factor can change the full regular representation gap without changing a single response probability. Likewise, decomposing an isotypic space into equivalent irreducible copies can change individual seed projections without changing the experiment. We remove both choices: expansion is measured in the actual action, and activation is optimized over isometric intertwiners. The latter optimization has an exact commutant covariance formula for its unweighted magnitude. These changes also permit nonspanning seeds and experiments with nonexpanding, genuinely acting factors.

Fix orthogonal matrices  $A_a$  on  $V = \mathbb{R}^D$ , indexed by a finite alphabet, and a nonempty finite set  $\mathcal{X}$  of unit seeds. For a word  $w = a_1 \cdots a_N$  let  $A_w = A_{a_N} \cdots A_{a_1}$ . With a selected coordinate  $j$  and a binary answer  $B$ , the law is

$$(1) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, A_w x \rangle}{2}.$$

The error is the maximum binary total-variation error over all seeds, words and queries. The width  $W_{N,\varepsilon}$  is the minimum of the maximum number of available persistent labels in a realizing

*Key words and phrases.* Positive realization, compact group, orbit dimension, entropy, hidden memory, quantum automata, numerical simulation.

machine, including the final two-label answer cut. The horizon and epoch, nonuniform row tables, arithmetic and exact atomic sampling are free. A different machine may be used for every  $N$ . These are finite positive realizations, not uniform space-bounded algorithms.

Let  $H = \overline{\langle A_a \rangle}$  be connected and put  $R = \text{span}(H\mathcal{X})$ ,  $r = \dim R$ . Its canonical isotypic decomposition has invariant part  $R_0$  and nontrivial types  $\lambda$ . For one irreducible model  $E_\lambda$  of each active type, define

$$s_\lambda = \min_{\|v\|=1} \dim(Hv), \quad \sigma_{\mathcal{X}} = \max_{\lambda} s_\lambda.$$

The maximum is zero if there is no nontrivial type. For an isometric intertwiner  $J : E_\lambda \rightarrow R_\lambda$ , let  $B(J) = \|J^*\|_{\ell_D^\infty \rightarrow \ell^2}$ , and define

$$c_\lambda = \max_{x \in \mathcal{X}, J} \frac{\|J^*x\|}{B(J)}.$$

All these quantities belong to the represented experiment and its specified query geometry. For a command probability  $p$ , the action gap on  $E_\lambda$  is  $g_\lambda = 1 - \|P_\lambda - \Pi_\lambda\|^2$ , where  $P_\lambda$  averages the commands on sphere functions and  $\Pi_\lambda$  is Haar projection onto the invariant functions.

**Theorem 1.1** (Intrinsic dominant-action law). *Suppose  $0 < \rho \leq \min\{1/10, 1/(8r)\}$ . If an active type  $\lambda_*$  attaining  $\sigma_{\mathcal{X}}$  has  $g_{\lambda_*} > 0$  and  $0 \leq \varepsilon < \rho c_{\lambda_*}/2$ , then*

$$(2) \quad W_{N,\varepsilon} = \Theta(N^{\sigma_{\mathcal{X}}/2}).$$

*No action gap is required on the other types. The lower bound permits arbitrary hidden states and time-dependent stochastic rows. An exact upper realization uses common command rows and a horizon-dependent terminal decoder, with its randomized branch identity charged to the register. If all active vectors are invariant, constant width suffices.*

The action gap is identical on sphere functions and on Lebesgue-square-integrable functions on the representation space. It has an exact harmonic-block norm description. A full regular-representation gap of the effective group remains a sufficient certificate, but is no longer required by the headline. Proposition 8.1 makes the extension strict: ten rational orthogonal commands act faithfully on  $\mathbb{R}^3 \oplus \mathbb{R}^2$ , generate  $\text{SO}(3) \times \text{SO}(2)$ , and have no full group norm gap, while their numerical width is  $\Theta(N)$ . The three-dimensional constituent expands; the circle constituent does not.

We also compute rather than merely name the orbit invariant. Theorem 9.1 determines every compact simple adjoint minimum by a single-node root deletion, including all exceptional types and the minimizing centralizers. Theorem 9.3 determines the invariant throughout the second exterior-power fundamental family. In its  $\text{SU}(6)$  example the minimizing orbit is  $\text{SU}(6)/\text{Sp}(3)$  of dimension fourteen; the decomposable highest-weight orbit has dimension seventeen. This illustrates why projective highest-weight geometry cannot be substituted for the real-vector orbit required by the memory theorem.

| Notation                          | Meaning                                                         |
|-----------------------------------|-----------------------------------------------------------------|
| $H, R$                            | Effective compact matrix group and invariant span of the seeds. |
| $R_\lambda, E_\lambda$            | Canonical isotypic part and one irreducible model.              |
| $s_\lambda, \sigma_{\mathcal{X}}$ | Minimum orbit dimension and dominant active minimum.            |
| $g_\lambda, c_\lambda$            | Intrinsic action gap and query-calibrated activation.           |
| $K_t, W_{N,\varepsilon}$          | Available labels at a cut and optimal whole-run peak.           |

The analytic foundation is the orbital entropy occupation theorem, whose complete proof is retained. Uniform orbit charts and contracted orbit hulls supply its geometric lower and constructive upper partners. Those results are inherited; the present extensions are the intrinsic action formulation, canonical activation on arbitrary seed spans, dominant-only expansion, and the

resulting faithful nongapped example. Root centralizers, skew congruence normal forms, covering geometry and positive attenuating embeddings are classical tools, not new names for discoveries. The original projective and arithmetic applications retain their separate signal ranges and external assumptions in the appendices. No main result relies on the optional numerical LPS input.

## 2. THE EXPERIMENT AND ITS POSITIVE REALIZATION

In the general notation below,  $G$  may be taken to be the effective matrix group  $H$  of Section 3;  $U_a = A_a$ . The main hypothesis is the constituent action gap, not the full regular gap of an arbitrary presenting group. Older sufficient full-group hypotheses are explicitly retained only where stated. Let  $G$  be a compact group, let  $U : G \rightarrow O(V)$  be a continuous orthogonal representation on  $V = \mathbb{R}^D$ , and fix a finite command alphabet  $\mathcal{A} \subset G$ . A finite seed set  $\mathcal{X} \subset \mathbb{S}(V)$  is given initially. For  $w = (a_1, \dots, a_N)$  write  $U_w = U_{a_N} \cdots U_{a_1}$ . Relative to an orthonormal basis  $e_1, \dots, e_D$ , the prescribed numerical experiment is

$$(3) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, U_w x \rangle}{2}, \quad b \in \{-1, 1\}, \quad j \in [D], \quad 0 < \rho \leq 1/10.$$

All seeds, words and queries are required, not only almost-sure words under one source law. The probabilities are between  $(1 - \rho)/2$  and  $(1 + \rho)/2$ .

**Definition 2.1** (Clocked atomic-row realization). A horizon- $N$  machine consists of finite sets  $\mathcal{S}_t$  with  $|\mathcal{S}_t| = K_t$ , a stochastic initialization  $E_x$  on  $\mathcal{S}_0$ , stochastic matrices  $T_{t,a} : \mathcal{S}_t \rightarrow \mathcal{S}_{t+1}$ , and columns  $d_j : \mathcal{S}_N \rightarrow [-1, 1]$ . Its mean response is

$$(4) \quad E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j.$$

It has error at most  $\varepsilon$  if this differs from  $\rho\langle e_j, U_w x \rangle$  by at most  $2\varepsilon$  for every  $(x, w, j)$ . Available labels, including padding, count. All rows, including unreachable ones, are normalized. Only the updated label persists. The seed, word prefix, old random choices and any data-dependent protocol information cannot be consulted again unless represented by that label. The external time, horizon, fixed program and exact sampling from its rows are free. The final binary answer may be sampled when  $j$  arrives; if retained, it uses a two-label final cut. Write  $W_{N,\varepsilon}$  for the minimum of  $\max(2, K_0, \dots, K_N)$ .

The state alphabets and matrices may be chosen anew for each  $N$ , but the command symbols and their experimental meanings are fixed. Nothing requires one autonomous device or one decoder to serve all stopping lengths. No adaptive choice of the command is optimized in this model. A complex unitary representation can be treated by its realification; all inner products in the entropy argument are real.

Fix one seed  $x$  and an independent command law at each epoch for the converse. Let  $Y_t = U_{a_t} \cdots U_{a_1} x$  and let  $S_t$  be the actual machine state under this test law. Define

$$(5) \quad Z_t = \mathbb{E}[Y_t \mid S_t], \quad q_t = \mathbb{E}\|Z_t\|, \quad v_t = \mathbb{E}\|Z_t\|^2.$$

These random vectors and their laws are analytical devices, not an additional runtime register or oracle.

**Lemma 2.2** (Quadratic budget and terminal calibration). *For the fresh command  $a$ , put  $X_t = U_a Z_t$ . Then*

$$(6) \quad Z_{t+1} = \mathbb{E}[X_t \mid S_{t+1}], \quad \Delta_t := \mathbb{E}\|X_t - Z_{t+1}\|^2 = v_t - v_{t+1}, \quad \sum_{t < N} \Delta_t \leq 1.$$

*The sequences  $q_t, v_t$  are nonincreasing and start at one. A machine with error at most  $\varepsilon$  satisfies*

$$(7) \quad q_t \geq q_N \geq \kappa := \rho/\sqrt{D} - 2\varepsilon \quad (0 \leq t \leq N).$$

*Proof.* The current command is independent of the past, and the new label is generated from  $(S_t, a)$  by a common row. Conditioning first on  $(S_t, a, S_{t+1})$  and then on  $S_{t+1}$  proves the first identity. The orthogonal projection identity for conditional expectation gives the second; Jensen and orthogonality give both monotonicities. The fixed seed has unit norm, even with randomized initialization. For calibration form  $d = (d_1, \dots, d_D)$  only in the proof, so  $\|d\| \leq \sqrt{D}$ . Conditioning on the complete word and using (3)–(4) gives  $\mathbb{E}\langle Y_N, d(S_N) \rangle \geq \rho - 2\sqrt{D}\varepsilon$ . On conditioning instead on  $S_N$ , this is at most  $\sqrt{D}q_N$ . This proves (7). It does not require a joint measurement of the  $D$  coordinates.  $\square$

For each fixed profile, the optimum actual error is attained: all stochastic rows and terminal columns form a finite product of compact sets and the objective is a maximum of finitely many continuous functions. Thus the subsequent lower bounds concern the actual optimization, not a sum of local error certificates.

### 3. EXPANSION OF THE EFFECTIVE ACTION

The stochastic experiment specifies matrices, not a presentation of a group. Let  $\mathcal{A}$  be its finite command alphabet, let  $A_a \in O(V)$  be its command matrices, and put

$$H = \overline{\langle A_a : a \in \mathcal{A} \rangle} \subset O(V).$$

We assume that this compact Lie group is connected. A probability  $p$  on  $\mathcal{A}$  is used only in a converse; the required numerical law remains wordwise. All the quantities below are defined from these matrices and  $p$ . For a nonzero invariant subspace  $E$ , write  $\sigma_E$  for uniform sphere probability and define operators on  $L^2(\mathbb{S}(E), \sigma_E)$  by

$$P_E f(u) = \sum_a p(a) f(A_a^{-1} u), \quad \Pi_E f(u) = \int_H f(h^{-1} u) dm_H(h).$$

The squared *action gap* is

$$(8) \quad g_E = 1 - \|P_E - \Pi_E\|_{2 \rightarrow 2}^2.$$

Thus  $0 \leq g_E \leq 1$ . When every function is invariant, the norm in this formula is zero. Such a subspace has no positive-dimensional orbit and is not used in an occupation lower bound.

**Proposition 3.1** (Presentation invariance and the relevant spectrum). *The action gap has the following properties.*

- (1) *It is unchanged by an orthogonal intertwining of the action, by splitting a command into identical letters with the same total mass, or by replacing a presenting group by any compact extension with the same matrices and pushed-forward command law.*
- (2) *On  $L^2(E, dz)$ , with the same formulas for  $P_E$  and  $\Pi_E$ , the optimal inequality is*

$$(9) \quad \|P_E f\|_2^2 \leq \|\Pi_E f\|_2^2 + (1 - g_E) \|f - \Pi_E f\|_2^2.$$

*In particular, the sphere and Lebesgue action gaps are identical.*

- (3) *Let  $\mathcal{H}_l(E)$  be the restrictions of homogeneous harmonic polynomials of degree  $l$ , and let  $P_{E,l}, \Pi_{E,l}$  be the corresponding finite-dimensional restrictions. Then*

$$(10) \quad 1 - g_E = \sup_{l \geq 0} \|P_{E,l} - \Pi_{E,l}\|_{2 \rightarrow 2}^2.$$

*No finite truncation of this supremum is an asserted gap certificate.*

- (4) *A mean-zero regular-representation norm bound  $\sqrt{1 - g}$  on  $H$  implies  $g_E \geq g$ . It is a sufficient certificate, not the definition of the hypothesis.*

*Proof.* The operators are determined by the probability measure  $\sum_a p(a)\delta_{A_a|E}$  and the effective compact image on  $E$ . An orthogonal intertwiner induces a unitary conjugacy of both operators. Haar probability pushes forward to Haar probability on a compact image. This proves the first assertion, including extensions with a nontrivial kernel.

Polar coordinates identify  $L^2(E, dz)$  with  $L^2((0, \infty), r^{d-1}dr) \hat{\otimes} L^2(\mathbb{S}(E), \sigma_E)$ , up to an immaterial fixed normalization. Both operators act as the identity on the radial factor. Consequently  $\|P_E - \Pi_E\|$  is the same in the two spaces. Haar invariance gives  $P_E \Pi_E = \Pi_E P_E = \Pi_E$ , so the invariant and orthogonal components separate, proving (9). The usual orthogonal harmonic decomposition of sphere functions is invariant under every orthogonal matrix; the norm of a block-diagonal operator is the supremum of its block norms. This gives (10).

For the last assertion apply the group norm inequality, for fixed  $u$ , to  $F_u(h) = f(h^{-1}u)$  and integrate in  $u$ . Orthogonal invariance of sphere measure identifies the terms with the corresponding action norms. One may first take continuous  $f$ , and then use density. This is the group-to-action transference argument, not an implication from a gap in the defining representation alone.  $\square$

**Corollary 3.2** (Constituent action hypotheses suffice). *In the orbital occupation theorem below, the full presenting-group assumption can be replaced by  $g_E > 0$  on the particular irreducible space in which the conditional centroid is tracked. Its conclusion is*

$$g_E \# \{0 \leq t < N : K_t \leq k\} \leq B_{d,A,s} \kappa^{-3-2/s} k^{2/s}.$$

*Other invariant summands need not have a positive action gap.*

*Proof.* Equation (9) is exactly the analytic inequality used in entropy production. Apply Theorem 5.5 in  $E$ . The register is still the actual whole-machine register; no constituent identifier is supplied to it. The orbit estimate is that of Theorem 4.1 for the image on  $E$ .  $\square$

The distinction is substantive even after removing trivially acting factors. Section 8 gives a faithful finite-alphabet experiment with an effective circle factor and no full group norm gap, yet with a matched numerical width law supplied by one dominant expanding constituent. The older full-group results remain valid as corollaries whenever their stronger hypotheses hold.

#### 4. THE SMALLEST ORBIT CONTROLS UNIFORM CONCENTRATION

In this section  $G$  is a compact connected Lie group,  $U : G \rightarrow O(V)$ , and  $V^G = \{0\}$ . Put

$$(11) \quad s(U) = \min_{u \in \mathbb{S}(V)} \dim(Gu).$$

The minimum is over *all* directions. It can be smaller than the dimension of a generic orbit. Since  $G$  is connected,  $s(U) \geq 1$ .

**Theorem 4.1** (Uniform concentration across orbit types). *There is a finite constant  $A_U \geq 1$  such that*

$$(12) \quad \sup_{u,v \in \mathbb{S}(V)} m_G\{g : \|U_g u - v\| \leq r\} \leq A_U r^{s(U)} \quad (0 < r \leq 1).$$

*This exponent is optimal among uniform power upper bounds: for a unit  $u_0$  with  $\dim(Gu_0) = s(U)$  there are  $c, r_0 > 0$  such that*

$$(13) \quad m_G\{g : \|U_g u_0 - u_0\| \leq r\} \geq c r^{s(U)} \quad (0 < r < r_0).$$

*No regular-orbit, constant-stabilizer, or simple-spectrum hypothesis is needed in (12).*

*Proof.* Write  $m = \dim G$ ,  $s = s(U)$  and let  $\mathfrak{g}$  be the Lie algebra. For  $u \in \mathbb{S}(V)$  the differential

$$A_u : \mathfrak{g} \longrightarrow V, \quad X \longmapsto dU(X)u$$

has rank  $\dim(Gu) \geq s$ . Its  $s$ th singular value is continuous in  $u$  and is strictly positive on the compact sphere. Its minimum is therefore positive. We give a chart argument that also records why variation of the stabilizer causes no loss in the exponent.

Fix  $(g_0, u_0) \in G \times \mathbb{S}(V)$ . In a smooth coordinate chart  $g = \psi(z, w)$ , where  $z \in \mathbb{R}^s$  and  $w \in \mathbb{R}^{m-s}$ , select  $s$  coordinate directions and a linear projection  $L : V \rightarrow \mathbb{R}^s$  for which

$$D_z[LU_{\psi(z,w)}u]_{(g_0, u_0)} = M$$

is invertible. This is possible by the rank bound. By shrinking to a product of bounded open rectangles  $Z \times W$  and a neighborhood  $J$  of  $u_0$ , arrange

$$\|D_z[LU_{\psi(z,w)}u] - M\|_{\text{op}} \leq \frac{1}{2}\sigma_{\min}(M) \quad (z, w, u) \in Z \times W \times J.$$

Take  $Z$  convex. For fixed  $(w, u)$ , integration along the segment from  $z$  to  $z'$  gives

$$(14) \quad \|LU_{\psi(z,w)}u - LU_{\psi(z',w)}u\| \geq \frac{1}{2}\sigma_{\min}(M)\|z - z'\|.$$

If both points lie in the inverse image of the radius- $r$  ball around  $v$ , their projected distance is at most  $2\|L\|r$ . This inverse image, on the fixed  $w$  slice, consequently has diameter at most  $4\|L\|r/\sigma_{\min}(M)$ , and hence  $s$ -dimensional Lebesgue measure at most a constant times  $r^s$ . Haar measure has a bounded smooth density in the chosen relatively compact chart. Integration in the remaining  $m - s$  coordinates yields the same bound there.

Choose finitely many of these product neighborhoods covering  $G \times \mathbb{S}(V)$ . For each fixed  $u$ , those whose  $J$  contains  $u$  cover  $G$ ; summing the preceding bounds proves (12). All constants are independent of the center  $v$ . An empty inverse image contributes zero. This use of a finite cover, rather than a separate density estimate on every orbit, is what controls neighborhoods of singular orbit types.

For the converse,  $Gu_0 \simeq G/G_{u_0}$  is a compact smooth embedded  $s$ -dimensional submanifold. The pushforward of Haar probability is its normalized invariant Riemannian volume: the induced metric is  $G$ -invariant and the invariant probability on this homogeneous space is unique. A smooth local graph at  $u_0$  has volume comparable to  $r^s$  in a small ambient ball. This proves (13). If a uniform estimate with exponent  $s' > s$  held, comparison at  $u_0$  as  $r \downarrow 0$  would contradict it.  $\square$

The rank computation in (11) is intrinsic to the representation. For example, given algebraic skew matrices  $B_1, \dots, B_m$  spanning its infinitesimal action, the condition  $s(U) \leq r$  is the existence of a real vector  $u$  with  $\sum u_i^2 = 1$  and all  $(r+1)$ -minors of  $[B_1u \cdots B_mu]$  zero. Thus it is an explicit real-algebraic decision problem for fully specified algebraic data; quantifier elimination applies [22]. This is not a test for a spectral gap, and no efficient algorithm in a succinct representation is asserted.

**Corollary 4.2** (Intrinsic occupation exponent). *Suppose the representation satisfies (17). In the setting of Lemma 2.2,  $q_N \geq \kappa > 0$  implies*

$$(15) \quad \sum_{\substack{0 \leq t \leq N \\ \bar{K}_t \leq k}} g_t \leq 2048D(16A_U)^{2/s(U)} \kappa^{-3-2/s(U)} k^{2/s(U)}.$$

*The estimate allows arbitrary hidden continuations and imposes no bound on the other cuts.*

*Proof.* Apply Theorem 5.5 with the uniform estimate (12). In particular the conditional means may change orbit type at every step; their directions still satisfy the same estimate.  $\square$

## 5. AN ORBITAL ENTROPY OCCUPATION THEOREM

Lebesgue measure is used on  $V = \mathbb{R}^D$  and normalized Haar measure on  $G$ . For a function on  $V$ , set

$$(16) \quad \mathcal{U}_a f(z) = f(U_a^{-1}z), \quad P_t = \sum_a p_t(a) \mathcal{U}_a, \quad \Pi f(z) = \int_G f(U_g^{-1}z) dm_G(g).$$

Thus  $\mathcal{U}_a^* = \mathcal{U}_{a^{-1}}$ ,  $\Pi$  is an orthogonal projection, and  $P_t \Pi = \Pi P_t = \Pi$ . The probability law  $p_t$  need not be symmetric. Its required squared norm gap is

$$(17) \quad \|P_t f\|_2^2 \leq \|\Pi f\|_2^2 + (1 - g_t) \|f - \Pi f\|_2^2, \quad 0 \leq g_t \leq 1.$$

Invariance in this formula means  $G$ -invariance, not necessarily radial symmetry. In a reducible representation invariant functions can carry many parameters.

**Lemma 5.1** (Transfer of a group norm gap). *If right convolution  $R_{p_t} F(g) = \sum_a p_t(a) F(ga)$  on  $L^2(G)$  has mean-zero norm at most  $\sqrt{1 - g_t}$ , then (17) holds in every orthogonal representation on  $V$ .*

*Proof.* For each  $z$  apply the group inequality to  $F_z(g) = f(U_g^{-1}z)$ . Its mean is  $\Pi f(z)$  and  $R_{p_t} F_z(g) = P_t f(U_g^{-1}z)$ . Integrate the resulting inequality in  $z$ . Orthogonal changes of variables and Fubini identify the three integrals with those in (17). First take bounded compactly supported  $f$  and then use density. This proof does not replace the full group gap by a gap in the defining representation.  $\square$

**5.1. The conditional-mean cost.** Let  $G_D$  be a standard independent real Gaussian vector and let  $\gamma_\tau$  be the density of  $\tau G_D$ .

**Lemma 5.2** (A one-sided Gaussian coupling inequality). *For bounded  $X$  and a finite-valued variable  $J$ , put  $M = \mathbb{E}[X \mid J]$ . For every  $\tau > 0$ ,*

$$(18) \quad h(X + \tau G_D) - h(M + \tau G_D) \leq \frac{\mathbb{E}\|X - M\|^2}{2\tau^2}.$$

*Proof.* Write  $f = \text{Law}(M) * \gamma_\tau$ . Differentiation of the Gaussian mixture and the conditional covariance identity give

$$(19) \quad \nabla^2 \log f(y) = -\tau^{-2} I + \tau^{-4} \text{Cov}(M \mid M + \tau G_D = y) \succeq -\tau^{-2} I.$$

Hence  $\phi(x) = -\mathbb{E} \log f(x + \tau G_D)$  has Hessian at most  $\tau^{-2} I$ . Taylor's inequality at  $M$  yields  $\phi(X) \leq \phi(M) + \langle \nabla \phi(M), X - M \rangle + \|X - M\|^2 / (2\tau^2)$ . The conditional expectation of the linear term given  $J$  is zero. If  $g = \text{Law}(X) * \gamma_\tau$ , nonnegativity of  $D(g \| f)$  gives  $h(g) \leq -\int g \log f = \mathbb{E} \phi(X)$ , whereas  $\mathbb{E} \phi(M) = h(f)$ . Boundedness of  $X, M$  provides Gaussian bounds with finite second moments and justifies differentiation and integration. These identities prove (18).  $\square$

This elementary consequence of Gaussian posterior identities is used as an estimate, not as a claim of priority over the Gaussian estimation literature [1, 14]. The estimate is one-sided and can have a negative left side. Here  $J$  can be a finite register with no Gaussian observation model; the smoothing noise is added after conditioning.

**Lemma 5.3** (Entropy production away from invariant functions). *For any bounded-support Gaussian mixture density  $f$ ,*

$$(20) \quad h(P_t f) - h(f) \geq g_t \|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq 0.$$

*Proof.* Put  $f_a = \mathcal{U}_a f$  and  $h = P_t f$ . Orthogonality preserves entropy, so  $\mathbf{h}(h) - \mathbf{h}(f) = \sum_a p_t(a) D(f_a \| h)$ . For probability densities  $u, v$ ,  $D(u \| v) \geq \|\sqrt{u} - \sqrt{v}\|_2^2$ ; it follows, for example, from  $-\log x \geq 2(1 - \sqrt{x})$  and integration. The mean is the least-squares minimizer, and thus

$$\sum_a p_t(a) \|\sqrt{f_a} - \sqrt{h}\|_2^2 \geq \sum_a p_t(a) \|\sqrt{f_a} - P_t \sqrt{f}\|_2^2 = 1 - \|P_t \sqrt{f}\|_2^2.$$

Apply (17) and  $\|\sqrt{f}\|_2 = 1$ . □

No logarithmic Sobolev inequality or point-mass mixing assertion is used in this step.

**5.2. Sparsity away from invariant densities.** Suppose that the representation obeys the uniform orbital bound

$$(21) \quad m_G\{g : \|U_g u - v\| \leq r\} \leq A r^s \quad (u, v \in \mathbb{S}(V), 0 < r \leq 1),$$

where  $A \geq 1$  and  $s > 0$ . In particular the representation has no nonzero fixed vector. It is essential that  $u$  range over all possible centroid directions, not merely the initial seed orbit.

**Lemma 5.4** (Finite centroids cannot be almost invariant). *Suppose  $Z$  has at most  $k$  values in the unit ball and  $\mathbb{E}\|Z\| \geq \kappa$ , where  $0 < \kappa \leq 1$ . Set*

$$(22) \quad r = \left( \frac{\kappa}{16Ak} \right)^{1/s}, \quad \tau = \frac{\kappa r}{8\sqrt{2D}}, \quad f = \text{Law}(Z) * \gamma_\tau.$$

Then  $\|\sqrt{f} - \Pi\sqrt{f}\|_2^2 \geq \kappa/16$ .

*Proof.* Atoms of norm at least  $\kappa/2$  have total mass at least  $\kappa/2$ . Let  $\Omega$  be the union of radius- $r$  caps around their directions, and let  $C_\Omega$  be its cone. By Markov's inequality,  $\mathbb{P}(\|G_D\| \leq \sqrt{2D}) \geq 1/2$ . On this event, perturbing a high-norm atom by  $\tau G_D$  changes its direction by at most  $4\tau\sqrt{2D}/\kappa = r/2$ . Therefore  $\int_{C_\Omega} f \geq \kappa/4$ .

For any  $G$ -invariant  $u \in L^2(V)$ , Haar averaging and (21) give

$$\int_{C_\Omega} |u(z)|^2 dz = \int |u(z)|^2 \int_G \mathbf{1}_{C_\Omega}(U_g z) dm_G(g) dz \leq k A r^s \|u\|_2^2.$$

The point  $z = 0$  is Lebesgue-null. Taking  $u = \Pi\sqrt{f}$ , whose norm is at most one, bounds this integral by  $\kappa/16$ . The reverse triangle inequality in  $L^2(C_\Omega)$  now gives a norm difference at least  $\sqrt{\kappa/4} - \sqrt{\kappa/16} = \sqrt{\kappa}/4$ . Repeated directions and zero centroids cause no change. □

**Theorem 5.5** (Orbital occupation budget). *Under (17) and (21), let a finite hidden register track a unit-vector command process as in (5). If  $q_N \geq \kappa > 0$ , then, for every  $k \geq 1$ ,*

$$(23) \quad \sum_{\substack{0 \leq t < N \\ \bar{K}_t \leq k}} g_t \leq B_{D,A,s} \kappa^{-3-2/s} k^{2/s}, \quad B_{D,A,s} = 2048D(16A)^{2/s}.$$

*The same inequality holds with  $K_t$  replaced by the number of positive-probability labels under the chosen test law. No bound is imposed on the other epochs.*

*Proof.* Fix  $k$  and the single scale (22) for the entire run. Write  $f_t = \text{Law}(Z_t) * \gamma_\tau$ . Isotropy of the Gaussian makes the density of  $U_a Z_t + \tau G_D$  equal to  $P_t f_t$ . By Lemmas 5.2 and 5.3,

$$\mathbf{h}(f_{t+1}) - \mathbf{h}(f_t) \geq g_t \|\sqrt{f_t} - \Pi\sqrt{f_t}\|_2^2 - \frac{\Delta_t}{2\tau^2}.$$

At an epoch with at most  $k$  labels, Lemma 5.4 bounds the norm term below by  $\kappa/16$ . Elsewhere it is nonnegative. The initial density is a translate of  $\gamma_\tau$ ; the terminal second moment is at most

$1 + D\tau^2$ . The Gaussian maximum-entropy bound and (6) yield

$$\frac{\kappa}{16} \sum_{K_t \leq k} g_t \leq \frac{D}{2} \log \left( 1 + \frac{1}{D\tau^2} \right) + \frac{1}{2\tau^2} \leq \frac{1}{\tau^2}.$$

Substitute (22). The same Gaussian scale is retained through all epochs; no repeated mixing-time charge is incurred.  $\square$

**Corollary 5.6** (Actual terminal error). *For a constant gap  $g > 0$ , let  $\mathcal{E}_N(\mathbf{K})$  be the minimum actual wordwise binary-TV error over a prescribed available profile, and put  $K = \max_t K_t$ . Then*

$$(24) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{D}} - \left( \frac{B_{D,A,s} K^{2/s}}{gN} \right)^{1/(3+2/s)} \right]_+.$$

In particular,  $K = o(N^{s/2})$  implies  $\liminf \mathcal{E}_N \geq \rho/(2\sqrt{D})$ .

*Proof.* If the actual error is below the calibration threshold, combine (7) with (23) and solve for it. Otherwise the displayed lower bound already holds. Attainment or a minimizing sequence gives the same conclusion for the optimum.  $\square$

Local simulation errors may cancel. Nothing in this corollary sums such errors or rules out cancellation; its objective is the actual final law.

## 6. EXACT SYNTHESIS FROM A MINIMAL ORBIT

Assume in this section that  $V$  is a nontrivial real irreducible orthogonal representation, of dimension  $d$ . Choose a unit vector  $v_0$  with orbit dimension  $s = s(U)$ , and set

$$\mathcal{O} = Gv_0, \quad C = \text{conv } \mathcal{O}.$$

The orbit may be a singular orbit in the unit sphere. As a homogeneous space in its own right it is nevertheless a smooth compact manifold.

**Lemma 6.1** (Inradius and quadratic support approximation). *One has  $d^{-1}\mathbb{B}(V) \subseteq C \subseteq \mathbb{B}(V)$ . There are  $c, C_0, h_0 > 0$ , depending on  $U$  and  $v_0$ , such that for  $0 < h \leq h_0$  a set  $\mathcal{V}_h \subset \mathcal{O}$  with  $|\mathcal{V}_h| \leq C_0 h^{-s}$  satisfies*

$$(25) \quad (1 - ch^2)C \subseteq \text{conv } \mathcal{V}_h \subseteq C \quad \text{whenever } ch^2 < 1.$$

*Proof.* The mean of  $U_g v_0$  is an invariant vector and is zero. Its covariance is  $I/d$ : the covariance is self-adjoint and commutes with the representation, so its eigenspaces are invariant; irreducibility and trace one give the claim. This is the real Schur orthogonality calculation, for example [21, Lemma 5]. For unit  $H$ , let  $f(g) = \langle H, U_g v_0 \rangle$  and  $M = \max_g f(g)$ . Since  $-1 \leq f \leq M$ ,

$$0 \leq \mathbb{E}[(M - f)(f + 1)] = M - \mathbb{E}f^2 = M - 1/d.$$

Every support function of  $C$  is thus at least  $1/d$ , which proves the inradius statement.

Equip  $\mathcal{O}$  with its induced Riemannian metric. Finitely many bounded smooth coordinate patches, with their inverses uniformly Lipschitz on smaller patches, give an intrinsic  $h$ -net with at most  $C_0 h^{-s}$  points. At a maximizer  $y$  of  $z \mapsto \langle H, z \rangle$  on  $\mathcal{O}$ , its tangential first derivative is zero. The second fundamental form of the compact embedded orbit is bounded. Along a unit-speed minimizing geodesic of length at most  $h$ , Taylor's formula therefore gives

$$\langle H, y \rangle - \langle H, v \rangle \leq L \|H\| h^2$$

for a nearby net point  $v$ , with  $L$  independent of  $H, y$ . The inradius bound gives  $\|H\| \leq dh_C(H)$ . Hence  $h_{\text{conv } \mathcal{V}_h}(H) \geq (1 - Ldh^2)h_C(H)$  for every  $H$ . Taking  $c \geq Ld$ , and using the support-function criterion, proves (25).  $\square$

The covering exponent  $s$  and quadratic loss at a support maximum are geometric facts, not new quantization exponents. What is needed for realization is an enclosure compatible with *every command* and *every layer*; the following construction supplies it.

**Theorem 6.2** (A minimal-orbit positive realization). *For any finite command alphabet, any finite unit seed set, and  $0 < \rho \leq 1/(8d)$ , the experiment (3) has an exact realization with at most  $C_U N^{s(U)/2}$  available labels, for  $N \geq 1$ . All command matrices can be chosen independent of the epoch; the final decoder may depend on  $N$ . Each row has at most  $d + 1$  successors. If the seeds belong to  $C \cap \mathbb{S}(V)$ , the amplitude range improves to  $0 < \rho \leq 1/10$ .*

*Proof.* Choose

$$h_N = \min\{h_0, (8cN)^{-1/2}\}, \quad \eta = 1 - ch_N^2 \geq 1 - 1/(8N), \quad a_t = \eta^{-t}/4.$$

Let  $v_1, \dots, v_M$  be the net points. The represented vector of a label  $i$  at layer  $t$  is  $a_t v_i$ . These vectors describe the fixed rows; they are not stored as real-valued runtime data.

The polytope  $\text{conv}\{v_i\}$  contains  $\eta C$  and hence a ball of radius  $\eta/d$ . For a unit seed  $x$ ,  $4\rho x \in \eta C$  if  $\rho \leq 1/(8d)$ , because  $4\rho \leq 1/(2d) < \eta/d$ . Choose its convex coordinates as the initial distribution. More generally, if  $x \in C$  and  $4\rho \leq 2/5 < \eta$ , the same initialization is valid. For each command  $a$  and label  $i$ , invariance of  $C$  gives

$$\eta U_a v_i \in \eta C \subseteq \text{conv}\{v_j\}.$$

Choose any convex coordinates of this point for the row  $T_a(i, \cdot)$ . They do not depend on  $t$ . Since  $a_{t+1}\eta = a_t$ , conditional expectation updates the represented vector by exactly  $U_a$ . Induction gives mean  $\rho U_w x$  after each complete prefix.

Use the terminal column  $d_j(i) = a_N \langle e_j, v_i \rangle$ . Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $|d_j(i)| \leq 2/7 < 1$ . This proves every numerical conditional law exactly. Carathéodory's theorem gives  $d + 1$  successors. Finally  $M \leq C_0 h_N^{-s} \leq C_U N^{s/2}$ , with the fixed two-state output cut absorbed into the constant. Neither convex feasibility nor row lookup is priced as computation in this model.  $\square$

**Corollary 6.3** (The irreducible width law). *Suppose a probability law on the finite command alphabet has a full mean-zero group norm gap. For a nontrivial real irreducible  $V$ , any nonempty finite unit seed set, fixed  $0 < \rho \leq 1/(8d)$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{d})$ ,*

$$(26) \quad W_{N,\varepsilon} = \Theta_{U,p,\rho,\varepsilon}(N^{s(U)/2}).$$

*The same order holds for exact vector-state realizations and for fixed-length realizations with common command rows. For seeds on a minimal orbit the amplitude range is  $0 < \rho \leq 1/10$ .*

*Proof.* A full group norm gap transfers to (17) with a fixed  $g > 0$ . Apply Corollary 4.2 at the peak  $k$ , using  $\kappa = \rho/\sqrt{d} - 2\varepsilon > 0$ . It gives  $gN \leq B\kappa^{-3-2/s}k^{2/s}$  and therefore the lower order. The exact machine in Theorem 6.2 is an upper bound for every allowed error, is vector-valued in its representation, and has common command rows. These subclasses lie inside the unrestricted clocked class, so the lower bound applies to them too. The last assertion uses the stronger initialization in that theorem.  $\square$

## 7. CANONICAL ACTIVATION AND THE REACHABLE EXPERIMENT

No spanning hypothesis is needed on the given seeds. Their invariant reachable space is

$$(27) \quad R_{\mathcal{X}} = \text{span}\{hx : h \in H, x \in \mathcal{X}\}, \quad r = \dim R_{\mathcal{X}}.$$

Orthogonality makes its orthogonal complement invariant. Every response in (3) is unchanged when its query vector is projected to  $R_{\mathcal{X}}$ . Choose the *canonical isotypic decomposition*

$$R_{\mathcal{X}} = R_0 \oplus \bigoplus_{\lambda \in \Lambda} R_{\lambda}, \quad R_0 = R_{\mathcal{X}}^H,$$

where  $R_\lambda$  contains all copies of the nontrivial real irreducible type  $E_\lambda$ . Let  $d_\lambda = \dim E_\lambda$ , let  $m_\lambda$  be its real irreducible multiplicity, and put

$$s_\lambda = \min_{\|u\|=1, u \in E_\lambda} \dim(Hu), \quad \sigma_\lambda = \max_{\lambda \in \Lambda} s_\lambda.$$

For an empty set  $\Lambda$  we set  $\sigma_\lambda = 0$ . An isometric intertwiner  $J : E_\lambda \rightarrow R_\lambda$  identifies a single irreducible copy, without choosing a decomposition into copies. The set  $\mathcal{J}_\lambda$  of such intertwiners is nonempty and compact: it is the intersection of the linear intertwining equations with  $J^*J = I$ .

**Definition 7.1** (Canonical seed and query calibration). Let  $P_\lambda$  be the isotypic orthogonal projection, and define

$$(28) \quad a_\lambda = \max_{x \in \mathcal{X}, J \in \mathcal{J}_\lambda} \|J^*x\|,$$

$$(29) \quad B(J) = \|J^*\|_{\ell_D^\infty \rightarrow \ell_{d_\lambda}^2} = \max_{\|u\|=1} \|Ju\|_1, \quad c_\lambda = \max_{x, J} \frac{\|J^*x\|}{B(J)}.$$

The  $\ell^1$  and  $\ell^\infty$  norms refer to the actual coordinate queries  $e_j$ . Thus  $c_\lambda$  is invariant under changes of model coordinates when the queries are transformed with them, but a physical change of the query family is not declared costless. One always has  $a_\lambda/\sqrt{D} \leq c_\lambda \leq a_\lambda$ .

The equality defining  $B$  is norm duality. Since  $J$  is an isometry,  $1 \leq B(J) \leq \sqrt{D}$ , so maxima exist and denominators are nonzero.

**Proposition 7.2** (A spectral formula in the commutant). *For  $x \in \mathcal{X}$  set*

$$C_{\lambda,x} = \int_H (hP_\lambda x)(hP_\lambda x)^* dm_H(h) \quad \text{on } R_\lambda.$$

*Then*

$$(30) \quad a_\lambda^2 = d_\lambda \max_{x \in \mathcal{X}} \lambda_{\max}(C_{\lambda,x}), \quad \frac{\max_x \|P_\lambda x\|}{\sqrt{m_\lambda}} \leq a_\lambda \leq \max_x \|P_\lambda x\|.$$

*Every active isotypic type has  $a_\lambda > 0$ . Both  $a_\lambda$  and  $c_\lambda$  are independent of a splitting into equivalent copies. For each fixed seed,  $C_{\lambda,x}$  is the Hilbert–Schmidt orthogonal projection of  $(P_\lambda x)(P_\lambda x)^*$  onto the matrix commutant. Consequently the spectral formula is finite linear algebra once the isotypic projection is supplied.*

*Proof.* Haar averaging is a self-adjoint idempotent on the space of real matrices, with image the matrices commuting with  $H$ . This proves the last assertion. For an isometric intertwiner  $J$ , the self-adjoint operator  $J^*C_{\lambda,x}J$  commutes with the irreducible action on  $E_\lambda$ . Its eigenspaces are invariant, so it is scalar, even in complex and quaternionic commutant types. Its trace is  $\|J^*x\|^2$ ; therefore it equals  $\|J^*x\|^2 I/d_\lambda$ . This gives the upper bound by  $\lambda_{\max}(C_{\lambda,x})$ .

Conversely, the top eigenspace of  $C_{\lambda,x}$  is invariant and contains an irreducible copy of type  $\lambda$ . Choose  $J$  with image in that eigenspace. The preceding scalar identity gives equality. The trace is  $\|P_\lambda x\|^2$ , the ambient dimension is  $m_\lambda d_\lambda$ , and the top eigenspace has dimension at least  $d_\lambda$ . These facts give both norm bounds in (30). If  $P_\lambda x = 0$  for every seed, then it is zero on their invariant span, contrary to the presence of  $R_\lambda$ . The remaining assertions follow from the definitions.  $\square$

This formula is not an appeal to a preferred basis of a multiplicity space. For instance, on two identical copies of a real-type  $d$ -dimensional irreducible, a seed  $(v, v)/\sqrt{2}$  has projection norm  $1/\sqrt{2}$  on each displayed copy and norm one on the diagonal copy. Its canonical  $a_\lambda$  is one. Taking a minimum over the displayed copies would produce a coordinate-dependent calibration. This seed need not span the ambient space; its reachable space is precisely the diagonal copy.

**Theorem 7.3** (Intrinsic numerical width with active seeds). *Assume  $H$  is connected,  $\mathcal{X}$  is a nonempty finite unit seed set, and  $0 < \rho \leq \min\{1/10, 1/(8r)\}$ . If  $\Lambda \neq \emptyset$ , suppose there is a type  $\lambda_*$  with*

$$(31) \quad s_{\lambda_*} = \sigma_{\mathcal{X}}, \quad g_{E_{\lambda_*}} > 0, \quad 0 \leq \varepsilon < \rho c_{\lambda_*}/2.$$

Then

$$(32) \quad W_{N,\varepsilon} = \Theta(N^{\sigma_{\mathcal{X}}/2}).$$

No action gap is required on the other types. The upper realization is exact and uses common command rows and an  $N$ -dependent decoder. If  $\Lambda$  is empty, an exact constant-width realization exists. All constants are for the fixed experiment, signal and error.

*Proof.* Fix a type with  $g_{E_{\lambda}} > 0$  and choose  $x, J$  attaining  $c_{\lambda}$ , writing  $a = \|J^*x\| > 0$  and  $B = B(J)$ . Track  $Y_t = U_{w_t}|_{E_{\lambda}} J^*x/a$  under independent commands with law  $p$ , conditioned on the *actual* register of any candidate machine. For its decoder vector  $d(S_N) \in [-1, 1]^D$ , the wordwise error implies

$$\mathbb{E}\langle JY_N, d(S_N) \rangle \geq \rho a - 2\varepsilon B.$$

Indeed  $JY_N$  lies in the chosen invariant copy, its pairing with  $U_w x$  is  $a$ , and its  $\ell^1$  norm is at most  $B$  for each word. On the other hand  $\|J^*d(S_N)\| \leq B$ , so conditioning on  $S_N$  bounds this correlation above by  $Bq_N$ . Thus

$$(33) \quad q_N \geq \kappa_{\lambda} := \rho c_{\lambda} - 2\varepsilon > 0.$$

Corollary 3.2 and the all-direction orbit bound now give  $W_{N,\varepsilon} \geq cN^{s_{\lambda}/2}$ . Apply this to  $\lambda_*$ . The proof charges no free information about  $J$  or the isotypic type: these are analytical choices for a converse.

For the upper bound choose, solely to construct a machine, any orthogonal irreducible decomposition of  $R_{\mathcal{X}}$ . Give a copy of dimension  $d_i$  the input-independent branch weight  $w_i = d_i/r$ . In that branch initialize the minimal-orbit construction of Theorem 6.2 at mean  $(\rho/w_i)\pi_i x$ . Its norm is at most  $\rho r/d_i \leq 1/(8d_i)$ , the sufficient initialization radius there. The same proof works for subunit initial vectors. Query  $j$  uses the restriction of the ambient functional  $e_j$ , of norm at most one. The disjoint union of branch labels stores the selected branch. Its weighted output mean is exactly  $\rho U_w x$ . A fixed subspace is implemented by the scaled cross-polytope construction in the proof of Theorem A.1; give it weight  $\dim R_0/r$ . The resulting total label count is

$$O(1) + \sum_{\lambda} m_{\lambda} C_{\lambda} N^{s_{\lambda}/2} = O(N^{\sigma_{\mathcal{X}}/2}).$$

All copies are fixed in number. Command rows are common in time; branch selection and the final two-label output cut are charged. If only fixed vectors are reachable, retain the finite seed identity or use the fixed polytope, and keep its state unchanged.  $\square$

**Corollary 7.4** (Canonical occupation and actual error). *For each type with  $g_{E_{\lambda}} > 0$ , set  $B_{\lambda} = B_{d_{\lambda}, A_{\lambda}, s_{\lambda}}$  from the orbit theorem. Every machine of error  $\varepsilon$  with  $\kappa_{\lambda} = \rho c_{\lambda} - 2\varepsilon > 0$  obeys*

$$g_{E_{\lambda}} \# \{t < N : K_t \leq k\} \leq B_{\lambda} \kappa_{\lambda}^{-3-2/s_{\lambda}} k^{2/s_{\lambda}}.$$

For a prescribed profile of peak  $K$ , the optimum actual error is at least

$$(34) \quad \frac{1}{2} \max_{\lambda: g_{E_{\lambda}} > 0} \left[ \rho c_{\lambda} - \left( \frac{B_{\lambda} K^{2/s_{\lambda}}}{g_{E_{\lambda}} N} \right)^{1/(3+2/s_{\lambda})} \right]_+.$$

An empty maximum means zero. In particular only one calibrated expanding type of maximal  $s_{\lambda}$  is needed for the matched exponent.

*Proof.* Use (33) in the same occupation theorem, then solve its peak form for  $\varepsilon$  and maximize the resulting lower bounds. If the actual error exceeds a type's threshold, its displayed bound is already true. Compactness of all rows and decoders for a fixed profile gives the same inequality for the optimum.  $\square$

*Proof of Theorem 1.1.* Apply Theorem 7.3 and Proposition 3.1. The definitions use only the effective command action, its reachable seed space, and the actual query norms.  $\square$

## 8. A FAITHFUL ACTION WITHOUT A FULL GROUP GAP

The action formulation is not merely a way to remove a superfluous factor from the notation. Here the nonexpanding factor acts nontrivially and is observed by the experiment.

**Proposition 8.1** (An expanding dominant summand is enough). *Let  $R_x, R_z \in \mathrm{SO}(3)$  be rotations about the first and third axes with cosine  $3/5$  and sine  $4/5$ , and let*

$$\mu_3 = \frac{1}{5}(\delta_I + \delta_{R_x} + \delta_{R_x^{-1}} + \delta_{R_z} + \delta_{R_z^{-1}}).$$

*Let  $R \in \mathrm{SO}(2)$  have the same cosine and sine, and let  $\nu = \frac{1}{2}(\delta_I + \delta_R)$ . The ten block-diagonal commands with product law  $\mu_3 \otimes \nu$  act faithfully on  $V = \mathbb{R}^3 \oplus \mathbb{R}^2$ . For seeds  $\{\pm e_1, \dots, \pm e_5\}$ ,  $0 < \rho \leq 1/40$  and  $0 \leq \varepsilon < \rho/(2\sqrt{3})$ ,*

$$(35) \quad W_{N,\varepsilon} = \Theta(N).$$

*The effective group is  $\mathrm{SO}(3) \times \mathrm{SO}(2)$  and its mean-zero regular convolution norm is one. Thus (35) is outside the full-effective-group-gap hypothesis as well as outside the full presenting-group-gap hypothesis.*

*Proof.* The complex number  $(3 + 4i)/5$  is not a root of unity: a root of unity and its inverse are algebraic integers, whereas their sum  $6/5$  is rational and not integral. The closure of its powers is therefore the circle. Powers of  $R_x$  and  $R_z$  give the two continuous axis rotation subgroups. Their infinitesimal generators and bracket span  $\mathfrak{so}(3)$ , so they generate a dense subgroup of  $\mathrm{SO}(3)$ . The product alphabet includes the identities needed to generate the two factors separately, proving the assertion about the effective group.

The matrices are rational. Benoist–de Saxcé’s algebraic-generator theorem [2, Theorem 1.2] supplies a regular spectral gap on the compact simple factor  $\mathrm{SO}(3)$ . Since  $\mu_3$  is symmetric, its operator is self-adjoint and spectral radius equals norm. (Its identity mass also bounds the negative spectral edge away from  $-1$ .) Proposition 3.1 gives  $g_{\mathbb{R}^3} > 0$ . On the effective circle, put  $R = e^{2\pi i \alpha}$  in complex notation. The functions  $e^{2\pi i l \theta}$  have eigenvalues  $(1 + e^{2\pi i l \alpha})/2$ . Infinitely many  $l$  have  $\|l\alpha\| \rightarrow 0$ , by the pigeonhole approximation argument. Their moduli tend to one, proving the failure of a full product norm gap.

The two real irreducible summands have minimum orbit dimensions two and one. The first is dominant and has  $c = 1/\sqrt{3}$ : its standard basis seeds have projection norm one and its coordinate-query norm is  $\sqrt{3}$ . Theorem 7.3 now applies with  $r = 5$ . The exact upper compiler uses  $O(N)$  sphere labels and  $O(N^{1/2})$  circle labels. No Diophantine assumption on  $\alpha$  and no numerical value of the qualitative  $\mathrm{SO}(3)$  gap is used.  $\square$

The external input in this example is the algebraic spectral-gap theorem for the simple factor, not a newly proved expansion result. The conclusion shows why requiring expansion on every activated type would also be unnecessarily restrictive for a maximum-exponent law.

## 9. MINIMUM ORBITS FROM ROOT AND SINGULAR-VALUE DATA

The width theorem becomes a numerical exponent only after its orbit invariant is evaluated. This section evaluates it on every compact simple adjoint representation, on the defining classical representations, and on an infinite family of fundamental representations. The root and normal-form tools are classical; they are not asserted to originate in this paper. What they determine here is the dynamic width exponent under the action and calibration hypotheses of Theorem 7.3. We use the conventional root systems and highest-weight notation of [31, Sections 21–23, 27, 30–32].

**9.1. All compact simple adjoint representations.** Let  $\mathfrak{h}$  be a compact simple real Lie algebra, with its invariant positive inner product, and let  $H$  be its connected adjoint group. Choose a maximal torus and a simple system  $\Delta$  in the root system  $\Phi$  of its complexification. For  $I \subset \Delta$  let  $\Phi_I$  be the root subsystem generated by  $I$ ; the empty subsystem has zero roots.

**Theorem 9.1** (Adjoint minimum-orbit formula). *For the adjoint action on  $\mathfrak{h}$ ,*

$$(36) \quad s(\text{Ad}) = |\Phi| - \max_{\alpha \in \Delta} |\Phi_{\Delta \setminus \{\alpha\}}|.$$

*Every minimizing unit vector is conjugate to a point on a fundamental coweight ray corresponding to a maximizing deletion in (36). Conversely every such ray minimizes. The compact centralizer has Lie algebra consisting of the deleted-node Levi algebra and a one-dimensional center. The values are listed in Table 1.*

*Proof.* Every element is conjugate into a closed Weyl chamber of the compact Cartan algebra. We identify that algebra with its real root-coordinate space. If  $X$  lies in this chamber, put  $I(X) = \{\alpha \in \Delta : \alpha(X) = 0\}$ . A positive root is a nonnegative integral combination of simple roots. Consequently its value on  $X$  vanishes exactly when it belongs to  $\Phi_{I(X)}$ . The real centralizer dimension is therefore  $\text{rank } \Phi + |\Phi_{I(X)}|$ , while  $\dim \mathfrak{h} = \text{rank } \Phi + |\Phi|$ . Hence

$$\dim(HX) = |\Phi| - |\Phi_{I(X)}|.$$

For  $X \neq 0$ , the simple roots span the dual Cartan space, so  $I(X)$  is proper. Every proper subset is contained in a subset obtained by one deletion. If it is strictly contained, adjoining a missing simple root adds at least that root and its negative, and strictly increases the root count. Thus the largest possible centralizer occurs precisely at a maximizing single deletion. Points of the closed chamber with exactly that zero set are the positive fundamental coweight ray. Normalization chooses its unit point. This proves the formula and all the assertions about the minimizers and their centralizers.

For completeness the root counts entering the table can be obtained without an orbit-type classification. For  $A_\ell$ , deletion of node  $i$  leaves  $A_{i-1} + A_{\ell-i}$  and has  $i(i-1) + (\ell-i)(\ell-i+1)$  roots. For  $B_\ell, C_\ell$  the analogous count is  $i(i-1) + 2(\ell-i)^2$ . These convex quadratic expressions are maximized at endpoints; they give the displayed counts, including the rank-two ties. For  $D_\ell$  the chain deletions give  $i(i-1) + 2(\ell-i)(\ell-i-1)$ , while a spin-end deletion gives  $\ell(\ell-1)$ . Their maximum is  $2(\ell-1)(\ell-2)$  for  $\ell \geq 4$ , with the familiar ties at  $D_4$ . The exceptional diagrams have at most eight nodes: deleting them gives respectively a maximal  $A_1, B_3$  or  $C_3, D_5, E_6$ , and  $E_7$  root subsystem. Their root counts are 2, 18, 40, 72, 126, whereas the original systems have 12, 48, 72, 126, 240 roots. These counts follow by reflection from their simple roots, or directly from the standard coordinate root lists. Substitution completes the table.  $\square$

These are orbits of actual real vectors in the compact Lie algebra. They are not complex nilpotent orbits or projective highest-weight orbits. Confusing these objects changes the dimensions. The table is an evaluation of a classical centralizer calculation, not a claim of new classification of compact simple Lie algebras.

TABLE 1. Compact adjoint orbits and their conditional width exponents. The central one-dimensional torus in the centralizer is not a root.

| Type                       | Largest deleted root subsystem | $s(\text{Ad})$ | $s/2$       |
|----------------------------|--------------------------------|----------------|-------------|
| $A_\ell$ ( $\ell \geq 1$ ) | $A_{\ell-1}$                   | $2\ell$        | $\ell$      |
| $B_\ell$ ( $\ell \geq 2$ ) | $B_{\ell-1}$                   | $4\ell - 2$    | $2\ell - 1$ |
| $C_\ell$ ( $\ell \geq 2$ ) | $C_{\ell-1}$                   | $4\ell - 2$    | $2\ell - 1$ |
| $D_\ell$ ( $\ell \geq 4$ ) | $D_{\ell-1}$                   | $4\ell - 4$    | $2\ell - 2$ |
| $G_2$                      | $A_1$                          | 10             | 5           |
| $F_4$                      | $B_3$ or $C_3$                 | 30             | 15          |
| $E_6$                      | $D_5$                          | 32             | 16          |
| $E_7$                      | $E_6$                          | 54             | 27          |
| $E_8$                      | $E_7$                          | 114            | 57          |

### 9.2. Defining and low-rank spin representations.

**Proposition 9.2** (Transitive defining actions). *The defining real actions of  $\text{SO}(n)$  on  $\mathbb{R}^n$ ,  $\text{SU}(n)$  on the underlying real space of  $\mathbb{C}^n$ , and  $\text{Sp}(n)$  on  $\mathbb{H}^n$  have minimum orbit dimensions*

$$n - 1, \quad 2n - 1, \quad 4n - 1,$$

*respectively ( $n \geq 3$ ,  $n \geq 2$ , and  $n \geq 1$ ). Their unit-vector stabilizers are  $\text{SO}(n - 1)$ ,  $\text{SU}(n - 1)$ , and  $\text{Sp}(n - 1)$ . The real spin representations of  $\text{Spin}(3)$  and  $\text{Spin}(5)$ , and either complex half-spin representation of  $\text{Spin}(6)$  viewed as a real representation, have minimum orbit dimensions 3, 7, 7.*

*Proof.* Extend a unit vector to an orthonormal basis over the respective field. In the special orthogonal and special unitary cases, adjust the determinant on its orthogonal complement. This proves transitivity on the sphere. A matrix fixing the first basis vector acts freely by the indicated smaller group on its complement, giving the stabilizers and the dimensions. The standard low-rank identifications  $\text{Spin}(3) = \text{Sp}(1)$ ,  $\text{Spin}(5) = \text{Sp}(2)$  and  $\text{Spin}(6) = \text{SU}(4)$  identify the stated spin modules with these defining modules (the two half-spin modules in the last case are dual). They follow also by matching the  $B_1$ ,  $B_2 = C_2$ , and  $D_3 = A_3$  fundamental weights and dimensions [31, Sections 30–32]. Apply the preceding transitivity.  $\square$

This proposition does not assert a formula for all higher spin modules. The adjoint table, including every exceptional type, and the next fundamental family have separate complete proofs.

**9.3. A fundamental family whose minimum need not be a highest-weight orbit.** Let  $\text{SU}(n)$  act on complex skew-symmetric matrices by  $A \mapsto gAg^T$ . This is  $\wedge^2 \mathbb{C}^n$ , with its underlying real Euclidean structure. A fixed scalar normalization of the Hilbert–Schmidt norm does not affect orbit dimensions.

**Theorem 9.3** (Second exterior powers). *For this action on its real unit sphere,*

$$(37) \quad s\left(\left(\bigwedge^2 \mathbb{C}^n\right)_{\mathbb{R}}\right) = \begin{cases} 5, & n = 3, 4, \\ 13, & n = 5, \\ 14, & n = 6, \\ 4n - 7, & n \geq 7. \end{cases}$$

*For  $n = 3$  and  $n \geq 5$  the underlying real representation is irreducible. For  $n = 4$  it is the sum of two equivalent real six-dimensional irreducibles, each with minimum orbit dimension five. At  $n = 6$  a minimizing vector is a full-rank symplectic form, with stabilizer  $\text{Sp}(3)$  and orbit  $\text{SU}(6)/\text{Sp}(3)$ ; the decomposable highest-weight vector instead has orbit dimension seventeen.*

*Proof.* We recall the skew-symmetric unitary congruence normal form and its argument. On  $\mathbb{C}^n$  define the antilinear map  $Fv = A\bar{v}$ . Skew symmetry implies  $F^2 = -AA^*$ . On a positive eigenspace of  $AA^*$  with eigenvalue  $a^2$ ,  $F/a$  is antiunitary, squares to  $-I$ , and pairs a unit vector with an orthogonal unit vector. Inductively choosing such pairs gives blocks  $aJ$ , where  $J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ , and a zero block. This is the classical unitary congruence construction [32]; the pairing argument supplies the needed special case. Although the basis change can have determinant different from one, conjugation by it preserves  $SU(n)$  and therefore the dimension of the stabilizer inside  $SU(n)$ .

Suppose the distinct positive singular values have multiplicities  $2k_1, \dots, 2k_b$ , with  $k = \sum_i k_i$  and  $l = n - 2k$ . A stabilizer preserves the eigenspaces of  $AA^*$  and commutes there with the associated quaternionic structure. Its unitary factors are therefore  $Sp(k_i)$ ; on the kernel they form  $U(l)$ . The symplectic factors have determinant one, so imposing determinant one leaves  $SU(l)$  on the kernel when  $l > 0$ . The stabilizer dimension is

$$\sum_i k_i(2k_i + 1) + \begin{cases} l^2 - 1, & l > 0, \\ 0, & l = 0. \end{cases}$$

At fixed rank, coalescing the positive singular values increases this quantity, because merging parts  $a, b$  increases it by  $4ab$ . Thus the smallest orbit at rank  $2k < n$  has dimension

$$(38) \quad n^2 - 1 - k(2k + 1) - ((n - 2k)^2 - 1) = k(4n - 6k - 1).$$

At full rank  $n = 2k$  it has dimension

$$(39) \quad n^2 - 1 - k(2k + 1) = n(n - 1)/2 - 1.$$

The quadratic in (38) is concave in  $k$ , so its minimum is at an endpoint. Comparing those endpoints with (39), when present, gives exactly (37). These minimizing strata are attained by normalized block forms, so this is not merely a dimension lower bound.

The complex module has highest weight  $\omega_2$  and dual weight  $\omega_{n-2}$ ; for  $n \neq 4$  these are different when  $n \geq 3$ . Consequently its underlying real module is irreducible of complex type. For  $n = 4$  the conjugate-linear Hodge involution on two-forms has square one and commutes with  $SU(4)$ ; its fixed real six-space and its imaginary multiple give the two equivalent real forms. The identification  $SU(4) = Spin(6)$  makes each the standard real six-dimensional module, so its minimum orbit dimension is five. Alternatively the full-rank equality in (39) gives the same whole-space minimum. Finally  $\dim SU(6) - \dim Sp(3) = 35 - 21 = 14$ , whereas (38) at  $k = 1$  gives seventeen.  $\square$

Under the intrinsic action-gap and calibration hypotheses, divide the numbers in (37) by two to obtain the width exponents. In particular the  $SU(6)$  fundamental module has order  $N^7$ , not  $N^{17/2}$ ; replacing the minimizing real-vector orbit by the highest-weight orbit would give the wrong answer. These results do not purport to classify every highest-weight representation. They compute the invariant, and its minimizing stabilizers, on the stated complete families rather than leaving those inputs as an existential rank test.

## 10. MATRIX AND HARMONIC REPRESENTATIONS

Theorem 4.1 identifies the correct geometric exponent without a separate estimate for every spectral type. We record its principal matrix consequences. The orbit dimensions below are classical; their role is to determine the dynamic width exponent.

**Proposition 10.1** (Three conjugation families). *On the real space of traceless self-adjoint  $q$  by  $q$  matrices over  $\mathbb{F} = \mathbb{R}, \mathbb{C}, \mathbb{H}$ , with inner product  $\text{Re tr}(AB)$ , let  $\beta = \dim_{\mathbb{R}} \mathbb{F}$ . The compact groups  $SO(q), SU(q), Sp(q)$ , respectively, act irreducibly for  $q \geq 2$ . The least nonzero unit-orbit dimension is  $\beta(q - 1)$ . Accordingly, under a full group gap, the width order in Corollary 6.3 is*

$$(40) \quad N^{(q-1)/2}, \quad N^{q-1}, \quad N^{2(q-1)},$$

respectively, in its fixed signal and fixed error ranges. The  $\mathrm{SO}(2)$  case supplies no finitely supported full-gap example.

*Proof.* A self-adjoint matrix with distinct eigenvalue multiplicities  $m_1, \dots, m_r$  has orbit dimension

$$\beta \sum_{i < j} m_i m_j = \frac{\beta}{2} \left( q^2 - \sum_i m_i^2 \right).$$

For real matrices subtract the dimensions of the orthogonal stabilizer blocks from  $q(q-1)/2$ ; their disconnected components do not affect dimension. For complex matrices subtract  $\sum m_i^2 - 1$  from  $q^2 - 1$ . For quaternionic matrices subtract  $\sum m_i(2m_i + 1)$  from  $q(2q + 1)$ . These computations also identify the least orbits as real, complex and quaternionic projective spaces. A nonzero traceless matrix has at least two eigenvalues. The largest possible  $\sum m_i^2$  under that restriction is  $(q-1)^2 + 1$ , attained by multiplicities  $(1, q-1)$ . This proves the minimum.

For completeness, the conjugation representation is irreducible over  $\mathbb{R}$ . Any nonzero invariant real subspace contains, after diagonalizing a nonzero member, a nonconstant traceless real diagonal matrix. Differences of its conjugates under coordinate interchanges give all traceless diagonal directions. Rotations in a pair of coordinate axes then give every self-adjoint off-diagonal direction; in the complex and quaternionic cases, diagonal unit phases give each real component of those entries. Signed interchanges and plane rotations can be chosen in the stated special groups. Thus the subspace is the entire traceless self-adjoint space. The general width law applies. Finally a finite measure on a torus has Fourier multipliers arbitrarily close to one by simultaneous approximation, so it has no full norm gap on its mean-zero  $L^2$  space.  $\square$

For complex matrices the projective seeds in (56) belong to a least-dimensional orbit. The signal need not be reduced to  $1/(8(q^2 - 1))$  in this specialization.

**Corollary 10.2** (The preserved projective width law). *Let  $q \geq 2$ ,  $0 < \rho \leq 1/10$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{q^2 - 1})$  be fixed. For the finite projective seeds and coordinate queries of Section C, any finite command alphabet supporting a full group norm gap has*

$$W_{N,\varepsilon} = \Theta(N^{q-1}).$$

*It has the fixed  $q$ -dimensional quantum realization of Proposition C.4. The explicit quantitative all-spectra estimate and the rational-projector net from the preceding revision are retained in Appendices B and C.*

**Proposition 10.3** (Every fixed spherical harmonic degree). *Let  $V_\ell$  be the real irreducible  $\mathrm{SO}(3)$  representation of harmonic homogeneous polynomials of degree  $\ell \geq 1$ , with  $\dim V_\ell = 2\ell + 1$ . Then  $s(V_\ell) = 2$ . Consequently every fixed  $\ell$  has width  $\Theta(N)$  under a full-gap command law, with the signal and query conventions of Corollary 6.3. The same six-command arithmetic alphabet in Appendix D supplies such a gap for all these representations.*

*Proof.* A nonzero vector has no three-dimensional stabilizer, since the representation is nontrivial irreducible. The Lie algebra  $\mathfrak{so}(3)$  has no two-dimensional subalgebra: identifying its bracket with a cross product, two independent elements bracket to a third independent direction. The stabilizer dimension is therefore at most one, so every orbit has dimension at least two. A zonal spherical harmonic is fixed by the circle of rotations about its axis and has a two-dimensional orbit. This gives the minimum. The final assertion follows from Proposition E.1: the spherical norm bound controls all nontrivial  $\mathrm{SO}(3)$  irreducibles, not just the defining three-dimensional action.  $\square$

The degree is fixed before  $N \rightarrow \infty$ ; no uniform-in- $\ell$  constants are claimed. Generic harmonic orbits can be three-dimensional, so their dimension would give the wrong exponent. In the real degree-two representation this is already the distinction between generic three-dimensional

matrix orbits and the two-dimensional projective orbit. These examples use the same general minimum-orbit theorem, not separate orbital cap computations.

## 11. NUMERICAL REALIZATION IS NOT CUTPOINT SIMULATION

A numerical simulator must preserve the values in (3), whereas a strict-cutpoint simulator need only preserve whether the answer probability is larger than  $1/2$ . The following construction makes the difference explicit in the present command model. Its stochastic embedding mechanism is classical; it is the quantitative width theorem that prevents numerical exactification at bounded width.

**Proposition 11.1** (A constant-width sign simulator). *For any orthogonal action on  $\mathbb{R}^D$ ,  $D \geq 2$ , there is a machine with  $D + 1$  command-layer labels, common command rows, and one common query decoder for all lengths such that*

$$(41) \quad \tilde{\mathbb{P}}(B = 1 \mid x, w, j) - \frac{1}{2} = \frac{1}{2} \lambda^{N+1} \langle e_j, U_w x \rangle, \quad \lambda = 1/(2D).$$

*It preserves every strict comparison of (3) with  $1/2$ , including equality. If  $\lambda^{N+1} \leq \rho$ , its worst numerical binary-TV error is at least  $(\rho - \lambda^{N+1})/(2\sqrt{D})$ .*

*Proof.* Let  $v_0, \dots, v_D$  be a regular simplex on the unit sphere of  $\mathbb{R}^D$ , centered at zero. Then

$$\sum_s v_s = 0, \quad \sum_s v_s v_s^T = \frac{D+1}{D} I, \quad b_s(z) = \frac{1 + D \langle v_s, z \rangle}{D+1}$$

are barycentric coordinates for every  $z$  in its convex hull. For  $\|z\| \leq 1/(2D)$  they are all positive and sum to one. Initialize with weights  $b_s(\lambda x)$ . For command  $a$  use  $T_a(s, r) = b_r(\lambda U_a v_s)$ ; these are stochastic rows, independent of  $N$  and of the epoch. Use the terminal mean  $d_j(s) = \langle e_j, v_s \rangle$ . The displayed barycentric identity shows inductively that the represented mean is  $\lambda^{N+1} U_w x$ . This proves (41) and its sign assertion. For every unit  $U_w x$  some coordinate has modulus at least  $1/\sqrt{D}$ ; binary total variation is half the difference of its means. This gives the numerical error bound. Only the label is stored. A held binary output uses a separate two-label cut.  $\square$

**Corollary 11.2** (Separation of numerical and sign-only width). *For every nontrivial expanding irreducible experiment in Theorem 7.3, numerical width is of order  $N^{s(U)/2}$  at the stated fixed positive accuracy, but strict-cutpoint width in the same reset-command-query interface is at most  $D + 1$  for all lengths simultaneously. For complex conjugation the numerical order is  $N^{q-1}$ , while the sign-only command width is at most  $q^2$ .*

*Proof.* Combine Proposition 11.1 with the corresponding numerical width theorem. Here  $D = q^2 - 1$  in the last assertion. The number counts command-layer labels, not the total state count of a language recognizer additionally parsing reset and query syntax.  $\square$

**11.1. The current quantum-automata comparison.** We fix the version before comparing its theorem. The primary arXiv submission record inspected on September 26, 2026 lists version 1 dated April 8 and version 2 dated August 27, 2026. In version 1 [24], Proposition 3.1 is the  $q^2$ -dimensional mixed-state linearization, Theorem 3.2 gives  $2k + 6$  PFA states from a  $k$ -state GFA, and Corollary 3.3 gives  $2q^2 + 6$ . In the explicitly versioned version 2, the title and theorem numbering change. The PDF's printed pages 4 and 5 contain, respectively, Proposition 3.1 and Theorem 3.2 with the improved constants used below. These are distinct primary versions, not interchangeable theorem numbers. We make no inference about why an earlier access exposed only one version.

Chen–Wu’s version-2 generalized-automaton conversion [23, Proposition 3.1] maps a  $k$ -dimensional real zero-cutpoint generalized finite automaton to a probabilistic automaton with  $k + 1$  states. For its parameters  $c, \delta > 0$  the conversion has

$$(42) \quad f_{\text{PFA}}(w) - 1/(k + 1) = \delta c^{|w|} f_{\text{GFA}}(w).$$

Their Theorem 3.2 consequently gives  $q^2 + 1$  states for strict-cutpoint simulation of a  $q$ -state general one-way QFA. The second version of that paper improves the larger bound in its original version. Mixed-state linearization is exact before the positive embedding; the factor in (42) is the distinction relevant here. The later paper [25, Proposition 4 and Theorems 11–12] uses the related conversion to compare hybrid quantum and classical language state costs. These are results about cutpoint languages, not fixed nonvanishing numerical accuracy.

For clarity, the algebra behind (42) is that a uniform-row matrix  $Q$  annihilates a zero-sum coordinate subspace, while a scaled matrix  $cK_a$  carries the desired signed dynamics there. Matrices  $Q + cK_a$  are made stochastic by choosing  $c$  small. After  $N$  commands the signed deviation is multiplied by  $c^N$ . A length-dependent decoder attempting to divide by this factor need not lie in  $[-1, 1]$  and is not a stochastic readout. More generally, a stochastic post-processing cannot increase total variation. Allowing redesign at every horizon does not overcome the numerical lower bound, which already permits that redesign.

A prefix–suffix sign or rank argument alone cannot substitute for the occupation proof. The matrix of centered target responses has entries  $\langle \rho U_p x, U_s^* e_j \rangle$  and ordinary rank at most  $D$  at every split, independently of the horizon. Adding the constant probability column gives rank at most  $D + 1$ . The prepare–test sign-rank and shattering statements in [25] control a threshold relation in this fixed operator space; they do not force the numerical hidden-width growth proved here. Conversely the present argument gives no growing lower bound for the sign-only task, as Proposition 11.1 demonstrates.

Chen’s subsequent work [26], including its invariant-algebra simulation results and Section 7’s stabilizer-orbit capacity analysis, also uses strict-cutpoint behavioral equivalence. Its dimensions and symmetry constraints belong in this comparison. Orbit dimension as  $\dim G - \dim G_v$ , and quantum operator-space linearization, are not claimed new here. Our invariant first takes the *minimum over all nonzero directions in each irreducible representation*, then the *maximum across active constituents*; it governs a growing fixed-accuracy numerical width as the word length grows. These are different optimization and asymptotic variables. No assertion of exhaustive priority clearance is made from this comparison.

## 12. GEOMETRIC, PROBABILISTIC AND COMPUTATIONAL BOUNDARIES

The new theorem concerns a growing execution constrained by a single retained label. It neither changes the classical dimension of an orbit nor identifies numerical simulation with a threshold language.

**12.1. What the covering exponent does and does not prove.** For a smooth compact  $s$ -manifold, covering by  $O(h^{-s})$  small balls is classical. Iacobelli’s manifold quantization theorem [27, Theorem 1.4] concerns the minimum integrated  $r$ th-power distance from a *fixed measure* to a codebook of  $k$  points, with its  $k^{-r/s}$  asymptotics under the stated hypotheses. The codebook in that problem sees one sample from that measure; there are no stochastic command rows to be implemented at all layers. Theorem 6.2 uses the classical covering count, a quadratic support loss, and an explicit stochastic realization. Its new lower partner is not a static quantization lower bound. The conditional means of a hidden machine generally leave the seed orbit, and neither their distribution nor their orbit type is fixed. Theorem 4.1 controls all those directions at once; the entropy budget then charges every small-state epoch to one finite quadratic loss. This is the mechanism that prevents hidden lifts from outperforming the geometric synthesis order.

Orbit convex hulls and their representation-theoretic geometry are classical objects [21, 28]. The covariance identity and local covering calculation are reproved here to fix constants and hypotheses, not claimed as new geometric discoveries. Our minimum-orbit theorem does not give local volume asymptotics uniformly for each spectrum; only its uniform exponent is sharp. The elementary finite-rank chart argument also explains why no separate spectral projector calculation is needed for a new representation. The earlier projector argument is retained because it gives an explicit, albeit large, constant in its matrix family.

**12.2. Positive rank and quantum dimension.** At a fixed cut, a numerical classical realization factors the matrix of future response probabilities through  $K_t$  positive normalized state continuations. With one output alphabet this is a nonnegative factorization; with several selectable queries, each decoder block must normalize. Quantum prepare–measure probabilities instead admit positive-semidefinite factorizations. These static dimension relations are classical [29]. They do not by themselves supply common transition rows connecting independently chosen factorizations at successive cuts. In the projective experiment a fixed  $q$ -dimensional quantum register supplies all layers, while the compatible classical numerical width grows with  $N$ . No new quantum operation, seed reset, or quantum-memory model is introduced by that comparison.

**Proposition 12.1** (Probabilistic ordered programs). *Definition 2.1 is equivalently a nonuniform ordered read-once layered program with stochastic command-labelled edges and real terminal columns. A selected column can be replaced by a Bernoulli acceptance row without changing any command-layer width; a retained final answer needs at most two labels.*

*Proof.* Identify  $T_{t,a}(s, s')$  with the outgoing edge weight at layer  $t$ . Summing path probabilities gives (4), and conversely those edge weights define the stochastic rows. At terminal label  $s$  the selected query accepts with probability  $(1 + d_j(s))/2$ .  $\square$

The Fourier-growth and pseudorandomness results in [15, 16, 9] have their stated deterministic, regular or permutation hypotheses and different objectives. The dominant action used by the converse has a norm gap; hidden reset rows and nonregular matrices remain allowed. Width is not total branching-program size, and real edge tables are not a uniform finite-bit implementation.

**12.3. Expansion and implementation.** Expansion in the present main theorem is a property of the actual command action on an activated irreducible space. It is unchanged by adding unused presenting factors. Theorem 7.3 requires it only on one dominant active type; Proposition 8.1 even allows a faithfully acting circle factor with no regular gap. Full effective-group expansion remains a sufficient certificate via Proposition 3.1. The algebraic alphabets in Proposition C.3 and in the mixed example use the deep external theorems [2, 3]; their constants are qualitative. Density or a finite harmonic calculation is not itself such a certificate. The optional numerical six-gate result uses exactly the separate external inequality (LPS5). Its original-source limitation is recorded in Appendix E.

Only one query is answered. A request for jointly independent answers to all queries changes the channel and need not satisfy the maximum law of Theorem 7.3. The model charges branch identifiers, but not the description length or construction of the row tables. Rational net coordinates do not make all transition weights rational when commands are merely algebraic. Carathéodory sparsity bounds successors, not table size. The separate fair-bit compilers in the preserved development incur further states and possibly error; they do not equate atomic width with bit complexity.

**12.4. Conclusions.** The effective action and the query-calibrated isotypic activation remove presentation and multiplicity choices from the width theorem. Arbitrary finite seeds first determine their invariant span. A single expanding type of maximal minimum-orbit dimension then determines

the matched exponent; other genuinely acting types may fail to expand. The upper realization charges its branch labels, while the lower bound continues to use the actual entire hidden register.

The root-deletion and singular-value calculations identify minimum orbits on the stated complete representation families. They do not classify all highest weights. Likewise the width law does not specify finite integer optima, sharp leading constants, arbitrary vanishing signals, nongapped dominant types, or uniform computational resources. Numerical probability preservation and strict-cutpoint recognition are separated by an explicit constant-width attenuating machine. The version-pinned comparison makes this semantic boundary independent of which Chen–Wu upper constant is quoted.

#### APPENDIX A. A MAXIMUM LAW FOR ORTHOGONAL SUMS

Let

$$(43) \quad V = V_0 \oplus V_1 \oplus \cdots \oplus V_m$$

be an orthogonal decomposition, where  $V_0 = V^G$  and each  $V_i$ ,  $i \geq 1$ , is a nontrivial real irreducible representation. Multiplicities are allowed. Put  $d_i = \dim V_i$ ,  $D = \dim V$  and

$$(44) \quad \sigma(U) = \max_{1 \leq i \leq m} s(U|_{V_i}), \quad \sigma(U) = 0 \quad \text{if } m = 0.$$

Equivalent irreducible orthogonal representations have isomorphic orbits. Thus  $\sigma(U)$  does not depend on the chosen decomposition of an isotypic summand. In general it is *not* the smallest orbit dimension on the sphere of the whole reducible representation.

For the lower bound assume that the finite unit seeds span  $V$  and write

$$(45) \quad a_i = \max_{x \in \mathcal{X}} \|\pi_i x\| > 0, \quad a_* = \min_{1 \leq i \leq m} a_i,$$

where  $\pi_i$  is orthogonal projection; set  $a_* = 1$  if  $m = 0$ . In a basis-adapted seed set  $\{\pm e_j\}$  all  $a_i$  equal one. The query basis need not respect the decomposition.

**Theorem A.1** (Irreducible maximum principle). *Suppose a law on the finite command alphabet has a full group norm gap. Let the seeds span  $V$ , let  $0 < \rho \leq \min\{1/10, 1/(8D)\}$ , and, when  $m > 0$ , let  $0 \leq \varepsilon < \rho a_*/(2\sqrt{D})$ . Then*

$$(46) \quad W_{N,\varepsilon} = \Theta(N^{\sigma(U)/2}).$$

*The constants may depend on the representation, command law, seed set, signal and error, but not on  $N$ . If  $m = 0$ , an exact constant-width machine exists. The upper realization uses common command rows and only one selected terminal numerical query.*

*Proof.* First fix  $i \geq 1$  and a seed  $x$  with  $\|\pi_i x\| = a_i$ . Track the unit-vector process  $Y_t^{(i)} = U_{a_t} \cdots U_{a_1} \pi_i x / a_i$  in  $V_i$  and its conditional mean given the *actual whole-machine state*. Form the ambient vector  $d = (d_1, \dots, d_D)$  from the terminal columns in the proof. It has norm at most  $\sqrt{D}$ . The prescribed row means and the uniform error give

$$\mathbb{E}\langle Y_N^{(i)}, \pi_i d(S_N) \rangle \geq \rho a_i - 2\sqrt{D}\varepsilon.$$

Conditioning on  $S_N$  bounds the left side above by  $\sqrt{D}\mathbb{E}\|\mathbb{E}[Y_N^{(i)} | S_N]\|$ . Hence the terminal conditional amplitude is at least  $\rho a_i / \sqrt{D} - 2\varepsilon > 0$ . The inherited entropy occupation argument applies in the representation  $V_i$  to these conditional means, even though the hidden label also serves every other constituent. Theorem 4.1 supplies its exponent  $s(U|_{V_i})$ . It follows that  $W_{N,\varepsilon} \geq c_i N^{s(U|_{V_i})/2}$ . Choose a constituent attaining (44).

For the upper bound include only nonzero summands and set  $w_i = d_i/D$ . Choose a branch  $i$  at initialization with probability  $w_i$ , independently of the seed. The branch identifier is part

of the state label, not a free future input. In branch  $i \geq 1$  use the minimal-orbit polytope of Theorem 6.2. Its initial represented mean is prescribed to be

$$(\rho/w_i)\pi_i x.$$

Its norm is at most  $\rho D/d_i \leq 1/(8d_i)$ , so the initialization proof there applies also to this possibly subunit vector. Subsequent rows are the common command rows from that construction. At a query  $j$  output the mean  $\langle e_j, a_N v_{i,s} \rangle$ . The conditional represented vector in the branch is  $(\rho/w_i)U_w \pi_i x$ ; multiplying by  $w_i$  and summing gives exactly  $\rho U_w x$ . All terminal means are bounded by  $2/7$ .

In the invariant branch, if present, use the fixed vectors  $\{\pm e : e \text{ in an orthonormal basis of } V_0\}$  scaled by  $1/4$ , with identity transitions. Their convex hull contains a ball of radius  $1/(4\sqrt{d_0})$ , which contains the required initial vector of norm at most  $1/(8d_0)$ . Its contribution is exact with  $2d_0$  labels. The entire register is the disjoint union of these branch labels. Its cardinality is at most

$$2d_0 + \sum_{i=1}^m C_i N^{s(U|V_i)/2} = O(N^{\sigma(U)/2}).$$

No product of independently correct outputs is required. If  $m = 0$  the invariant construction proves the asserted constant bound. The fixed two-label answer cut does not change the orders.  $\square$

The original full-group maximum principle is retained here in its original sufficient range. Theorem 7.3 strengthens it by using the active span, canonical activation and only one dominant action gap; its proof of the current main theorem appears in Section 7.

The maximum in (44), rather than a sum, is substantive. For the direct product action of  $\text{SO}(3) \times \text{SU}(3)$  on  $\mathbb{R}^3 \oplus \text{Herm}_0(3)$ , the two least orbit dimensions are two and four. With a full-gap product command law and the above signal conventions the label order is  $N^2$ , not  $N^3$ ; a generic product orbit and a joint-output product task describe different quantities. Adding a fixed subspace creates zero-dimensional whole-space orbits but does not remove this  $N^2$  requirement. The proof explains both phenomena by paid branch labels and a constituent-wise converse.

**Proposition A.2** (All separate cuts have constant positive minimum). *For any orthogonal command family on  $\mathbb{R}^D$ , seeds  $\mathcal{X} = \{\pm e_1, \dots, \pm e_D\}$ , and  $0 < \rho \leq 1/D$ , the normalized residual row rank and the separate positive minimum are both  $D + 1$  at every internal cut. The separate minimum permits unrestricted memory at the other cuts. The assertion requires no group gap and does not assert simultaneous attainment.*

*Proof.* For a vector  $z$ , its remaining response on suffix  $v$  and query  $j$  has mean  $\langle e_j, U_v z \rangle$ . The resulting affine map from  $z$  to the normalized response array is injective: fix one suffix and vary the coordinate query;  $U_v$  is invertible. At a fixed cut, fix one preceding word  $w$  and vary the seeds. The vectors  $\{\pm \rho U_w e_j\}$  affinely span  $\mathbb{R}^D$ . Thus the normalized residual arrays have row rank  $D + 1$ , giving the positive lower bound.

A regular unit simplex in  $\mathbb{R}^D$  contains the ball of radius  $1/D$ . Every actual represented vector at that cut has norm  $\rho$  and is therefore a convex combination of its  $D + 1$  vertices. A vertex  $v_s$  defines a legal normalized continuation, since  $|\langle e_j, U_v v_s \rangle| \leq 1$  for every suffix and query. These are  $D + 1$  positive generators of all cut rows. To embed the factorization in a whole machine, retain the complete finite prefix until the selected cut, sample its convex coordinates there, then retain the chosen label together with the remaining command prefix. There is no cap at those other cuts. The resulting finite machine attains  $D + 1$  at the selected cut. This verifies the operational, not merely amputated-matrix, meaning of the separate minimum.  $\square$

## APPENDIX B. UNIFORM GEOMETRY OF HERMITIAN CONJUGATION

Fix  $q \geq 2$  and let  $V = \text{Herm}_0(q)$  be the real space of traceless Hermitian  $q$  by  $q$  matrices, with inner product  $\text{tr}(AB)$ . Its dimension is  $D = q^2 - 1$ . Unitary conjugation is orthogonal on this space. The pure-state orbit has dimension  $2(q-1)$ , but normalized hidden centroids can have arbitrary spectra. We therefore prove a bound on *every* unit sphere orbit.

**B.1. A Grassmann small-ball estimate.** Let  $P_0$  be a rank- $k$  orthogonal projector in  $\mathbb{C}^q$ ,  $1 \leq k < q$ , and let  $P$  be a Haar-distributed rank- $k$  projector. Put  $m = k(q-k)$  and

$$(47) \quad b_{q,k} = \frac{1}{m!} \prod_{j=1}^k \frac{\Gamma(q-k+j)}{\Gamma(j)}.$$

**Lemma B.1** (Projector balls). *For  $0 < R \leq 1$ ,*

$$(48) \quad \mathbb{P}(\|P - P_0\|_{\text{HS}} \leq R) \leq b_{q,k} R^{2k(q-k)}.$$

*Proof.* By invariance take  $P_0$  onto the first  $k$  coordinates. Apart from a null set, a Haar subspace is the graph of  $Z \in \mathbb{C}^{(q-k) \times k}$ . Its density with respect to complex Euclidean Lebesgue measure is

$$(49) \quad \pi^{-m} \prod_{j=1}^k \frac{\Gamma(q-k+j)}{\Gamma(j)} \det(I + Z^*Z)^{-q}.$$

For completeness, take a  $q$  by  $k$  matrix of independent standard complex Gaussian entries and split it into a square top block  $A$  and bottom block  $B$ . Its column space is Haar and  $Z = BA^{-1}$  almost surely. The change  $B = ZA$  has real Jacobian  $|\det A|^{2(q-k)}$ . Integrating  $A$  with weight  $\exp[-\text{tr} A^*(I + Z^*Z)A]$  gives the determinant factor  $\det(I + Z^*Z)^{-q}$ . Complex Gaussian Gram-Schmidt gives  $\mathbb{E}|\det A|^{2(q-k)} = \prod_{j=1}^k \Gamma(q-k+j)/\Gamma(j)$ , since its squared orthogonal lengths have gamma shapes  $1, \dots, k$ . The powers of  $\pi$  give (49).

If  $\theta_i$  are the principal angles, then  $\|P - P_0\|_{\text{HS}}^2 = 2 \sum_i \sin^2 \theta_i$  and  $\|Z\|_{\text{HS}}^2 = \sum_i \tan^2 \theta_i$ . On the event in (48) each  $\sin^2 \theta_i \leq R^2/2$ , whence

$$\|Z\|_{\text{HS}}^2 \leq \frac{R^2}{2 - R^2} \leq R^2.$$

The density (49) is bounded by its value at zero. Multiply this value by the volume  $\pi^m R^{2m}/m!$  of a real  $2m$ -dimensional ball. This proves the assertion.  $\square$

Define the explicit finite constant

$$(50) \quad A_q = \max_{1 \leq k < q} \left\{ \max(1, b_{q,k}) [9q(q-1)^2]^{k(q-k)} \right\}.$$

It is rational and at least one; no optimality is claimed.

**Theorem B.2** (All-spectra orbital anti-concentration). *For all  $A, B \in \text{Herm}_0(q)$  of Hilbert-Schmidt norm one and all  $0 < r \leq 1$ ,*

$$(51) \quad m_{\text{SU}(q)}\{U : \|UAU^* - B\|_{\text{HS}} \leq r\} \leq A_q r^{2(q-1)}.$$

*In particular, the estimate is uniform at repeated eigenvalues and over mixed-state centroid directions. No lower bound on each eigenvalue gap is assumed.*

*Proof.* Let  $\lambda_1 \geq \dots \geq \lambda_q$  be the eigenvalues of  $A$ . Trace zero and  $\sum_i \lambda_i^2 = 1$  imply  $\lambda_1 - \lambda_q \geq q^{-1/2}$ . Hence some  $k$  has

$$(52) \quad \lambda_k - \lambda_{k+1} \geq \delta_q := \frac{1}{\sqrt{q}(q-1)}.$$

For two conjugates  $C, D$  of  $A$ , let  $P_C, P_D$  be their top- $k$  spectral projectors. Eigenvectors  $u_i$  of  $C$  and  $v_j$  of  $D$  obey

$$(\lambda_i - \lambda_j)\langle u_i, v_j \rangle = \langle u_i, (C - D)v_j \rangle.$$

Summing squares for  $i \leq k < j$  and using equal projector ranks gives

$$(53) \quad \|P_C - P_D\|_{\text{HS}}^2 = 2 \sum_{i \leq k < j} |\langle u_i, v_j \rangle|^2 \leq 2\delta_q^{-2} \|C - D\|_{\text{HS}}^2.$$

If the event in (51) is empty there is nothing to prove. Otherwise choose one conjugate  $D$  in that event. Every other  $C$  in the event has  $\|C - D\|_{\text{HS}} \leq 2r$ . The image  $P_C$  is a Haar rank- $k$  projector and lies within  $2\sqrt{2}\delta_q^{-1}r$  of  $P_D$ . Set  $c_q = 3\sqrt{q}(q-1)$ , which is larger than this coefficient. If  $c_q r \leq 1$ , Lemma B.1 gives a bound  $b_{q,k}(c_q r)^{2k(q-k)}$ . Since  $k(q-k) \geq q-1$  and  $r \leq 1$ , this is at most the right side of (51). If  $c_q r > 1$ , then  $A_q r^{2(q-1)} \geq c_q^{2(q-1)} r^{2(q-1)} > 1$ , so the trivial probability bound suffices. Haar conjugation under  $\text{SU}(q)$  and under  $U(q)$  has the same law, completing the proof.  $\square$

The proof isolates one uniformly separated spectral cut rather than requiring a simple spectrum. This is why pure-state and highly mixed centroids are handled by the same constant. The smallest possible nontrivial Grassmann exponent is  $2(q-1)$ .

**Corollary B.3** (Conjugation occupation). *For conjugation commands satisfying a group gap  $g_t$ , any hidden register with  $q_N \geq \kappa > 0$  obeys*

$$(54) \quad \sum_{K_t \leq k} g_t \leq C_q \kappa^{-3-1/(q-1)} k^{1/(q-1)}, \quad C_q = 2048(q^2 - 1)(16A_q)^{1/(q-1)}.$$

For a constant gap  $g > 0$  and wordwise error  $\varepsilon$  with  $\kappa = \rho/\sqrt{q^2 - 1} - 2\varepsilon > 0$ ,

$$(55) \quad W_{N,\varepsilon} \geq \left( \frac{g\kappa^{3+1/(q-1)}}{C_q} N \right)^{q-1}.$$

*Proof.* Apply Lemma 5.1, Theorem B.2 and Theorem 5.5, then use Lemma 2.2.  $\square$

A group gap is stronger than a gap only on functions on the pure-state homogeneous quotient. The proof genuinely needs uniform control of the mixed-centroid directions, and does not silently replace this hypothesis by the weaker quotient gap.

## APPENDIX C. SHARP MEMORY ON COMPLEX PROJECTIVE ORBITS

Write  $r_q = \sqrt{1 - 1/q}$  and associate to a rank-one orthogonal projector  $P$  the unit vector

$$(56) \quad Y(P) = \frac{P - I/q}{r_q} \in \text{Herm}_0(q), \quad \mathcal{K}_q = \text{conv}\{Y(P) : \text{rank } P = 1\}.$$

The body  $\mathcal{K}_q$  consists of normalized centered density matrices. It is invariant under conjugation and contains zero. Its extreme orbit is  $\mathbb{CP}^{q-1}$ . Fix an orthonormal real basis  $F_1, \dots, F_D$  of  $\text{Herm}_0(q)$  and use its coordinate queries in (3). One may take as seeds the  $q^2$  rank-one projectors onto  $e_i$ ,  $(e_i + e_j)/\sqrt{2}$  and  $(e_i + ie_j)/\sqrt{2}$ ,  $i < j$ . Their centered matrices affinely span  $\text{Herm}_0(q)$ . All seed and query alphabets are fixed when  $q$  is fixed.

**C.1. A projective enclosure with quadratic loss.** For rank-one projectors use the distance  $d(P, Q) = \sqrt{1 - \text{tr}(PQ)}$ , the sine of their principal angle.

**Lemma C.1** (Finite projective synthesis). *For  $0 < h \leq 1$ , there is an  $h$ -net  $\mathcal{V}_h$  of rank-one projectors with at most*

$$(57) \quad q(2\lceil 2\sqrt{2(q-1)/h} \rceil + 1)^{2(q-1)}$$

*elements, and the entries of all these projectors can be chosen in  $\mathbb{Q} + i\mathbb{Q}$ . If  $qh^2 < 1$ , then*

$$(58) \quad (1 - qh^2)\mathcal{K}_q \subseteq \text{conv}\{Y(P) : P \in \mathcal{V}_h\} \subseteq \mathcal{K}_q.$$

*Proof.* Every complex line has a representative with a largest coordinate scaled to one and the real and imaginary parts of all other coordinates in  $[-1, 1]$ . In each of the  $q$  charts round these  $2(q-1)$  real coordinates to the grid of step  $1/M$ , where  $M = \lceil 2\sqrt{2(q-1)/h} \rceil$ . If  $v, w$  are the original and rounded representatives, their norms are at least one and  $\|v - w\| \leq \sqrt{2(q-1)}/(2M)$ . Normalization changes their distance by at most a factor two, and the sine distance is at most the distance of these normalized representatives. Thus the stated set is an  $h$ -net. The projector  $w w^* / \|w\|^2$  has rational real and imaginary entries, and the grid count is (57).

For a nonzero traceless Hermitian  $H$ , let  $\lambda_1$  and  $\lambda_q$  be its largest and smallest eigenvalues. A net projector within  $h$  of a top eigenline satisfies

$$\text{tr}(HP) \geq \lambda_1 - (\lambda_1 - \lambda_q)h^2 \geq (1 - qh^2)\lambda_1.$$

Indeed  $-\lambda_q \leq (q-1)\lambda_1$  by trace zero. The support function of  $\mathcal{K}_q$  at  $H$  is  $\lambda_1/r_q$ . The support-function criterion for convex containment proves (58). It applies to every direction, not just a finite set of tested queries.  $\square$

**Theorem C.2** (A finite-alphabet exact upper machine). *For every finite unitary command alphabet and  $0 < \rho \leq 1/10$ , the experiment on (56) has an exact machine of width  $O_q(N^{q-1})$ . For each  $N$ , all command transition matrices can be chosen independent of the epoch. Each row uses at most  $q^2$  successors. The final decoder may depend on  $N$ .*

*Proof.* Take  $h = (8qN)^{-1/2}$  and  $\eta = 1 - 1/(8N)$  in Lemma C.1. Let  $V$  be the resulting finite set of centered vectors, and put  $a_t = \eta^{-t}/4$ . A label  $i$  represents  $a_t Y(P_i)$  at epoch  $t$ . This is a proof description of a label; no matrix is stored in the register.

Since  $\rho/a_0 = 4\rho \leq 2/5 < \eta$  and  $0 \in \mathcal{K}_q$ , any seed  $\rho Y(P)$  is a convex combination of  $a_0 V$ . For each label  $i$  and each command  $U$ , the vector  $\eta U Y(P_i) U^*$  lies in  $\text{conv } V$ . Choose a convex representation and use its weights as the stochastic transition row. The choices depend on the command and label but not on  $t$ . Multiplying by  $a_{t+1}$  shows that the expected represented vector is updated by exact conjugation, since  $a_{t+1}\eta = a_t$ .

Induction gives expected vector  $\rho Y(U_w P U_w^*)$ . The terminal column for query  $j$  is  $a_N \text{tr}(F_j Y(P_i))$ . It is legal because  $|\text{tr}(F_j Y(P_i))| \leq 1$  and Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $a_N \leq 2/7$ . Sampling a binary answer with this mean proves every conditional probability in (3) exactly. Carathéodory's theorem in real dimension  $D = q^2 - 1$  permits  $q^2$  successors. The number in (57) is  $O_q(h^{-2(q-1)}) = O_q(N^{q-1})$ .  $\square$

The upper argument uses a quadratic support loss along the projective orbit. Applying a net on the full ambient sphere would instead give the larger exponent  $(q^2 - 2)/2$ .

**C.2. Fixed finite algebraic alphabets.** For  $1 \leq j < q$  let  $R_j, D_j \in \text{SU}(q)$  act as the identity outside the adjacent coordinate pair  $(j, j+1)$  and on that pair as

$$(59) \quad R = \frac{1}{5} \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}, \quad D = \begin{pmatrix} \zeta & 0 \\ 0 & \bar{\zeta} \end{pmatrix}, \quad \zeta = \frac{3 + 4i}{5}.$$

The alphabet has  $4(q-1) + 1$  symbols:  $\{I, R_j^{\pm 1}, D_j^{\pm 1} : 1 \leq j < q\}$ . Assign probability  $1/2$  to  $I$  and  $1/[8(q-1)]$  to each other symbol.

**Proposition C.3** (Qualitative group expansion). *This command law has a norm gap on  $L_0^2(\text{SU}(q))$  for every fixed  $q$ . Its entries and probabilities are algebraic. No numerical gap value is asserted for this family.*

*Proof.* The number  $\zeta$  is not a root of unity:  $\zeta + \zeta^{-1} = 6/5$  is rational but not an algebraic integer. The powers of  $R_j$  and  $D_j$  therefore have closures containing two distinct one-parameter subgroups in the corresponding embedded  $\text{SU}(2)$ . Their Lie brackets generate that  $\mathfrak{su}(2)$ . The adjacent embedded Lie algebras generate  $\mathfrak{su}(q)$ : adjacent elementary off-diagonal directions produce all other off-diagonal directions by brackets, and their self-brackets produce the traceless diagonal directions. The closed generated subgroup is consequently  $\text{SU}(q)$ .

The adjoint entries are algebraic. The spectral-gap theorem of Benoist–de Saxcé [2, Theorem 1.2] applies to an adapted algebraic measure on this compact connected group with simple Lie algebra. Equivalently, one may use the algebraic unitary result of Bourgain–Gamburd [3]. The symmetric average has an upper gap; weight  $1/2$  at the identity makes its spectrum nonnegative. Its mean-zero operator norm is therefore strictly below one. This is the external full-group theorem, not a calculation in the defining  $q$ -dimensional representation.  $\square$

*Proof of Corollary 10.2.* Corollary B.3 gives the lower order, for every fixed positive calibration  $\kappa$ . Theorem C.2 gives the matching exact upper order. Proposition C.3 supplies fixed finite alphabets. The quantum assertion follows from the next proposition. Taking binary logarithms gives the label-bit formula.  $\square$

**Proposition C.4** (A fixed quantum realization). *The projective experiment has an exact quantum realization on  $\mathbb{C}^q$  using fixed seed resets, the prescribed unitary commands and fixed query measurements. It is independent of  $N$ .*

*Proof.* On seed  $P$  reset the density matrix to

$$\sigma_P = I/q + \rho Y(P) = (1 - \rho/r_q)I/q + (\rho/r_q)P.$$

This is positive and has trace one, since  $0 < \rho \leq 1/10 < r_q$ . Commands act by conjugation. For query  $j$ , use effects  $(I + F_j)/2, (I - F_j)/2$ . Hilbert–Schmidt normalization implies  $\|F_j\|_{\text{op}} \leq 1$ , so these are positive effects summing to  $I$ . Their outcome mean is  $\text{tr}(F_j \sigma_{U_w P U_w^*}) = \rho \text{tr}(F_j Y(U_w P U_w^*))$ . This is precisely (3). The seed reset is a channel, not a unitary; only one query is measured.  $\square$

The comparison is a fixed  $q$ -dimensional quantum register versus  $(q-1) \log_2 N + O(1)$  classical label bits. Dimension or entropy advantages for quantum models are prior phenomena [6, 17, 5]. The assertion here is the proved classical width order for this complete worst-word numerical behavior. It does not request jointly independent answers to all queries or optimize arbitrary adaptive experiments.

#### APPENDIX D. AN EFFECTIVE SIX-COMMAND RATIONAL EXAMPLE

The preceding group-gap application is qualitative. We now choose a separate arithmetic alphabet for which a classical theorem supplies a numerical infinite-dimensional norm bound. This does not evaluate the gap of the earlier five-command example.

Let  $R_x, R_y, R_z$  be rotations about the coordinate axes with cosine  $-3/5$  and sine  $4/5$ ; explicitly,

$$(60) \quad R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -3/5 & -4/5 \\ 0 & 4/5 & -3/5 \end{pmatrix}, \quad R_y = \begin{pmatrix} -3/5 & 0 & 4/5 \\ 0 & 1 & 0 \\ -4/5 & 0 & -3/5 \end{pmatrix}, \quad R_z = \begin{pmatrix} -3/5 & -4/5 & 0 \\ 4/5 & -3/5 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Use the fixed six-letter alphabet  $\mathcal{A}_V = \{R_x^{\pm 1}, R_y^{\pm 1}, R_z^{\pm 1}\}$  and its uniform law. These are the adjoint rotations of the classical norm-five quaternions  $1 \pm 2\mathbf{i}$ ,  $1 \pm 2\mathbf{j}$ ,  $1 \pm 2\mathbf{k}$ , normalized by  $\sqrt{5}$ .

**Proposition D.1** (External arithmetic gap certificate). *For  $P_V f = (1/6) \sum_{R \in \mathcal{A}_V} f(R^{-1} \cdot)$  on  $L_0^2(\mathbb{S}^2)$ ,*

$$(61) \quad \|P_V\| \leq \frac{2\sqrt{5}}{6} = \frac{\sqrt{5}}{3}.$$

Consequently  $1 - \|P_V\|^2 \geq 4/9$ .

*Proof.* This is the  $p = 5$  specialization of the Lubotzky–Phillips–Sarnak spherical Hecke bound [10, 11]. In its unnormalized convention the  $p + 1$  norm- $p$  quaternion representatives act by a sum of rotations whose mean-zero norm is at most  $2\sqrt{p}$ . The representatives have positive odd real coordinate and even other coordinates when  $p \equiv 1 \pmod{4}$ ; at  $p = 5$  they are exactly the six displayed ones. Appendix E records the operator normalization and its source boundary. The coauthor account [12, Section 3.2, the  $V$ -gate example] spells out these representatives and their Hecke interpretation. The unnormalized spherical norm convention is also stated in [13, Theorem 3(ii)]. Dividing by six gives (61). Passing from quaternions to adjoint rotations identifies  $\mathbb{S}^2$  as the homogeneous quotient; inverse signs do not affect this symmetric average. The arithmetic bound is invoked as an external theorem, not reproved by finite harmonic tests.  $\square$

Use six seeds  $\{\pm e_j : 1 \leq j \leq 3\}$ , amplitude  $\rho = 1/10$  and three final coordinate queries in (3).

**Theorem D.2** (Numerical finite-horizon width certificate). *For  $0 \leq \varepsilon < 1/(20\sqrt{3})$  and every integer  $N \geq 1$ ,*

$$(62) \quad \frac{(1/(10\sqrt{3}) - 2\varepsilon)^4}{221184} N \leq W_{N,\varepsilon}(\mathcal{A}_V) \leq W_{N,0}(\mathcal{A}_V) < 150N.$$

*The upper machine has exact rational command and decoder rows, common command matrices, and an  $N$ -dependent decoder. At zero error every internal selected cut has separate positive minimum four, while*

$$(63) \quad W_{N,0} \geq \frac{N}{19\,906\,560\,000}.$$

*The constants are proof constants, not sharp asymptotic constants.*

*Proof.* For the standard  $\text{SO}(3)$  action the orbit of every unit vector is uniform on  $\mathbb{S}^2$ . A chordal cap of radius  $r \leq 1$  has probability  $r^2/4 \leq r^2$ , so take  $D = 3, s = 2, A = 1$  in Theorem 5.5. The sphere gap transfers to  $L^2(\mathbb{R}^3)$  by polar coordinates. Thus  $B_{3,1,2} = 98304$ , and the squared gap  $4/9$  gives the lower bound in (62). At  $\varepsilon = 0$  the fourth power of  $1/(10\sqrt{3})$  is  $1/90000$ , which yields (63).

Here is an explicit cardinality estimate for the upper construction. Take both rational stereographic charts

$$t \mapsto \frac{(2t_1, 2t_2, \pm(1 - \|t\|^2))}{1 + \|t\|^2}, \quad t \in [-1, 1]^2,$$

with a grid of step  $1/M$  and  $M = \lceil 2\sqrt{2N} \rceil$ . Every hemisphere is covered by its chart on the unit disk. Each chart is 2-Lipschitz, so its grid images form a sphere net of chordal radius at most  $\sqrt{2}/M \leq 1/(2\sqrt{N})$ . Its convex hull contains  $\eta$  times the unit ball, with  $\eta = 1 - 1/(8N)$ , by the support function identity  $u \cdot v = 1 - \|u - v\|^2/2$ . There are at most  $2(2M + 1)^2 \leq (82 + 48\sqrt{2})N < 150N$  labels. Use scales  $a_t = \eta^{-t}/4$ , initialization representing  $\rho x$ , rows representing  $\eta R u$  in this hull, and decoder  $a_N e_j \cdot u$ . The verification is the induction in Theorem C.2. All data are rational; each nonempty rational convex system has rational weights, with at most four successors. The final decoder is bounded by  $2/7$ .

At a selected internal cut, fix any common command prefix. The six seed images affinely span  $\mathbb{R}^3$ , so the normalized continuation rank is four; future coordinate queries still separate these dimensions after any common suffix. For an upper factorization take a regular tetrahedron containing the radius- $\rho$  ball and having circumradius  $3\rho < 1$ . Its four vectors give legal continuations under all future rotations. One embeds this selected-cut factorization in a complete machine by allowing uncapped raw histories elsewhere. Therefore the separate minimum is exactly four. This does not give a four-state machine at all cuts simultaneously.  $\square$

For example, (63) exceeds four once  $N \geq 79\,626\,240\,001$ . The size of this number illustrates the conservative constants; the benefit is that no unspecified spectral constant is needed for this alphabet.

The associated qubit operations are  $(I - 2i\sigma_j)/\sqrt{5}$  and their inverses, with seed Bloch vector  $x/10$  and final Pauli query. They realize the numerical experiment exactly, independently of  $N$ . This quantum construction and the arithmetic gates are classical; (62) is the finite-register consequence. The earlier five-gate alphabet remains qualitatively gapped with a non-evaluated constant, and is retained unchanged in the supporting material.

#### APPENDIX E. THE ARITHMETIC OPERATOR AND ITS NORMALIZATION

This appendix fixes the exact external input used in Proposition D.1, then proves the remaining representation and normalization steps. Write  $\mathbf{i}, \mathbf{j}, \mathbf{k}$  for quaternion units and

$$\mathcal{Q}_5 = \{1 \pm 2\mathbf{i}, 1 \pm 2\mathbf{j}, 1 \pm 2\mathbf{k}\}, \quad r_q(z) = qzq^{-1} \quad (z \in \text{Im } \mathbb{H}).$$

The required external LPS spherical Hecke inequality, specialized to this representative convention, is

$$\text{(LPS5)} \quad \left\| \sum_{q \in \mathcal{Q}_5} f(r_q^{-1} \cdot) \right\|_{L^2(\mathbb{S}^2)} \leq 2\sqrt{5} \|f\|_{L^2(\mathbb{S}^2)}, \quad \int f = 0.$$

This is an imported arithmetic theorem, not a finite-dimensional calculation. The original sources are [10, 11]; the unnormalized norm theorem is explicitly restated in [13, Theorem 3(ii), p. 8 of the preprint], while the quaternionic and Hecke representative conventions are discussed in [12, Section 3.2]. The restated existence theorem alone would not identify an arbitrary six rotations: the representative convention in (LPS5) is essential.

**Proposition E.1** (Parity, quotient and full spherical spectrum). *With the external input (LPS5), the uniform average over the six rotations in (60) has mean-zero norm at most  $\sqrt{5}/3$  both on  $L^2(\mathbb{S}^2)$  and on  $L^2(\text{SO}(3))$ . Its squared gap is at least  $4/9$ . The conclusion does not assert the same numerical gap for all of  $L_0^2(\text{SU}(2))$ .*

*Proof.* An integral quaternion of norm five has one coordinate of magnitude one, one of magnitude two, and two zero coordinates. There are  $4 \cdot 3 \cdot 4 = 48$  such quaternions. Multiplication by a Lipschitz unit in  $\{\pm 1, \pm \mathbf{i}, \pm \mathbf{j}, \pm \mathbf{k}\}$  places the odd coordinate in the real position and makes it positive. This gives a unique representative with positive odd real part and even other coordinates, namely one of the six members of  $\mathcal{Q}_5$ . This specifies the parity class; it is not an average over all 48 quaternions or an extra quotient by their unit group.

Normalizing  $q$  to  $q/\sqrt{5}$  does not change  $r_q$ . Quaternionic conjugation identifies the imaginary unit sphere with  $\text{SO}(3)/\text{SO}(2)$ , and  $q$  and  $-q$  give the same rotation. For  $(1 + 2\mathbf{i})/\sqrt{5}$  direct multiplication gives

$$\mathbf{i} \mapsto \mathbf{i}, \quad \mathbf{j} \mapsto (-3\mathbf{j} + 4\mathbf{k})/5, \quad \mathbf{k} \mapsto (-4\mathbf{j} - 3\mathbf{k})/5.$$

These are the columns of  $R_x$  in (60); cyclic permutation gives  $R_y, R_z$ . Conjugating a quaternion changes the sign of its imaginary coordinate and gives its normalized inverse. Thus the six

representatives already include inverse rotations, with one copy each. Division of the sum in (LPS5) by six gives  $2\sqrt{5}/6 = \sqrt{5}/3$ , and squaring gives  $1 - 5/9 = 4/9$ .

For the full-group statement, the complexified spherical space is the orthogonal sum of the harmonic spaces  $\mathcal{H}_\ell$ ,  $\ell \geq 0$ . These are precisely all irreducible unitary representations of  $\mathrm{SO}(3)$ , one copy of each. The degree-zero space is the constants. The regular representation on  $\mathrm{SO}(3)$  contains the same irreducibles with multiplicity  $2\ell + 1$ . Convolution acts on each copy by the same matrix, so its mean-zero operator norm is the supremum of the same matrix norms on both spaces. No extra invariant subspace is removed: on the sphere the constant is the only  $\mathrm{SO}(3)$ -invariant function. The symmetric alphabet makes the inverse/right versus left convention immaterial for these norms. Half-integer-spin representations occur on  $\mathrm{SU}(2)$  but not on its  $\mathrm{SO}(3)$  quotient; this argument makes no claim about those extra blocks.  $\square$

Source boundary. The original LPS publisher records were checked, but their complete 1986/1987 page images were not obtained in this revision. We therefore do not invent an original theorem number or label the secondary restatement as an inspected original proof. Equation (LPS5) states exactly the arithmetic line required, and the proposition proves every subsequent convention change. The effective theorem retains this explicit external dependency. The main width classification is conditional on an arbitrary full gap and does not depend on this numerical example or on an original-page attribution.

# GENERAL THETA FOUNDATIONS I: MINIMAL ORBITS AND THE WIDTH OF NUMERICAL EXPERIMENTS

QIAN QI

**ABSTRACT.** For a compact connected Lie group acting orthogonally on a fixed finite-dimensional space, we identify the hidden-label width exponent of its numerical command experiment under a full group norm gap. In an irreducible representation, let  $s$  be the least dimension of a nonzero unit-vector orbit. We prove a uniform orbital small-ball bound of exponent  $s$  across every stabilizer type. Combined with an orbital entropy occupation budget and a compatible minimal-orbit construction, this gives sharp width  $\Theta(N^{s/2})$  at fixed positive signal and fixed sufficiently small wordwise error. For reducible representations and spanning seeds at small fixed signal, the exponent is one half the maximum of the least orbit dimensions of the nontrivial irreducible constituents. The upper machine charges its randomized branch label and uses common command rows; the lower bound permits arbitrary hidden directions and time-dependent rows. We distinguish this numerical law from strict-cutpoint simulation by an explicit constant-width sign simulator with attenuated probabilities. The projective and arithmetic qubit results retain their original scope. The counted resource is nonuniform clocked atomic-row label width; tables, arithmetic and horizon-specific design are not charged.

## 1. INTRODUCTION

A low-dimensional linear statistic may have a small positive realization at every selected time and still require a large hidden register to follow a whole command sequence. The issue is compatibility: one stochastic update must serve all pasts that share a label. We study this constraint for numerical matrix coefficients of compact-group representations. The input alphabet is finite and fixed; the time horizon grows. Each numerical response is required on every input word, with one selected coordinate query at the end.

Our main result identifies a representation invariant rather than an analyst-chosen family of geometric witnesses. Let a compact connected Lie group act orthogonally on  $V$ , and decompose  $V$  as its invariant subspace and real irreducible constituents  $V_i$ . Define

$$s_i = \min_{v \in \mathbb{S}(V_i)} \dim(Gv), \quad \sigma(U) = \max_i s_i,$$

with  $\sigma(U) = 0$  when there is no nontrivial constituent. Equivalent constituents have the same  $s_i$ , so this definition is independent of the orthogonal decomposition. It is the smallest orbit within each constituent, followed by a maximum across constituents, not the dimension of a generic orbit or of one chosen seed orbit.

**Theorem 1.1** (Minimum orbits and numerical width). *Let  $G$  be a compact connected Lie group,  $U : G \rightarrow O(\mathbb{R}^D)$  a fixed representation, and  $\mathcal{A} \subset G$  a fixed finite alphabet supporting a probability law with full mean-zero  $L^2(G)$  norm strictly below one. Let the finite unit seeds span  $V$ , and let  $0 < \rho \leq \min\{1/10, 1/(8D)\}$ . For every fixed  $0 \leq \varepsilon < \rho a_*/(2\sqrt{D})$ , with the positive activation*

---

constant  $a_*$  in (25) when a nontrivial constituent is present,

$$(1) \quad W_{N,\varepsilon} = \Theta_{G,U,\mathcal{A},p,\mathcal{X},\rho,\varepsilon}(N^{\sigma(U)/2}).$$

Here width means the maximum number of available labels in a nonuniform clocked atomic-row machine of Definition 2.1. A new machine may be chosen for every  $N$ . The lower bound allows arbitrary hidden states and cut-dependent rows. The upper bound is exact and uses common command rows with an  $N$ -dependent decoder. For a purely invariant representation an exact constant-width machine exists. In a nontrivial irreducible representation, any nonempty unit seed set suffices; if its seeds lie on a minimum-dimensional orbit, the amplitude range extends to  $0 < \rho \leq 1/10$ .

For conjugation on complex traceless Hermitian matrices,  $s = 2(q - 1)$  and the theorem recovers  $N^{q-1}$  labels while preserving the earlier projective seed and signal conventions. It also gives  $N^{(q-1)/2}$  and  $N^{2(q-1)}$  for the real and quaternionic self-adjoint families under the corresponding full gap. On every fixed nontrivial spherical-harmonic representation of  $\mathrm{SO}(3)$  the least orbit dimension is two, giving linear label growth regardless of the harmonic degree. The representation dimension is held fixed in each asymptotic statement. For a reducible action the exponent can remain unchanged after adding a large invariant component or many copies of an easier constituent.

**1.1. The proof mechanism.** The geometric input is now derived, rather than assumed separately for each application. A uniform rank bound for the differential of  $(g, u) \mapsto U_g u$ , followed by a finite chart covering, gives

$$\sup_{u,v} m_G \{g : \|U_g u - v\| \leq r\} \leq A r^{s(U)}.$$

This holds across all stabilizer types, including directions of mixed hidden conditional means. The orbital entropy occupation theorem then turns it into a cumulative bound on small-register epochs. That entropy theorem, proved in the preceding revision and reproduced here, is the dynamic converse input.

For the other direction choose a least-dimensional orbit, not a net on the ambient sphere. Its convex hull contains a fixed ball by irreducible orthogonality. At a support maximum the tangential first derivative vanishes, so an  $h$ -net loses only  $O(h^2)$  in support. Taking  $h \asymp N^{-1/2}$  gives exact compatible stochastic updates with  $O(N^{s/2})$  labels. A randomized branch construction, with the branch identity charged inside the label, proves the maximum rule for reducible representations. One cannot replace this construction by a free selector or by a claim about joint-output products.

**1.2. The numerical objective.** Recent one-way quantum-automata simulation theorems use strict-cutpoint language equivalence [23, 24, 25]. Their positive embedding may attenuate a signed matrix coefficient exponentially with word length. Proposition 8.1 gives an explicit constant-label sign simulator for our own task, whereas Theorem 1.1 requires growing width to preserve its numerical probabilities at fixed accuracy. This comparison does not claim that exact mixed-state linearization or classical quantization geometry is new.

| Symbol                   | Meaning                                                |
|--------------------------|--------------------------------------------------------|
| $D, \rho, \varepsilon$   | Fixed real dimension, signal, binary-TV error          |
| $K_t, W_{N,\varepsilon}$ | Available labels at a cut; minimum peak                |
| $s(U), \sigma(U)$        | Least irreducible orbit dimension; constituent maximum |
| $Z_t, q_t, \Delta_t$     | Conditional centroid, amplitude, quadratic loss        |
| $g_t, \Pi$               | Squared norm gap; Haar-invariant projection            |
| $C, \mathcal{V}_h$       | Minimal-orbit convex hull; finite orbit net            |

The new conclusions are the uniform minimum-orbit concentration principle, the sharp representation width law and its reducible maximum rule. The entropy occupation argument and the quantitative projective and six-gate results are retained with their proofs. Classical orbit geometry, covering dimensions, stochastic positive embedding and external spectral gaps are explicitly attributed. For symmetric basis seeds, every separate internal cut still has positive minimum  $D + 1$  (Proposition 6.2); the growing width is therefore a simultaneous compatibility cost. No program description, arithmetic cost or independent quantum query product is included in the label count.

## 2. THE EXPERIMENT AND ITS POSITIVE REALIZATION

Let  $G$  be a compact group, let  $U : G \rightarrow O(V)$  be a continuous orthogonal representation on  $V = \mathbb{R}^D$ , and fix a finite command alphabet  $\mathcal{A} \subset G$ . A finite seed set  $\mathcal{X} \subset \mathbb{S}(V)$  is given initially. For  $w = (a_1, \dots, a_N)$  write  $U_w = U_{a_N} \cdots U_{a_1}$ . Relative to an orthonormal basis  $e_1, \dots, e_D$ , the prescribed numerical experiment is

$$(2) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, U_w x \rangle}{2}, \quad b \in \{-1, 1\}, \quad j \in [D], \quad 0 < \rho \leq 1/10.$$

All seeds, words and queries are required, not only almost-sure words under one source law. The probabilities are between  $(1 - \rho)/2$  and  $(1 + \rho)/2$ .

**Definition 2.1** (Clocked atomic-row realization). A horizon- $N$  machine consists of finite sets  $\mathcal{S}_t$  with  $|\mathcal{S}_t| = K_t$ , a stochastic initialization  $E_x$  on  $\mathcal{S}_0$ , stochastic matrices  $T_{t,a} : \mathcal{S}_t \rightarrow \mathcal{S}_{t+1}$ , and columns  $d_j : \mathcal{S}_N \rightarrow [-1, 1]$ . Its mean response is

$$(3) \quad E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j.$$

It has error at most  $\varepsilon$  if this differs from  $\rho\langle e_j, U_w x \rangle$  by at most  $2\varepsilon$  for every  $(x, w, j)$ . Available labels, including padding, count. All rows, including unreachable ones, are normalized. Only the updated label persists. The seed, word prefix, old random choices and any data-dependent protocol information cannot be consulted again unless represented by that label. The external time, horizon, fixed program and exact sampling from its rows are free. The final binary answer may be sampled when  $j$  arrives; if retained, it uses a two-label final cut. Write  $W_{N,\varepsilon}$  for the minimum of  $\max(2, K_0, \dots, K_N)$ .

The state alphabets and matrices may be chosen anew for each  $N$ , but the command symbols and their experimental meanings are fixed. Nothing requires one autonomous device or one decoder to serve all stopping lengths. No adaptive choice of the command is optimized in this model. A complex unitary representation can be treated by its realification; all inner products in the entropy argument are real.

Fix one seed  $x$  and an independent command law at each epoch for the converse. Let  $Y_t = U_{a_t} \cdots U_{a_1} x$  and let  $S_t$  be the actual machine state under this test law. Define

$$(4) \quad Z_t = \mathbb{E}[Y_t \mid S_t], \quad q_t = \mathbb{E}\|Z_t\|, \quad v_t = \mathbb{E}\|Z_t\|^2.$$

These random vectors and their laws are analytical devices, not an additional runtime register or oracle.

**Lemma 2.2** (Quadratic budget and terminal calibration). *For the fresh command  $a$ , put  $X_t = U_a Z_t$ . Then*

$$(5) \quad Z_{t+1} = \mathbb{E}[X_t \mid S_{t+1}], \quad \Delta_t := \mathbb{E}\|X_t - Z_{t+1}\|^2 = v_t - v_{t+1}, \quad \sum_{t < N} \Delta_t \leq 1.$$

*The sequences  $q_t, v_t$  are nonincreasing and start at one. A machine with error at most  $\varepsilon$  satisfies*

$$(6) \quad q_t \geq q_N \geq \kappa := \rho/\sqrt{D} - 2\varepsilon \quad (0 \leq t \leq N).$$

*Proof.* The current command is independent of the past, and the new label is generated from  $(S_t, a)$  by a common row. Conditioning first on  $(S_t, a, S_{t+1})$  and then on  $S_{t+1}$  proves the first identity. The orthogonal projection identity for conditional expectation gives the second; Jensen and orthogonality give both monotonicities. The fixed seed has unit norm, even with randomized initialization. For calibration form  $d = (d_1, \dots, d_D)$  only in the proof, so  $\|d\| \leq \sqrt{D}$ . Conditioning on the complete word and using (2)–(3) gives  $\mathbb{E}\langle Y_N, d(S_N) \rangle \geq \rho - 2\sqrt{D}\varepsilon$ . On conditioning instead on  $S_N$ , this is at most  $\sqrt{D}q_N$ . This proves (6). It does not require a joint measurement of the  $D$  coordinates.  $\square$

For each fixed profile, the optimum actual error is attained: all stochastic rows and terminal columns form a finite product of compact sets and the objective is a maximum of finitely many continuous functions. Thus the subsequent lower bounds concern the actual optimization, not a sum of local error certificates.

### 3. THE SMALLEST ORBIT CONTROLS UNIFORM CONCENTRATION

In this section  $G$  is a compact connected Lie group,  $U : G \rightarrow O(V)$ , and  $V^G = \{0\}$ . Put

$$(7) \quad s(U) = \min_{u \in \mathbb{S}(V)} \dim(Gu).$$

The minimum is over *all* directions. It can be smaller than the dimension of a generic orbit. Since  $G$  is connected,  $s(U) \geq 1$ .

**Theorem 3.1** (Uniform concentration across orbit types). *There is a finite constant  $A_U \geq 1$  such that*

$$(8) \quad \sup_{u, v \in \mathbb{S}(V)} m_G\{g : \|U_g u - v\| \leq r\} \leq A_U r^{s(U)} \quad (0 < r \leq 1).$$

*This exponent is optimal among uniform power upper bounds: for a unit  $u_0$  with  $\dim(Gu_0) = s(U)$  there are  $c, r_0 > 0$  such that*

$$(9) \quad m_G\{g : \|U_g u_0 - u_0\| \leq r\} \geq c r^{s(U)} \quad (0 < r < r_0).$$

*No regular-orbit, constant-stabilizer, or simple-spectrum hypothesis is needed in (8).*

*Proof.* Write  $m = \dim G$ ,  $s = s(U)$  and let  $\mathfrak{g}$  be the Lie algebra. For  $u \in \mathbb{S}(V)$  the differential

$$A_u : \mathfrak{g} \longrightarrow V, \quad X \longmapsto dU(X)u$$

has rank  $\dim(Gu) \geq s$ . Its  $s$ th singular value is continuous in  $u$  and is strictly positive on the compact sphere. Its minimum is therefore positive. We give a chart argument that also records why variation of the stabilizer causes no loss in the exponent.

Fix  $(g_0, u_0) \in G \times \mathbb{S}(V)$ . In a smooth coordinate chart  $g = \psi(z, w)$ , where  $z \in \mathbb{R}^s$  and  $w \in \mathbb{R}^{m-s}$ , select  $s$  coordinate directions and a linear projection  $L : V \rightarrow \mathbb{R}^s$  for which

$$D_z[LU_{\psi(z, w)}u]_{(g_0, u_0)} = M$$

is invertible. This is possible by the rank bound. By shrinking to a product of bounded open rectangles  $Z \times W$  and a neighborhood  $J$  of  $u_0$ , arrange

$$\|D_z[LU_{\psi(z, w)}u] - M\|_{\text{op}} \leq \frac{1}{2}\sigma_{\min}(M) \quad (z, w, u) \in Z \times W \times J.$$

Take  $Z$  convex. For fixed  $(w, u)$ , integration along the segment from  $z$  to  $z'$  gives

$$(10) \quad \|LU_{\psi(z, w)}u - LU_{\psi(z', w)}u\| \geq \frac{1}{2}\sigma_{\min}(M)\|z - z'\|.$$

If both points lie in the inverse image of the radius- $r$  ball around  $v$ , their projected distance is at most  $2\|L\|r$ . This inverse image, on the fixed  $w$  slice, consequently has diameter at most  $4\|L\|r/\sigma_{\min}(M)$ , and hence  $s$ -dimensional Lebesgue measure at most a constant times  $r^s$ . Haar

measure has a bounded smooth density in the chosen relatively compact chart. Integration in the remaining  $m - s$  coordinates yields the same bound there.

Choose finitely many of these product neighborhoods covering  $G \times \mathbb{S}(V)$ . For each fixed  $u$ , those whose  $J$  contains  $u$  cover  $G$ ; summing the preceding bounds proves (8). All constants are independent of the center  $v$ . An empty inverse image contributes zero. This use of a finite cover, rather than a separate density estimate on every orbit, is what controls neighborhoods of singular orbit types.

For the converse,  $Gu_0 \simeq G/G_{u_0}$  is a compact smooth embedded  $s$ -dimensional submanifold. The pushforward of Haar probability is its normalized invariant Riemannian volume: the induced metric is  $G$ -invariant and the invariant probability on this homogeneous space is unique. A smooth local graph at  $u_0$  has volume comparable to  $r^s$  in a small ambient ball. This proves (9). If a uniform estimate with exponent  $s' > s$  held, comparison at  $u_0$  as  $r \downarrow 0$  would contradict it.  $\square$

The rank computation in (7) is intrinsic to the representation. For example, given algebraic skew matrices  $B_1, \dots, B_m$  spanning its infinitesimal action, the condition  $s(U) \leq r$  is the existence of a real vector  $u$  with  $\sum u_i^2 = 1$  and all  $(r+1)$ -minors of  $[B_1 u \cdots B_m u]$  zero. Thus it is an explicit real-algebraic decision problem for fully specified algebraic data; quantifier elimination applies [22]. This is not a test for a spectral gap, and no efficient algorithm in a succinct representation is asserted.

**Corollary 3.2** (Intrinsic occupation exponent). *Suppose the representation satisfies (13). In the setting of Lemma 2.2,  $q_N \geq \kappa > 0$  implies*

$$(11) \quad \sum_{\substack{0 \leq t \leq N \\ K_t \leq k}} g_t \leq 2048 D (16 A_U)^{2/s(U)} \kappa^{-3-2/s(U)} k^{2/s(U)}.$$

*The estimate allows arbitrary hidden continuations and imposes no bound on the other cuts.*

*Proof.* Apply Theorem 4.5 with the uniform estimate (8). In particular the conditional means may change orbit type at every step; their directions still satisfy the same estimate.  $\square$

#### 4. AN ORBITAL ENTROPY OCCUPATION THEOREM

Lebesgue measure is used on  $V = \mathbb{R}^D$  and normalized Haar measure on  $G$ . For a function on  $V$ , set

$$(12) \quad \mathcal{U}_a f(z) = f(U_a^{-1} z), \quad P_t = \sum_a p_t(a) \mathcal{U}_a, \quad \Pi f(z) = \int_G f(U_g^{-1} z) dm_G(g).$$

Thus  $\mathcal{U}_a^* = \mathcal{U}_{a^{-1}}$ ,  $\Pi$  is an orthogonal projection, and  $P_t \Pi = \Pi P_t = \Pi$ . The probability law  $p_t$  need not be symmetric. Its required squared norm gap is

$$(13) \quad \|P_t f\|_2^2 \leq \|\Pi f\|_2^2 + (1 - g_t) \|f - \Pi f\|_2^2, \quad 0 \leq g_t \leq 1.$$

Invariance in this formula means  $G$ -invariance, not necessarily radial symmetry. In a reducible representation invariant functions can carry many parameters.

**Lemma 4.1** (Transfer of a group norm gap). *If right convolution  $R_{p_t} F(g) = \sum_a p_t(a) F(ga)$  on  $L^2(G)$  has mean-zero norm at most  $\sqrt{1 - g_t}$ , then (13) holds in every orthogonal representation on  $V$ .*

*Proof.* For each  $z$  apply the group inequality to  $F_z(g) = f(U_g^{-1} z)$ . Its mean is  $\Pi f(z)$  and  $R_{p_t} F_z(g) = P_t f(U_g^{-1} z)$ . Integrate the resulting inequality in  $z$ . Orthogonal changes of variables and Fubini identify the three integrals with those in (13). First take bounded compactly supported  $f$  and then use density. This proof does not replace the full group gap by a gap in the defining representation.  $\square$

**4.1. The conditional-mean cost.** Let  $G_D$  be a standard independent real Gaussian vector and let  $\gamma_\tau$  be the density of  $\tau G_D$ .

**Lemma 4.2** (A one-sided Gaussian coupling inequality). *For bounded  $X$  and a finite-valued variable  $J$ , put  $M = \mathbb{E}[X \mid J]$ . For every  $\tau > 0$ ,*

$$(14) \quad \mathbf{h}(X + \tau G_D) - \mathbf{h}(M + \tau G_D) \leq \frac{\mathbb{E}\|X - M\|^2}{2\tau^2}.$$

*Proof.* Write  $f = \text{Law}(M) * \gamma_\tau$ . Differentiation of the Gaussian mixture and the conditional covariance identity give

$$(15) \quad \nabla^2 \log f(y) = -\tau^{-2}I + \tau^{-4} \text{Cov}(M \mid M + \tau G_D = y) \succeq -\tau^{-2}I.$$

Hence  $\phi(x) = -\mathbb{E} \log f(x + \tau G_D)$  has Hessian at most  $\tau^{-2}I$ . Taylor's inequality at  $M$  yields  $\phi(X) \leq \phi(M) + \langle \nabla \phi(M), X - M \rangle + \|X - M\|^2 / (2\tau^2)$ . The conditional expectation of the linear term given  $J$  is zero. If  $g = \text{Law}(X) * \gamma_\tau$ , nonnegativity of  $D(g \parallel f)$  gives  $\mathbf{h}(g) \leq -\int g \log f = \mathbb{E}\phi(X)$ , whereas  $\mathbb{E}\phi(M) = \mathbf{h}(f)$ . Boundedness of  $X, M$  provides Gaussian bounds with finite second moments and justifies differentiation and integration. These identities prove (14).  $\square$

This elementary consequence of Gaussian posterior identities is used as an estimate, not as a claim of priority over the Gaussian estimation literature [1, 14]. The estimate is one-sided and can have a negative left side. Here  $J$  can be a finite register with no Gaussian observation model; the smoothing noise is added after conditioning.

**Lemma 4.3** (Entropy production away from invariant functions). *For any bounded-support Gaussian mixture density  $f$ ,*

$$(16) \quad \mathbf{h}(P_t f) - \mathbf{h}(f) \geq g_t \|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq 0.$$

*Proof.* Put  $f_a = \mathcal{U}_a f$  and  $h = P_t f$ . Orthogonality preserves entropy, so  $\mathbf{h}(h) - \mathbf{h}(f) = \sum_a p_t(a) D(f_a \parallel h)$ . For probability densities  $u, v$ ,  $D(u \parallel v) \geq \|\sqrt{u} - \sqrt{v}\|_2^2$ ; it follows, for example, from  $-\log x \geq 2(1 - \sqrt{x})$  and integration. The mean is the least-squares minimizer, and thus

$$\sum_a p_t(a) \|\sqrt{f_a} - \sqrt{h}\|_2^2 \geq \sum_a p_t(a) \|\sqrt{f_a} - P_t \sqrt{f}\|_2^2 = 1 - \|P_t \sqrt{f}\|_2^2.$$

Apply (13) and  $\|\sqrt{f}\|_2 = 1$ .  $\square$

No logarithmic Sobolev inequality or point-mass mixing assertion is used in this step.

**4.2. Sparsity away from invariant densities.** Suppose that the representation obeys the uniform orbital bound

$$(17) \quad m_G\{g : \|U_g u - v\| \leq r\} \leq A r^s \quad (u, v \in \mathbb{S}(V), 0 < r \leq 1),$$

where  $A \geq 1$  and  $s > 0$ . In particular the representation has no nonzero fixed vector. It is essential that  $u$  range over all possible centroid directions, not merely the initial seed orbit.

**Lemma 4.4** (Finite centroids cannot be almost invariant). *Suppose  $Z$  has at most  $k$  values in the unit ball and  $\mathbb{E}\|Z\| \geq \kappa$ , where  $0 < \kappa \leq 1$ . Set*

$$(18) \quad r = \left( \frac{\kappa}{16Ak} \right)^{1/s}, \quad \tau = \frac{\kappa r}{8\sqrt{2D}}, \quad f = \text{Law}(Z) * \gamma_\tau.$$

*Then  $\|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq \kappa/16$ .*

*Proof.* Atoms of norm at least  $\kappa/2$  have total mass at least  $\kappa/2$ . Let  $\Omega$  be the union of radius- $r$  caps around their directions, and let  $C_\Omega$  be its cone. By Markov's inequality,  $\mathbb{P}(\|G_D\| \leq \sqrt{2D}) \geq 1/2$ . On this event, perturbing a high-norm atom by  $\tau G_D$  changes its direction by at most  $4\tau\sqrt{2D}/\kappa = r/2$ . Therefore  $\int_{C_\Omega} f \geq \kappa/4$ .

For any  $G$ -invariant  $u \in L^2(V)$ , Haar averaging and (17) give

$$\int_{C_\Omega} |u(z)|^2 dz = \int |u(z)|^2 \int_G \mathbf{1}_{C_\Omega}(U_g z) dm_G(g) dz \leq k A r^s \|u\|_2^2.$$

The point  $z = 0$  is Lebesgue-null. Taking  $u = \Pi\sqrt{f}$ , whose norm is at most one, bounds this integral by  $\kappa/16$ . The reverse triangle inequality in  $L^2(C_\Omega)$  now gives a norm difference at least  $\sqrt{\kappa/4} - \sqrt{\kappa/16} = \sqrt{\kappa}/4$ . Repeated directions and zero centroids cause no change.  $\square$

**Theorem 4.5** (Orbital occupation budget). *Under (13) and (17), let a finite hidden register track a unit-vector command process as in (4). If  $q_N \geq \kappa > 0$ , then, for every  $k \geq 1$ ,*

$$(19) \quad \sum_{\substack{0 \leq t < N \\ \bar{K}_t \leq k}} g_t \leq B_{D,A,s} \kappa^{-3-2/s} k^{2/s}, \quad B_{D,A,s} = 2048 D (16A)^{2/s}.$$

*The same inequality holds with  $K_t$  replaced by the number of positive-probability labels under the chosen test law. No bound is imposed on the other epochs.*

*Proof.* Fix  $k$  and the single scale (18) for the entire run. Write  $f_t = \text{Law}(Z_t) * \gamma_\tau$ . Isotropy of the Gaussian makes the density of  $U_a Z_t + \tau G_D$  equal to  $P_t f_t$ . By Lemmas 4.2 and 4.3,

$$\mathbf{h}(f_{t+1}) - \mathbf{h}(f_t) \geq g_t \|\sqrt{f_t} - \Pi\sqrt{f_t}\|_2^2 - \frac{\Delta_t}{2\tau^2}.$$

At an epoch with at most  $k$  labels, Lemma 4.4 bounds the norm term below by  $\kappa/16$ . Elsewhere it is nonnegative. The initial density is a translate of  $\gamma_\tau$ ; the terminal second moment is at most  $1 + D\tau^2$ . The Gaussian maximum-entropy bound and (5) yield

$$\frac{\kappa}{16} \sum_{K_t \leq k} g_t \leq \frac{D}{2} \log \left( 1 + \frac{1}{D\tau^2} \right) + \frac{1}{2\tau^2} \leq \frac{1}{\tau^2}.$$

Substitute (18). The same Gaussian scale is retained through all epochs; no repeated mixing-time charge is incurred.  $\square$

**Corollary 4.6** (Actual terminal error). *For a constant gap  $g > 0$ , let  $\mathcal{E}_N(\mathbf{K})$  be the minimum actual wordwise binary-TV error over a prescribed available profile, and put  $K = \max_t K_t$ . Then*

$$(20) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{D}} - \left( \frac{B_{D,A,s} K^{2/s}}{gN} \right)^{1/(3+2/s)} \right]_+.$$

*In particular,  $K = o(N^{s/2})$  implies  $\liminf \mathcal{E}_N \geq \rho/(2\sqrt{D})$ .*

*Proof.* If the actual error is below the calibration threshold, combine (6) with (19) and solve for it. Otherwise the displayed lower bound already holds. Attainment or a minimizing sequence gives the same conclusion for the optimum.  $\square$

Local simulation errors may cancel. Nothing in this corollary sums such errors or rules out cancellation; its objective is the actual final law.

## 5. EXACT SYNTHESIS FROM A MINIMAL ORBIT

Assume in this section that  $V$  is a nontrivial real irreducible orthogonal representation, of dimension  $d$ . Choose a unit vector  $v_0$  with orbit dimension  $s = s(U)$ , and set

$$\mathcal{O} = Gv_0, \quad C = \text{conv } \mathcal{O}.$$

The orbit may be a singular orbit in the unit sphere. As a homogeneous space in its own right it is nevertheless a smooth compact manifold.

**Lemma 5.1** (Inradius and quadratic support approximation). *One has  $d^{-1}\mathbb{B}(V) \subseteq C \subseteq \mathbb{B}(V)$ . There are  $c, C_0, h_0 > 0$ , depending on  $U$  and  $v_0$ , such that for  $0 < h \leq h_0$  a set  $\mathcal{V}_h \subset \mathcal{O}$  with  $|\mathcal{V}_h| \leq C_0 h^{-s}$  satisfies*

$$(21) \quad (1 - ch^2)C \subseteq \text{conv } \mathcal{V}_h \subseteq C \quad \text{whenever } ch^2 < 1.$$

*Proof.* The mean of  $U_g v_0$  is an invariant vector and is zero. Its covariance is  $I/d$ : the covariance is self-adjoint and commutes with the representation, so its eigenspaces are invariant; irreducibility and trace one give the claim. This is the real Schur orthogonality calculation, for example [21, Lemma 5]. For unit  $H$ , let  $f(g) = \langle H, U_g v_0 \rangle$  and  $M = \max_g f(g)$ . Since  $-1 \leq f \leq M$ ,

$$0 \leq \mathbb{E}[(M - f)(f + 1)] = M - \mathbb{E}f^2 = M - 1/d.$$

Every support function of  $C$  is thus at least  $1/d$ , which proves the inradius statement.

Equip  $\mathcal{O}$  with its induced Riemannian metric. Finitely many bounded smooth coordinate patches, with their inverses uniformly Lipschitz on smaller patches, give an intrinsic  $h$ -net with at most  $C_0 h^{-s}$  points. At a maximizer  $y$  of  $z \mapsto \langle H, z \rangle$  on  $\mathcal{O}$ , its tangential first derivative is zero. The second fundamental form of the compact embedded orbit is bounded. Along a unit-speed minimizing geodesic of length at most  $h$ , Taylor's formula therefore gives

$$\langle H, y \rangle - \langle H, v \rangle \leq L \|H\| h^2$$

for a nearby net point  $v$ , with  $L$  independent of  $H, y$ . The inradius bound gives  $\|H\| \leq dh_C(H)$ . Hence  $h_{\text{conv } \mathcal{V}_h}(H) \geq (1 - Ldh^2)h_C(H)$  for every  $H$ . Taking  $c \geq Ld$ , and using the support-function criterion, proves (21).  $\square$

The covering exponent  $s$  and quadratic loss at a support maximum are geometric facts, not new quantization exponents. What is needed for realization is an enclosure compatible with *every command* and *every layer*; the following construction supplies it.

**Theorem 5.2** (A minimal-orbit positive realization). *For any finite command alphabet, any finite unit seed set, and  $0 < \rho \leq 1/(8d)$ , the experiment (2) has an exact realization with at most  $C_U N^{s(U)/2}$  available labels, for  $N \geq 1$ . All command matrices can be chosen independent of the epoch; the final decoder may depend on  $N$ . Each row has at most  $d + 1$  successors. If the seeds belong to  $C \cap \mathbb{S}(V)$ , the amplitude range improves to  $0 < \rho \leq 1/10$ .*

*Proof.* Choose

$$h_N = \min\{h_0, (8cN)^{-1/2}\}, \quad \eta = 1 - ch_N^2 \geq 1 - 1/(8N), \quad a_t = \eta^{-t}/4.$$

Let  $v_1, \dots, v_M$  be the net points. The represented vector of a label  $i$  at layer  $t$  is  $a_t v_i$ . These vectors describe the fixed rows; they are not stored as real-valued runtime data.

The polytope  $\text{conv}\{v_i\}$  contains  $\eta C$  and hence a ball of radius  $\eta/d$ . For a unit seed  $x$ ,  $4\rho x \in \eta C$  if  $\rho \leq 1/(8d)$ , because  $4\rho \leq 1/(2d) < \eta/d$ . Choose its convex coordinates as the initial distribution. More generally, if  $x \in C$  and  $4\rho \leq 2/5 < \eta$ , the same initialization is valid. For each command  $a$  and label  $i$ , invariance of  $C$  gives

$$\eta U_a v_i \in \eta C \subseteq \text{conv}\{v_j\}.$$

Choose any convex coordinates of this point for the row  $T_a(i, \cdot)$ . They do not depend on  $t$ . Since  $a_{t+1}\eta = a_t$ , conditional expectation updates the represented vector by exactly  $U_a$ . Induction gives mean  $\rho U_w x$  after each complete prefix.

Use the terminal column  $d_j(i) = a_N \langle e_j, v_i \rangle$ . Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $|d_j(i)| \leq 2/7 < 1$ . This proves every numerical conditional law exactly. Carathéodory's theorem gives  $d+1$  successors. Finally  $M \leq C_0 h_N^{-s} \leq C_U N^{s/2}$ , with the fixed two-state output cut absorbed into the constant. Neither convex feasibility nor row lookup is priced as computation in this model.  $\square$

**Corollary 5.3** (The irreducible width law). *Suppose a probability law on the finite command alphabet has a full mean-zero group norm gap. For a nontrivial real irreducible  $V$ , any nonempty finite unit seed set, fixed  $0 < \rho \leq 1/(8d)$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{d})$ ,*

$$(22) \quad W_{N,\varepsilon} = \Theta_{U,p,\rho,\varepsilon}(N^{s(U)/2}).$$

*The same order holds for exact vector-state realizations and for fixed-length realizations with common command rows. For seeds on a minimal orbit the amplitude range is  $0 < \rho \leq 1/10$ .*

*Proof.* A full group norm gap transfers to (13) with a fixed  $g > 0$ . Apply Corollary 3.2 at the peak  $k$ , using  $\kappa = \rho/\sqrt{d} - 2\varepsilon > 0$ . It gives  $gN \leq B\kappa^{-3-2/s}k^{2/s}$  and therefore the lower order. The exact machine in Theorem 5.2 is an upper bound for every allowed error, is vector-valued in its representation, and has common command rows. These subclasses lie inside the unrestricted clocked class, so the lower bound applies to them too. The last assertion uses the stronger initialization in that theorem.  $\square$

## 6. A MAXIMUM LAW FOR ORTHOGONAL SUMS

Let

$$(23) \quad V = V_0 \oplus V_1 \oplus \cdots \oplus V_m$$

be an orthogonal decomposition, where  $V_0 = V^G$  and each  $V_i$ ,  $i \geq 1$ , is a nontrivial real irreducible representation. Multiplicities are allowed. Put  $d_i = \dim V_i$ ,  $D = \dim V$  and

$$(24) \quad \sigma(U) = \max_{1 \leq i \leq m} s(U|_{V_i}), \quad \sigma(U) = 0 \quad \text{if } m = 0.$$

Equivalent irreducible orthogonal representations have isomorphic orbits. Thus  $\sigma(U)$  does not depend on the chosen decomposition of an isotypic summand. In general it is *not* the smallest orbit dimension on the sphere of the whole reducible representation.

For the lower bound assume that the finite unit seeds span  $V$  and write

$$(25) \quad a_i = \max_{x \in \mathcal{X}} \|\pi_i x\| > 0, \quad a_* = \min_{1 \leq i \leq m} a_i,$$

where  $\pi_i$  is orthogonal projection; set  $a_* = 1$  if  $m = 0$ . In a basis-adapted seed set  $\{\pm e_j\}$  all  $a_i$  equal one. The query basis need not respect the decomposition.

**Theorem 6.1** (Irreducible maximum principle). *Suppose a law on the finite command alphabet has a full group norm gap. Let the seeds span  $V$ , let  $0 < \rho \leq \min\{1/10, 1/(8D)\}$ , and, when  $m > 0$ , let  $0 \leq \varepsilon < \rho a_*/(2\sqrt{D})$ . Then*

$$(26) \quad W_{N,\varepsilon} = \Theta(N^{\sigma(U)/2}).$$

*The constants may depend on the representation, command law, seed set, signal and error, but not on  $N$ . If  $m = 0$ , an exact constant-width machine exists. The upper realization uses common command rows and only one selected terminal numerical query.*

*Proof.* First fix  $i \geq 1$  and a seed  $x$  with  $\|\pi_i x\| = a_i$ . Track the unit-vector process  $Y_t^{(i)} = U_{a_t} \cdots U_{a_1} \pi_i x / a_i$  in  $V_i$  and its conditional mean given the *actual whole-machine state*. Form the ambient vector  $d = (d_1, \dots, d_D)$  from the terminal columns in the proof. It has norm at most  $\sqrt{D}$ . The prescribed row means and the uniform error give

$$\mathbb{E}\langle Y_N^{(i)}, \pi_i d(S_N) \rangle \geq \rho a_i - 2\sqrt{D}\varepsilon.$$

Conditioning on  $S_N$  bounds the left side above by  $\sqrt{D}\mathbb{E}\|Y_N^{(i)} \mid S_N\|$ . Hence the terminal conditional amplitude is at least  $\rho a_i / \sqrt{D} - 2\varepsilon > 0$ . The inherited entropy occupation argument applies in the representation  $V_i$  to these conditional means, even though the hidden label also serves every other constituent. Theorem 3.1 supplies its exponent  $s(U|V_i)$ . It follows that  $W_{N,\varepsilon} \geq c_i N^{s(U|V_i)/2}$ . Choose a constituent attaining (24).

For the upper bound include only nonzero summands and set  $w_i = d_i/D$ . Choose a branch  $i$  at initialization with probability  $w_i$ , independently of the seed. The branch identifier is part of the state label, not a free future input. In branch  $i \geq 1$  use the minimal-orbit polytope of Theorem 5.2. Its initial represented mean is prescribed to be

$$(\rho/w_i)\pi_i x.$$

Its norm is at most  $\rho D/d_i \leq 1/(8d_i)$ , so the initialization proof there applies also to this possibly subunit vector. Subsequent rows are the common command rows from that construction. At a query  $j$  output the mean  $\langle e_j, a_N v_{i,s} \rangle$ . The conditional represented vector in the branch is  $(\rho/w_i)U_w \pi_i x$ ; multiplying by  $w_i$  and summing gives exactly  $\rho U_w x$ . All terminal means are bounded by  $2/7$ .

In the invariant branch, if present, use the fixed vectors  $\{\pm e : e \text{ in an orthonormal basis of } V_0\}$  scaled by  $1/4$ , with identity transitions. Their convex hull contains a ball of radius  $1/(4\sqrt{d_0})$ , which contains the required initial vector of norm at most  $1/(8d_0)$ . Its contribution is exact with  $2d_0$  labels. The entire register is the disjoint union of these branch labels. Its cardinality is at most

$$2d_0 + \sum_{i=1}^m C_i N^{s(U|V_i)/2} = O(N^{\sigma(U)/2}).$$

No product of independently correct outputs is required. If  $m = 0$  the invariant construction proves the asserted constant bound. The fixed two-label answer cut does not change the orders.  $\square$

*Proof of Theorem 1.1.* Theorem 6.1 proves the stated general law. Corollary 5.3 gives its irreducible and minimal-orbit signal refinements.  $\square$

The maximum in (24), rather than a sum, is substantive. For the direct product action of  $\text{SO}(3) \times \text{SU}(3)$  on  $\mathbb{R}^3 \oplus \text{Herm}_0(3)$ , the two least orbit dimensions are two and four. With a full-gap product command law and the above signal conventions the label order is  $N^2$ , not  $N^3$ ; a generic product orbit and a joint-output product task describe different quantities. Adding a fixed subspace creates zero-dimensional whole-space orbits but does not remove this  $N^2$  requirement. The proof explains both phenomena by paid branch labels and a constituent-wise converse.

**Proposition 6.2** (All separate cuts have constant positive minimum). *For any orthogonal command family on  $\mathbb{R}^D$ , seeds  $\mathcal{X} = \{\pm e_1, \dots, \pm e_D\}$ , and  $0 < \rho \leq 1/D$ , the normalized residual row rank and the separate positive minimum are both  $D + 1$  at every internal cut. The separate minimum permits unrestricted memory at the other cuts. The assertion requires no group gap and does not assert simultaneous attainment.*

*Proof.* For a vector  $z$ , its remaining response on suffix  $v$  and query  $j$  has mean  $\langle e_j, U_v z \rangle$ . The resulting affine map from  $z$  to the normalized response array is injective: fix one suffix and vary the coordinate query;  $U_v$  is invertible. At a fixed cut, fix one preceding word  $w$  and vary the

seeds. The vectors  $\{\pm \rho U_w e_j\}$  affinely span  $\mathbb{R}^D$ . Thus the normalized residual arrays have row rank  $D + 1$ , giving the positive lower bound.

A regular unit simplex in  $\mathbb{R}^D$  contains the ball of radius  $1/D$ . Every actual represented vector at that cut has norm  $\rho$  and is therefore a convex combination of its  $D + 1$  vertices. A vertex  $v_s$  defines a legal normalized continuation, since  $|\langle e_j, U_v v_s \rangle| \leq 1$  for every suffix and query. These are  $D + 1$  positive generators of all cut rows. To embed the factorization in a whole machine, retain the complete finite prefix until the selected cut, sample its convex coordinates there, then retain the chosen label together with the remaining command prefix. There is no cap at those other cuts. The resulting finite machine attains  $D + 1$  at the selected cut. This verifies the operational, not merely amputated-matrix, meaning of the separate minimum.  $\square$

## 7. MATRIX AND HARMONIC REPRESENTATIONS

Theorem 3.1 identifies the correct geometric exponent without a separate estimate for every spectral type. We record its principal matrix consequences. The orbit dimensions below are classical; their role is to determine the dynamic width exponent.

**Proposition 7.1** (Three conjugation families). *On the real space of traceless self-adjoint  $q$  by  $q$  matrices over  $\mathbb{F} = \mathbb{R}, \mathbb{C}, \mathbb{H}$ , with inner product  $\text{Re tr}(AB)$ , let  $\beta = \dim_{\mathbb{R}} \mathbb{F}$ . The compact groups  $\text{SO}(q), \text{SU}(q), \text{Sp}(q)$ , respectively, act irreducibly for  $q \geq 2$ . The least nonzero unit-orbit dimension is  $\beta(q - 1)$ . Accordingly, under a full group gap, the width order in Corollary 5.3 is*

$$(27) \quad N^{(q-1)/2}, \quad N^{q-1}, \quad N^{2(q-1)},$$

respectively, in its fixed signal and fixed error ranges. The  $\text{SO}(2)$  case supplies no finitely supported full-gap example.

*Proof.* A self-adjoint matrix with distinct eigenvalue multiplicities  $m_1, \dots, m_r$  has orbit dimension

$$\beta \sum_{i < j} m_i m_j = \frac{\beta}{2} \left( q^2 - \sum_i m_i^2 \right).$$

For real matrices subtract the dimensions of the orthogonal stabilizer blocks from  $q(q - 1)/2$ ; their disconnected components do not affect dimension. For complex matrices subtract  $\sum m_i^2 - 1$  from  $q^2 - 1$ . For quaternionic matrices subtract  $\sum m_i(2m_i + 1)$  from  $q(2q + 1)$ . These computations also identify the least orbits as real, complex and quaternionic projective spaces. A nonzero traceless matrix has at least two eigenvalues. The largest possible  $\sum m_i^2$  under that restriction is  $(q - 1)^2 + 1$ , attained by multiplicities  $(1, q - 1)$ . This proves the minimum.

For completeness, the conjugation representation is irreducible over  $\mathbb{R}$ . Any nonzero invariant real subspace contains, after diagonalizing a nonzero member, a nonconstant traceless real diagonal matrix. Differences of its conjugates under coordinate interchanges give all traceless diagonal directions. Rotations in a pair of coordinate axes then give every self-adjoint off-diagonal direction; in the complex and quaternionic cases, diagonal unit phases give each real component of those entries. Signed interchanges and plane rotations can be chosen in the stated special groups. Thus the subspace is the entire traceless self-adjoint space. The general width law applies. Finally a finite measure on a torus has Fourier multipliers arbitrarily close to one by simultaneous approximation, so it has no full norm gap on its mean-zero  $L^2$  space.  $\square$

For complex matrices the projective seeds in (39) belong to a least-dimensional orbit. The signal need not be reduced to  $1/(8(q^2 - 1))$  in this specialization.

**Corollary 7.2** (The preserved projective width law). *Let  $q \geq 2$ ,  $0 < \rho \leq 1/10$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{q^2 - 1})$  be fixed. For the finite projective seeds and coordinate queries of Section B, any*

finite command alphabet supporting a full group norm gap has

$$W_{N,\varepsilon} = \Theta(N^{q-1}).$$

It has the fixed  $q$ -dimensional quantum realization of Proposition B.4. The explicit quantitative all-spectra estimate and the rational-projector net from the preceding revision are retained in Appendices A and B.

**Proposition 7.3** (Every fixed spherical harmonic degree). *Let  $V_\ell$  be the real irreducible  $\mathrm{SO}(3)$  representation of harmonic homogeneous polynomials of degree  $\ell \geq 1$ , with  $\dim V_\ell = 2\ell + 1$ . Then  $s(V_\ell) = 2$ . Consequently every fixed  $\ell$  has width  $\Theta(N)$  under a full-gap command law, with the signal and query conventions of Corollary 5.3. The same six-command arithmetic alphabet in Appendix C supplies such a gap for all these representations.*

*Proof.* A nonzero vector has no three-dimensional stabilizer, since the representation is nontrivial irreducible. The Lie algebra  $\mathfrak{so}(3)$  has no two-dimensional subalgebra: identifying its bracket with a cross product, two independent elements bracket to a third independent direction. The stabilizer dimension is therefore at most one, so every orbit has dimension at least two. A zonal spherical harmonic is fixed by the circle of rotations about its axis and has a two-dimensional orbit. This gives the minimum. The final assertion follows from Proposition D.1: the spherical norm bound controls all nontrivial  $\mathrm{SO}(3)$  irreducibles, not just the defining three-dimensional action.  $\square$

The degree is fixed before  $N \rightarrow \infty$ ; no uniform-in- $\ell$  constants are claimed. Generic harmonic orbits can be three-dimensional, so their dimension would give the wrong exponent. In the real degree-two representation this is already the distinction between generic three-dimensional matrix orbits and the two-dimensional projective orbit. These examples use the same general minimum-orbit theorem, not separate orbital cap computations.

## 8. NUMERICAL REALIZATION IS NOT CUTPOINT SIMULATION

A numerical simulator must preserve the values in (2), whereas a strict-cutpoint simulator need only preserve whether the answer probability is larger than  $1/2$ . The following construction makes the difference explicit in the present command model. Its stochastic embedding mechanism is classical; it is the quantitative width theorem that prevents numerical exactification at bounded width.

**Proposition 8.1** (A constant-width sign simulator). *For any orthogonal action on  $\mathbb{R}^D$ ,  $D \geq 2$ , there is a machine with  $D + 1$  command-layer labels, common command rows, and one common query decoder for all lengths such that*

$$(28) \quad \tilde{\mathbb{P}}(B = 1 \mid x, w, j) - \frac{1}{2} = \frac{1}{2} \lambda^{N+1} \langle e_j, U_w x \rangle, \quad \lambda = 1/(2D).$$

*It preserves every strict comparison of (2) with  $1/2$ , including equality. If  $\lambda^{N+1} \leq \rho$ , its worst numerical binary-TV error is at least  $(\rho - \lambda^{N+1})/(2\sqrt{D})$ .*

*Proof.* Let  $v_0, \dots, v_D$  be a regular simplex on the unit sphere of  $\mathbb{R}^D$ , centered at zero. Then

$$\sum_s v_s = 0, \quad \sum_s v_s v_s^T = \frac{D+1}{D} I, \quad b_s(z) = \frac{1 + D \langle v_s, z \rangle}{D+1}$$

are barycentric coordinates for every  $z$  in its convex hull. For  $\|z\| \leq 1/(2D)$  they are all positive and sum to one. Initialize with weights  $b_s(\lambda x)$ . For command  $a$  use  $T_a(s, r) = b_r(\lambda U_a v_s)$ ; these are stochastic rows, independent of  $N$  and of the epoch. Use the terminal mean  $d_j(s) = \langle e_j, v_s \rangle$ . The displayed barycentric identity shows inductively that the represented mean is  $\lambda^{N+1} U_w x$ . This proves (28) and its sign assertion. For every unit  $U_w x$  some coordinate has modulus at least  $1/\sqrt{D}$ ; binary total variation is half the difference of its means. This gives the numerical error bound. Only the label is stored. A held binary output uses a separate two-label cut.  $\square$

**Corollary 8.2** (Separation of numerical and sign-only width). *For every nontrivial expanding irreducible experiment in Corollary 5.3, numerical width is of order  $N^{s(U)/2}$  at the stated fixed positive accuracy, but strict-cutpoint width in the same reset-command-query interface is at most  $D + 1$  for all lengths simultaneously. For complex conjugation the numerical order is  $N^{q-1}$ , while the sign-only command width is at most  $q^2$ .*

*Proof.* Combine Proposition 8.1 with the corresponding numerical width theorem. Here  $D = q^2 - 1$  in the last assertion. The number counts command-layer labels, not the total state count of a language recognizer additionally parsing reset and query syntax.  $\square$

**8.1. The current quantum-automata comparison.** Chen–Wu’s revised generalized-automaton conversion [23, Proposition 3.1] maps a  $k$ -dimensional real zero-cutpoint generalized finite automaton to a probabilistic automaton with  $k + 1$  states. For its parameters  $c, \delta > 0$  the conversion has

$$(29) \quad f_{\text{PFA}}(w) - 1/(k + 1) = \delta c^{|w|} f_{\text{GFA}}(w).$$

Their Theorem 3.2 consequently gives  $q^2 + 1$  states for strict-cutpoint simulation of a  $q$ -state general one-way QFA. The second version of that paper improves the larger bound in its original version. Mixed-state linearization is exact before the positive embedding; the factor in (29) is the distinction relevant here. The later paper [24, Proposition 4 and Theorems 11–12] uses the related conversion to compare hybrid quantum and classical language state costs. These are results about cutpoint languages, not fixed nonvanishing numerical accuracy.

For clarity, the algebra behind (29) is that a uniform-row matrix  $Q$  annihilates a zero-sum coordinate subspace, while a scaled matrix  $cK_a$  carries the desired signed dynamics there. Matrices  $Q + cK_a$  are made stochastic by choosing  $c$  small. After  $N$  commands the signed deviation is multiplied by  $c^N$ . A length-dependent decoder attempting to divide by this factor need not lie in  $[-1, 1]$  and is not a stochastic readout. More generally, a stochastic post-processing cannot increase total variation. Allowing redesign at every horizon does not overcome the numerical lower bound, which already permits that redesign.

A prefix-suffix sign or rank argument alone cannot substitute for the occupation proof. The matrix of centered target responses has entries  $\langle \rho U_p x, U_s^* e_j \rangle$  and ordinary rank at most  $D$  at every split, independently of the horizon. Adding the constant probability column gives rank at most  $D + 1$ . The prepare-test sign-rank and shattering statements in [24] control a threshold relation in this fixed operator space; they do not force the numerical hidden-width growth proved here. Conversely the present argument gives no growing lower bound for the sign-only task, as Proposition 8.1 demonstrates.

Chen’s subsequent work [25], including its invariant-algebra simulation results and Section 7’s stabilizer-orbit capacity analysis, also uses strict-cutpoint behavioral equivalence. Its dimensions and symmetry constraints belong in this comparison. Orbit dimension as  $\dim G - \dim G_v$ , and quantum operator-space linearization, are not claimed new here. Our invariant first takes the *minimum over all nonzero directions in each irreducible representation*, then the *maximum across active constituents*; it governs a growing fixed-accuracy numerical width as the word length grows. These are different optimization and asymptotic variables. No assertion of exhaustive priority clearance is made from this comparison.

## 9. GEOMETRIC, PROBABILISTIC AND COMPUTATIONAL BOUNDARIES

The new theorem concerns a growing execution constrained by a single retained label. It neither changes the classical dimension of an orbit nor identifies numerical simulation with a threshold language.

**9.1. What the covering exponent does and does not prove.** For a smooth compact  $s$ -manifold, covering by  $O(h^{-s})$  small balls is classical. Iacobelli’s manifold quantization theorem [26, Theorem 1.4] concerns the minimum integrated  $r$ th-power distance from a *fixed measure* to a codebook of  $k$  points, with its  $k^{-r/s}$  asymptotics under the stated hypotheses. The codebook in that problem sees one sample from that measure; there are no stochastic command rows to be implemented at all layers. Theorem 5.2 uses the classical covering count, a quadratic support loss, and an explicit stochastic realization. Its new lower partner is not a static quantization lower bound. The conditional means of a hidden machine generally leave the seed orbit, and neither their distribution nor their orbit type is fixed. Theorem 3.1 controls all those directions at once; the entropy budget then charges every small-state epoch to one finite quadratic loss. This is the mechanism that prevents hidden lifts from outperforming the geometric synthesis order.

Orbit convex hulls and their representation-theoretic geometry are classical objects [21, 27]. The covariance identity and local covering calculation are reproved here to fix constants and hypotheses, not claimed as new geometric discoveries. Our minimum-orbit theorem does not give local volume asymptotics uniformly for each spectrum; only its uniform exponent is sharp. The elementary finite-rank chart argument also explains why no separate spectral projector calculation is needed for a new representation. The earlier projector argument is retained because it gives an explicit, albeit large, constant in its matrix family.

**9.2. Positive rank and quantum dimension.** At a fixed cut, a numerical classical realization factors the matrix of future response probabilities through  $K_t$  positive normalized state continuations. With one output alphabet this is a nonnegative factorization; with several selectable queries, each decoder block must normalize. Quantum prepare–measure probabilities instead admit positive-semidefinite factorizations. These static dimension relations are classical [28]. They do not by themselves supply common transition rows connecting independently chosen factorizations at successive cuts. In the projective experiment a fixed  $q$ -dimensional quantum register supplies all layers, while the compatible classical numerical width grows with  $N$ . No new quantum operation, seed reset, or quantum-memory model is introduced by that comparison.

**Proposition 9.1** (Probabilistic ordered programs). *Definition 2.1 is equivalently a nonuniform ordered read-once layered program with stochastic command-labelled edges and real terminal columns. A selected column can be replaced by a Bernoulli acceptance row without changing any command-layer width; a retained final answer needs at most two labels.*

*Proof.* Identify  $T_{t,a}(s, s')$  with the outgoing edge weight at layer  $t$ . Summing path probabilities gives (3), and conversely those edge weights define the stochastic rows. At terminal label  $s$  the selected query accepts with probability  $(1 + d_j(s))/2$ .  $\square$

The Fourier-growth and pseudorandomness results in [15, 16, 9] have their stated deterministic, regular or permutation hypotheses and different objectives. Our external group law has a norm gap; hidden reset rows and nonregular matrices remain allowed. Width is not total branching-program size, and real edge tables are not a uniform finite-bit implementation.

**9.3. Expansion and implementation.** Full group expansion is an explicit hypothesis, not a consequence of orbit dimension, density alone, or a calculation in the defining representation. The algebraic alphabets in Proposition B.3 use the deep external theorems [2, 3]; their gap constants remain qualitative. The numerical six-gate certificate uses the different external line (LPS5). It is not certified by a finite harmonic truncation. For example the circle has positive-dimensional orbits but admits no finite-command full group norm gap, and its earlier arithmetic width theorem is not an instance of the present hypothesis.

Only one query is answered. A request for jointly independent answers to all queries changes the channel and need not satisfy the maximum law of Theorem 6.1. The model charges branch

identifiers, but not the description length or construction of the row tables. Rational net coordinates do not make all transition weights rational when commands are merely algebraic. Carathéodory sparsity bounds successors, not table size. The separate fair-bit compilers in the preserved development incur further states and possibly error; they do not equate atomic width with bit complexity.

**9.4. Conclusions.** Under a full compact-group gap and the stated nonvanishing numerical calibration, the minimum nontrivial orbit dimension of each irreducible constituent determines the sharp hidden-width exponent. For spanning seed sets at small fixed signal, the largest of those exponents determines the whole representation, with an exact common-row upper realization. The uniform small-ball theorem and paid randomized-sum construction replace the former matrix-specific geometric verification by a representation-level conclusion.

The theorem is not an all-alphabet classification. It does not optimize leading constants, numerical gap values, uniform program size, variable-signal limits, or arbitrary experimental action selection. Strict-cutpoint simulation is a different task and has a constant-width implementation in the same interface. These boundaries are consequences of the definitions and explicit constructions, not an identification of several resource models.

#### APPENDIX A. UNIFORM GEOMETRY OF HERMITIAN CONJUGATION

Fix  $q \geq 2$  and let  $V = \text{Herm}_0(q)$  be the real space of traceless Hermitian  $q$  by  $q$  matrices, with inner product  $\text{tr}(AB)$ . Its dimension is  $D = q^2 - 1$ . Unitary conjugation is orthogonal on this space. The pure-state orbit has dimension  $2(q - 1)$ , but normalized hidden centroids can have arbitrary spectra. We therefore prove a bound on *every* unit sphere orbit.

**A.1. A Grassmann small-ball estimate.** Let  $P_0$  be a rank- $k$  orthogonal projector in  $\mathbb{C}^q$ ,  $1 \leq k < q$ , and let  $P$  be a Haar-distributed rank- $k$  projector. Put  $m = k(q - k)$  and

$$(30) \quad b_{q,k} = \frac{1}{m!} \prod_{j=1}^k \frac{\Gamma(q - k + j)}{\Gamma(j)}.$$

**Lemma A.1** (Projector balls). *For  $0 < R \leq 1$ ,*

$$(31) \quad \mathbb{P}(\|P - P_0\|_{\text{HS}} \leq R) \leq b_{q,k} R^{2k(q-k)}.$$

*Proof.* By invariance take  $P_0$  onto the first  $k$  coordinates. Apart from a null set, a Haar subspace is the graph of  $Z \in \mathbb{C}^{(q-k) \times k}$ . Its density with respect to complex Euclidean Lebesgue measure is

$$(32) \quad \pi^{-m} \prod_{j=1}^k \frac{\Gamma(q - k + j)}{\Gamma(j)} \det(I + Z^* Z)^{-q}.$$

For completeness, take a  $q$  by  $k$  matrix of independent standard complex Gaussian entries and split it into a square top block  $A$  and bottom block  $B$ . Its column space is Haar and  $Z = BA^{-1}$  almost surely. The change  $B = ZA$  has real Jacobian  $|\det A|^{2(q-k)}$ . Integrating  $A$  with weight  $\exp[-\text{tr } A^*(I + Z^*Z)A]$  gives the determinant factor  $\det(I + Z^*Z)^{-q}$ . Complex Gaussian Gram-Schmidt gives  $\mathbb{E}|\det A|^{2(q-k)} = \prod_{j=1}^k \Gamma(q - k + j)/\Gamma(j)$ , since its squared orthogonal lengths have gamma shapes  $1, \dots, k$ . The powers of  $\pi$  give (32).

If  $\theta_i$  are the principal angles, then  $\|P - P_0\|_{\text{HS}}^2 = 2 \sum_i \sin^2 \theta_i$  and  $\|Z\|_{\text{HS}}^2 = \sum_i \tan^2 \theta_i$ . On the event in (31) each  $\sin^2 \theta_i \leq R^2/2$ , whence

$$\|Z\|_{\text{HS}}^2 \leq \frac{R^2}{2 - R^2} \leq R^2.$$

The density (32) is bounded by its value at zero. Multiply this value by the volume  $\pi^m R^{2m}/m!$  of a real  $2m$ -dimensional ball. This proves the assertion.  $\square$

Define the explicit finite constant

$$(33) \quad A_q = \max_{1 \leq k < q} \left\{ \max(1, b_{q,k}) [9q(q-1)^2]^{k(q-k)} \right\}.$$

It is rational and at least one; no optimality is claimed.

**Theorem A.2** (All-spectra orbital anti-concentration). *For all  $A, B \in \text{Herm}_0(q)$  of Hilbert–Schmidt norm one and all  $0 < r \leq 1$ ,*

$$(34) \quad m_{\text{SU}(q)}\{U : \|UAU^* - B\|_{\text{HS}} \leq r\} \leq A_q r^{2(q-1)}.$$

*In particular, the estimate is uniform at repeated eigenvalues and over mixed-state centroid directions. No lower bound on each eigenvalue gap is assumed.*

*Proof.* Let  $\lambda_1 \geq \dots \geq \lambda_q$  be the eigenvalues of  $A$ . Trace zero and  $\sum_i \lambda_i^2 = 1$  imply  $\lambda_1 - \lambda_q \geq q^{-1/2}$ . Hence some  $k$  has

$$(35) \quad \lambda_k - \lambda_{k+1} \geq \delta_q := \frac{1}{\sqrt{q}(q-1)}.$$

For two conjugates  $C, D$  of  $A$ , let  $P_C, P_D$  be their top- $k$  spectral projectors. Eigenvectors  $u_i$  of  $C$  and  $v_j$  of  $D$  obey

$$(\lambda_i - \lambda_j) \langle u_i, v_j \rangle = \langle u_i, (C - D)v_j \rangle.$$

Summing squares for  $i \leq k < j$  and using equal projector ranks gives

$$(36) \quad \|P_C - P_D\|_{\text{HS}}^2 = 2 \sum_{i \leq k < j} |\langle u_i, v_j \rangle|^2 \leq 2\delta_q^{-2} \|C - D\|_{\text{HS}}^2.$$

If the event in (34) is empty there is nothing to prove. Otherwise choose one conjugate  $D$  in that event. Every other  $C$  in the event has  $\|C - D\|_{\text{HS}} \leq 2r$ . The image  $P_C$  is a Haar rank- $k$  projector and lies within  $2\sqrt{2}\delta_q^{-1}r$  of  $P_D$ . Set  $c_q = 3\sqrt{q}(q-1)$ , which is larger than this coefficient. If  $c_q r \leq 1$ , Lemma A.1 gives a bound  $b_{q,k}(c_q r)^{2k(q-k)}$ . Since  $k(q-k) \geq q-1$  and  $r \leq 1$ , this is at most the right side of (34). If  $c_q r > 1$ , then  $A_q r^{2(q-1)} \geq c_q^{2(q-1)} r^{2(q-1)} > 1$ , so the trivial probability bound suffices. Haar conjugation under  $\text{SU}(q)$  and under  $U(q)$  has the same law, completing the proof.  $\square$

The proof isolates one uniformly separated spectral cut rather than requiring a simple spectrum. This is why pure-state and highly mixed centroids are handled by the same constant. The smallest possible nontrivial Grassmann exponent is  $2(q-1)$ .

**Corollary A.3** (Conjugation occupation). *For conjugation commands satisfying a group gap  $g_t$ , any hidden register with  $q_N \geq \kappa > 0$  obeys*

$$(37) \quad \sum_{K_t \leq k} g_t \leq C_q \kappa^{-3-1/(q-1)} k^{1/(q-1)}, \quad C_q = 2048(q^2 - 1)(16A_q)^{1/(q-1)}.$$

*For a constant gap  $g > 0$  and wordwise error  $\varepsilon$  with  $\kappa = \rho/\sqrt{q^2 - 1} - 2\varepsilon > 0$ ,*

$$(38) \quad W_{N,\varepsilon} \geq \left( \frac{g\kappa^{3+1/(q-1)}}{C_q} N \right)^{q-1}.$$

*Proof.* Apply Lemma 4.1, Theorem A.2 and Theorem 4.5, then use Lemma 2.2.  $\square$

A group gap is stronger than a gap only on functions on the pure-state homogeneous quotient. The proof genuinely needs uniform control of the mixed-centroid directions, and does not silently replace this hypothesis by the weaker quotient gap.

## APPENDIX B. SHARP MEMORY ON COMPLEX PROJECTIVE ORBITS

Write  $r_q = \sqrt{1 - 1/q}$  and associate to a rank-one orthogonal projector  $P$  the unit vector

$$(39) \quad Y(P) = \frac{P - I/q}{r_q} \in \text{Herm}_0(q), \quad \mathcal{K}_q = \text{conv}\{Y(P) : \text{rank } P = 1\}.$$

The body  $\mathcal{K}_q$  consists of normalized centered density matrices. It is invariant under conjugation and contains zero. Its extreme orbit is  $\mathbb{CP}^{q-1}$ . Fix an orthonormal real basis  $F_1, \dots, F_D$  of  $\text{Herm}_0(q)$  and use its coordinate queries in (2). One may take as seeds the  $q^2$  rank-one projectors onto  $e_i$ ,  $(e_i + e_j)/\sqrt{2}$  and  $(e_i + ie_j)/\sqrt{2}$ ,  $i < j$ . Their centered matrices affinely span  $\text{Herm}_0(q)$ . All seed and query alphabets are fixed when  $q$  is fixed.

**B.1. A projective enclosure with quadratic loss.** For rank-one projectors use the distance  $d(P, Q) = \sqrt{1 - \text{tr}(PQ)}$ , the sine of their principal angle.

**Lemma B.1** (Finite projective synthesis). *For  $0 < h \leq 1$ , there is an  $h$ -net  $\mathcal{V}_h$  of rank-one projectors with at most*

$$(40) \quad q(2\lceil 2\sqrt{2(q-1)}/h \rceil + 1)^{2(q-1)}$$

*elements, and the entries of all these projectors can be chosen in  $\mathbb{Q} + i\mathbb{Q}$ . If  $qh^2 < 1$ , then*

$$(41) \quad (1 - qh^2)\mathcal{K}_q \subseteq \text{conv}\{Y(P) : P \in \mathcal{V}_h\} \subseteq \mathcal{K}_q.$$

*Proof.* Every complex line has a representative with a largest coordinate scaled to one and the real and imaginary parts of all other coordinates in  $[-1, 1]$ . In each of the  $q$  charts round these  $2(q-1)$  real coordinates to the grid of step  $1/M$ , where  $M = \lceil 2\sqrt{2(q-1)}/h \rceil$ . If  $v, w$  are the original and rounded representatives, their norms are at least one and  $\|v - w\| \leq \sqrt{2(q-1)}/(2M)$ . Normalization changes their distance by at most a factor two, and the sine distance is at most the distance of these normalized representatives. Thus the stated set is an  $h$ -net. The projector  $ww^*/\|w\|^2$  has rational real and imaginary entries, and the grid count is (40).

For a nonzero traceless Hermitian  $H$ , let  $\lambda_1$  and  $\lambda_q$  be its largest and smallest eigenvalues. A net projector within  $h$  of a top eigenline satisfies

$$\text{tr}(HP) \geq \lambda_1 - (\lambda_1 - \lambda_q)h^2 \geq (1 - qh^2)\lambda_1.$$

Indeed  $-\lambda_q \leq (q-1)\lambda_1$  by trace zero. The support function of  $\mathcal{K}_q$  at  $H$  is  $\lambda_1/r_q$ . The support-function criterion for convex containment proves (41). It applies to every direction, not just a finite set of tested queries.  $\square$

**Theorem B.2** (A finite-alphabet exact upper machine). *For every finite unitary command alphabet and  $0 < \rho \leq 1/10$ , the experiment on (39) has an exact machine of width  $O_q(N^{q-1})$ . For each  $N$ , all command transition matrices can be chosen independent of the epoch. Each row uses at most  $q^2$  successors. The final decoder may depend on  $N$ .*

*Proof.* Take  $h = (8qN)^{-1/2}$  and  $\eta = 1 - 1/(8N)$  in Lemma B.1. Let  $V$  be the resulting finite set of centered vectors, and put  $a_t = \eta^{-t}/4$ . A label  $i$  represents  $a_t Y(P_i)$  at epoch  $t$ . This is a proof description of a label; no matrix is stored in the register.

Since  $\rho/a_0 = 4\rho \leq 2/5 < \eta$  and  $0 \in \mathcal{K}_q$ , any seed  $\rho Y(P)$  is a convex combination of  $a_0 V$ . For each label  $i$  and each command  $U$ , the vector  $\eta U Y(P_i) U^*$  lies in  $\text{conv } V$ . Choose a convex representation and use its weights as the stochastic transition row. The choices depend on the command and label but not on  $t$ . Multiplying by  $a_{t+1}$  shows that the expected represented vector is updated by exact conjugation, since  $a_{t+1}\eta = a_t$ .

Induction gives expected vector  $\rho Y(U_w P U_w^*)$ . The terminal column for query  $j$  is  $a_N \text{tr}(F_j Y(P_i))$ . It is legal because  $|\text{tr}(F_j Y(P_i))| \leq 1$  and Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $a_N \leq 2/7$ .

Sampling a binary answer with this mean proves every conditional probability in (2) exactly. Carathéodory's theorem in real dimension  $D = q^2 - 1$  permits  $q^2$  successors. The number in (40) is  $O_q(h^{-2(q-1)}) = O_q(N^{q-1})$ .  $\square$

The upper argument uses a quadratic support loss along the projective orbit. Applying a net on the full ambient sphere would instead give the larger exponent  $(q^2 - 2)/2$ .

**B.2. Fixed finite algebraic alphabets.** For  $1 \leq j < q$  let  $R_j, D_j \in \text{SU}(q)$  act as the identity outside the adjacent coordinate pair  $(j, j+1)$  and on that pair as

$$(42) \quad R = \frac{1}{5} \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}, \quad D = \begin{pmatrix} \zeta & 0 \\ 0 & \bar{\zeta} \end{pmatrix}, \quad \zeta = \frac{3+4i}{5}.$$

The alphabet has  $4(q-1) + 1$  symbols:  $\{I, R_j^{\pm 1}, D_j^{\pm 1} : 1 \leq j < q\}$ . Assign probability  $1/2$  to  $I$  and  $1/[8(q-1)]$  to each other symbol.

**Proposition B.3** (Qualitative group expansion). *This command law has a norm gap on  $L_0^2(\text{SU}(q))$  for every fixed  $q$ . Its entries and probabilities are algebraic. No numerical gap value is asserted for this family.*

*Proof.* The number  $\zeta$  is not a root of unity:  $\zeta + \zeta^{-1} = 6/5$  is rational but not an algebraic integer. The powers of  $R_j$  and  $D_j$  therefore have closures containing two distinct one-parameter subgroups in the corresponding embedded  $\text{SU}(2)$ . Their Lie brackets generate that  $\mathfrak{su}(2)$ . The adjacent embedded Lie algebras generate  $\mathfrak{su}(q)$ : adjacent elementary off-diagonal directions produce all other off-diagonal directions by brackets, and their self-brackets produce the traceless diagonal directions. The closed generated subgroup is consequently  $\text{SU}(q)$ .

The adjoint entries are algebraic. The spectral-gap theorem of Benoist–de Saxcé [2, Theorem 1.2] applies to an adapted algebraic measure on this compact connected group with simple Lie algebra. Equivalently, one may use the algebraic unitary result of Bourgain–Gamburd [3]. The symmetric average has an upper gap; weight  $1/2$  at the identity makes its spectrum nonnegative. Its mean-zero operator norm is therefore strictly below one. This is the external full-group theorem, not a calculation in the defining  $q$ -dimensional representation.  $\square$

*Proof of Corollary 7.2.* Corollary A.3 gives the lower order, for every fixed positive calibration  $\kappa$ . Theorem B.2 gives the matching exact upper order. Proposition B.3 supplies fixed finite alphabets. The quantum assertion follows from the next proposition. Taking binary logarithms gives the label-bit formula.  $\square$

**Proposition B.4** (A fixed quantum realization). *The projective experiment has an exact quantum realization on  $\mathbb{C}^q$  using fixed seed resets, the prescribed unitary commands and fixed query measurements. It is independent of  $N$ .*

*Proof.* On seed  $P$  reset the density matrix to

$$\sigma_P = I/q + \rho Y(P) = (1 - \rho/r_q)I/q + (\rho/r_q)P.$$

This is positive and has trace one, since  $0 < \rho \leq 1/10 < r_q$ . Commands act by conjugation. For query  $j$ , use effects  $(I + F_j)/2, (I - F_j)/2$ . Hilbert–Schmidt normalization implies  $\|F_j\|_{\text{op}} \leq 1$ , so these are positive effects summing to  $I$ . Their outcome mean is  $\text{tr}(F_j \sigma_{U_w P U_w^*}) = \rho \text{tr}(F_j Y(U_w P U_w^*))$ . This is precisely (2). The seed reset is a channel, not a unitary; only one query is measured.  $\square$

The comparison is a fixed  $q$ -dimensional quantum register versus  $(q-1) \log_2 N + O(1)$  classical label bits. Dimension or entropy advantages for quantum models are prior phenomena [6, 17, 5]. The assertion here is the proved classical width order for this complete worst-word numerical behavior. It does not request jointly independent answers to all queries or optimize arbitrary adaptive experiments.

## APPENDIX C. AN EFFECTIVE SIX-COMMAND RATIONAL EXAMPLE

The preceding group-gap application is qualitative. We now choose a separate arithmetic alphabet for which a classical theorem supplies a numerical infinite-dimensional norm bound. This does not evaluate the gap of the earlier five-command example.

Let  $R_x, R_y, R_z$  be rotations about the coordinate axes with cosine  $-3/5$  and sine  $4/5$ ; explicitly,

$$(43) \quad R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -3/5 & -4/5 \\ 0 & 4/5 & -3/5 \end{pmatrix}, \quad R_y = \begin{pmatrix} -3/5 & 0 & 4/5 \\ 0 & 1 & 0 \\ -4/5 & 0 & -3/5 \end{pmatrix}, \quad R_z = \begin{pmatrix} -3/5 & -4/5 & 0 \\ 4/5 & -3/5 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Use the fixed six-letter alphabet  $\mathcal{A}_V = \{R_x^{\pm 1}, R_y^{\pm 1}, R_z^{\pm 1}\}$  and its uniform law. These are the adjoint rotations of the classical norm-five quaternions  $1 \pm 2\mathbf{i}, 1 \pm 2\mathbf{j}, 1 \pm 2\mathbf{k}$ , normalized by  $\sqrt{5}$ .

**Proposition C.1** (External arithmetic gap certificate). *For  $P_V f = (1/6) \sum_{R \in \mathcal{A}_V} f(R^{-1} \cdot)$  on  $L_0^2(\mathbb{S}^2)$ ,*

$$(44) \quad \|P_V\| \leq \frac{2\sqrt{5}}{6} = \frac{\sqrt{5}}{3}.$$

Consequently  $1 - \|P_V\|^2 \geq 4/9$ .

*Proof.* This is the  $p = 5$  specialization of the Lubotzky–Phillips–Sarnak spherical Hecke bound [10, 11]. In its unnormalized convention the  $p + 1$  norm- $p$  quaternion representatives act by a sum of rotations whose mean-zero norm is at most  $2\sqrt{p}$ . The representatives have positive odd real coordinate and even other coordinates when  $p \equiv 1 \pmod{4}$ ; at  $p = 5$  they are exactly the six displayed ones. Appendix D records the operator normalization and its source boundary. The coauthor account [12, Section 3.2, the  $V$ -gate example] spells out these representatives and their Hecke interpretation. The unnormalized spherical norm convention is also stated in [13, Theorem 3(ii)]. Dividing by six gives (44). Passing from quaternions to adjoint rotations identifies  $\mathbb{S}^2$  as the homogeneous quotient; inverse signs do not affect this symmetric average. The arithmetic bound is invoked as an external theorem, not reproved by finite harmonic tests.  $\square$

Use six seeds  $\{\pm e_j : 1 \leq j \leq 3\}$ , amplitude  $\rho = 1/10$  and three final coordinate queries in (2).

**Theorem C.2** (Numerical finite-horizon width certificate). *For  $0 \leq \varepsilon < 1/(20\sqrt{3})$  and every integer  $N \geq 1$ ,*

$$(45) \quad \frac{(1/(10\sqrt{3}) - 2\varepsilon)^4}{221184} N \leq W_{N,\varepsilon}(\mathcal{A}_V) \leq W_{N,0}(\mathcal{A}_V) < 150N.$$

*The upper machine has exact rational command and decoder rows, common command matrices, and an  $N$ -dependent decoder. At zero error every internal selected cut has separate positive minimum four, while*

$$(46) \quad W_{N,0} \geq \frac{N}{19\,906\,560\,000}.$$

*The constants are proof constants, not sharp asymptotic constants.*

*Proof.* For the standard  $\mathrm{SO}(3)$  action the orbit of every unit vector is uniform on  $\mathbb{S}^2$ . A chordal cap of radius  $r \leq 1$  has probability  $r^2/4 \leq r^2$ , so take  $D = 3, s = 2, A = 1$  in Theorem 4.5. The sphere gap transfers to  $L^2(\mathbb{R}^3)$  by polar coordinates. Thus  $B_{3,1,2} = 98304$ , and the squared gap  $4/9$  gives the lower bound in (45). At  $\varepsilon = 0$  the fourth power of  $1/(10\sqrt{3})$  is  $1/90000$ , which yields (46).

Here is an explicit cardinality estimate for the upper construction. Take both rational stereographic charts

$$t \mapsto \frac{(2t_1, 2t_2, \pm(1 - \|t\|^2))}{1 + \|t\|^2}, \quad t \in [-1, 1]^2,$$

with a grid of step  $1/M$  and  $M = \lceil 2\sqrt{2N} \rceil$ . Every hemisphere is covered by its chart on the unit disk. Each chart is 2-Lipschitz, so its grid images form a sphere net of chordal radius at most  $\sqrt{2}/M \leq 1/(2\sqrt{N})$ . Its convex hull contains  $\eta$  times the unit ball, with  $\eta = 1 - 1/(8N)$ , by the support function identity  $u \cdot v = 1 - \|u - v\|^2/2$ . There are at most  $2(2M + 1)^2 \leq (82 + 48\sqrt{2})N < 150N$  labels. Use scales  $a_t = \eta^{-t}/4$ , initialization representing  $\rho x$ , rows representing  $\eta R u$  in this hull, and decoder  $a_{Ne_j} \cdot u$ . The verification is the induction in Theorem B.2. All data are rational; each nonempty rational convex system has rational weights, with at most four successors. The final decoder is bounded by  $2/7$ .

At a selected internal cut, fix any common command prefix. The six seed images affinely span  $\mathbb{R}^3$ , so the normalized continuation rank is four; future coordinate queries still separate these dimensions after any common suffix. For an upper factorization take a regular tetrahedron containing the radius- $\rho$  ball and having circumradius  $3\rho < 1$ . Its four vectors give legal continuations under all future rotations. One embeds this selected-cut factorization in a complete machine by allowing uncapped raw histories elsewhere. Therefore the separate minimum is exactly four. This does not give a four-state machine at all cuts simultaneously.  $\square$

For example, (46) exceeds four once  $N \geq 79\,626\,240\,001$ . The size of this number illustrates the conservative constants; the benefit is that no unspecified spectral constant is needed for this alphabet.

The associated qubit operations are  $(I - 2i\sigma_j)/\sqrt{5}$  and their inverses, with seed Bloch vector  $x/10$  and final Pauli query. They realize the numerical experiment exactly, independently of  $N$ . This quantum construction and the arithmetic gates are classical; (45) is the finite-register consequence. The earlier five-gate alphabet remains qualitatively gapped with a non-evaluated constant, and is retained unchanged in the supporting material.

#### APPENDIX D. THE ARITHMETIC OPERATOR AND ITS NORMALIZATION

This appendix fixes the exact external input used in Proposition C.1, then proves the remaining representation and normalization steps. Write  $\mathbf{i}, \mathbf{j}, \mathbf{k}$  for quaternion units and

$$\mathcal{Q}_5 = \{1 \pm 2\mathbf{i}, 1 \pm 2\mathbf{j}, 1 \pm 2\mathbf{k}\}, \quad r_q(z) = qzq^{-1} \quad (z \in \text{Im } \mathbb{H}).$$

The required external LPS spherical Hecke inequality, specialized to this representative convention, is

$$(LPS5) \quad \left\| \sum_{q \in \mathcal{Q}_5} f(r_q^{-1} \cdot) \right\|_{L^2(\mathbb{S}^2)} \leq 2\sqrt{5} \|f\|_{L^2(\mathbb{S}^2)}, \quad \int f = 0.$$

This is an imported arithmetic theorem, not a finite-dimensional calculation. The original sources are [10, 11]; the unnormalized norm theorem is explicitly restated in [13, Theorem 3(ii), p. 8 of the preprint], while the quaternionic and Hecke representative conventions are discussed in [12, Section 3.2]. The restated existence theorem alone would not identify an arbitrary six rotations: the representative convention in (LPS5) is essential.

**Proposition D.1** (Parity, quotient and full spherical spectrum). *With the external input (LPS5), the uniform average over the six rotations in (43) has mean-zero norm at most  $\sqrt{5}/3$  both on  $L^2(\mathbb{S}^2)$  and on  $L^2(\text{SO}(3))$ . Its squared gap is at least  $4/9$ . The conclusion does not assert the same numerical gap for all of  $L_0^2(\text{SU}(2))$ .*

*Proof.* An integral quaternion of norm five has one coordinate of magnitude one, one of magnitude two, and two zero coordinates. There are  $4 \cdot 3 \cdot 4 = 48$  such quaternions. Multiplication by a Lipschitz unit in  $\{\pm 1, \pm \mathbf{i}, \pm \mathbf{j}, \pm \mathbf{k}\}$  places the odd coordinate in the real position and makes it positive. This gives a unique representative with positive odd real part and even other coordinates, namely one of the six members of  $\mathcal{Q}_5$ . This specifies the parity class; it is not an average over all 48 quaternions or an extra quotient by their unit group.

Normalizing  $q$  to  $q/\sqrt{5}$  does not change  $r_q$ . Quaternionic conjugation identifies the imaginary unit sphere with  $\mathrm{SO}(3)/\mathrm{SO}(2)$ , and  $q$  and  $-q$  give the same rotation. For  $(1 + 2\mathbf{i})/\sqrt{5}$  direct multiplication gives

$$\mathbf{i} \mapsto \mathbf{i}, \quad \mathbf{j} \mapsto (-3\mathbf{j} + 4\mathbf{k})/5, \quad \mathbf{k} \mapsto (-4\mathbf{j} - 3\mathbf{k})/5.$$

These are the columns of  $R_x$  in (43); cyclic permutation gives  $R_y, R_z$ . Conjugating a quaternion changes the sign of its imaginary coordinate and gives its normalized inverse. Thus the six representatives already include inverse rotations, with one copy each. Division of the sum in (LPS5) by six gives  $2\sqrt{5}/6 = \sqrt{5}/3$ , and squaring gives  $1 - 5/9 = 4/9$ .

For the full-group statement, the complexified spherical space is the orthogonal sum of the harmonic spaces  $\mathcal{H}_\ell$ ,  $\ell \geq 0$ . These are precisely all irreducible unitary representations of  $\mathrm{SO}(3)$ , one copy of each. The degree-zero space is the constants. The regular representation on  $\mathrm{SO}(3)$  contains the same irreducibles with multiplicity  $2\ell + 1$ . Convolution acts on each copy by the same matrix, so its mean-zero operator norm is the supremum of the same matrix norms on both spaces. No extra invariant subspace is removed: on the sphere the constant is the only  $\mathrm{SO}(3)$ -invariant function. The symmetric alphabet makes the inverse/right versus left convention immaterial for these norms. Half-integer-spin representations occur on  $\mathrm{SU}(2)$  but not on its  $\mathrm{SO}(3)$  quotient; this argument makes no claim about those extra blocks.  $\square$

Source boundary. The original LPS publisher records were checked, but their complete 1986/1987 page images were not obtained in this revision. We therefore do not invent an original theorem number or label the secondary restatement as an inspected original proof. Equation (LPS5) states exactly the arithmetic line required, and the proposition proves every subsequent convention change. The effective theorem retains this explicit external dependency. The main width classification is conditional on an arbitrary full gap and does not depend on this numerical example or on an original-page attribution.

# GENERAL THETA FOUNDATIONS I: ORBIT GEOMETRY AND ENTROPY BUDGETS FOR FINITE MEMORY

QIAN QI

**ABSTRACT.** We prove a finite-memory occupation theorem for orthogonal representations of compact groups. A norm gap away from invariant functions and a uniform orbital small-ball bound of exponent  $s$  force the gap-weighted number of  $k$ -state epochs to be  $O(k^{2/s})$ . The competing transducer may have arbitrary hidden states and unrelated stochastic rows at every epoch. The small-ball hypothesis is required on the directions of all possible conditional means, not only on the original orbit. For conjugation on traceless Hermitian  $q$  by  $q$  matrices we establish it uniformly over all spectra with exponent  $2(q-1)$ . A projective-net construction then gives matching  $\Theta(N^{q-1})$  classical labels for finite algebraic unitary alphabets with a full group spectral gap, at exact output and at every fixed sufficiently small wordwise error. The same numerical behavior has a fixed  $q$ -dimensional quantum realization. We also give a separate six-command rational three-dimensional example with an analytic numerical gap certificate from the classical Ramanujan bound, yielding an explicit finite-horizon lower constant. The resource is nonuniform clocked atomic-row width, not uniform computational space. Gaussian entropy identities, classical expansion and coding antecedents are distinguished from the orbital occupation and synthesis conclusions.

## 1. INTRODUCTION

A finite probabilistic device can preserve a linear statistic through a long sequence of transformations without retaining the underlying point. Consequently the dimension of the statistic does not determine the size of an exact positive realization. The distinction is particularly visible when the transformation group expands functions on its orbits. Mixing creates entropy, while replacement by finitely many conditional means removes it. An occupation inequality can compare these operations without assigning an observable vector to each hidden basis state.

The spherical form of this argument gives the order  $N^{(d-1)/2}$  under a full spherical spectral gap [20]. Two issues arise beyond the sphere. First, invariant densities need not be radial. Second, a conditional mean of orbit points need not be another orbit point. The second issue is decisive for unitary conjugation: a conditional mean of pure states usually has several nontrivial eigenvalues. Applying a pure-state cap estimate directly to these means would be invalid.

We resolve both issues through orbital averaging on the whole ambient representation and a spectral-projector estimate uniform over all traceless Hermitian directions. The resulting exponent is intrinsic to the smallest nontrivial conjugation orbit, rather than the dimension of the ambient sphere. A construction on complex projective space matches this lower exponent. Thus the theorem is not obtained by substituting  $q^2 - 1$  into a spherical formula.

**1.1. Principal statements.** Let  $G$  act orthogonally on  $V = \mathbb{R}^D$ . Write  $\Pi_G$  for Haar averaging and suppose that a finitely supported command law has squared norm gap  $g > 0$  away from  $\Pi_G$

---

*Date:* September 25, 2026. Revision 38.

*2020 Mathematics Subject Classification.* Primary 93B15, 22D10; Secondary 94A17, 68Q10, 81P45.

*Key words and phrases.* Positive realization, compact group, entropy, conditional expectation, projective space, probabilistic branching program, quantum memory.

on  $L^2(V)$ . Assume, for  $s > 0$  and  $A \geq 1$ ,

$$(1) \quad \sup_{u,v \in \mathbb{S}(V)} m_G\{a : \|au - v\| \leq r\} \leq Ar^s \quad (0 < r \leq 1).$$

The input word is universally quantified; the command law is chosen only for the lower proof. Theorem 3.5 proves

$$(2) \quad \sum_{t: K_t \leq k} g_t \leq 2048D(16A)^{2/s} \kappa^{-3-2/s} k^{2/s},$$

whenever a terminal correlation forces  $\mathbb{E}\|\mathbb{E}[Y_N | S_N]\| \geq \kappa$ . Widths at the other epochs are unrestricted. The gap may vary with time.

For  $q \geq 2$ , put  $D = q^2 - 1$  and consider the normalized pure-state orbit in  $\text{Herm}_0(q)$ , equipped with its Hilbert–Schmidt inner product. A fixed finite unitary alphabet drives this orbit. One final query asks for a coordinate of the resulting vector, with fixed amplitude  $0 < \rho \leq 1/10$ .

**Theorem 1.1** (Projective-orbit memory order). *Suppose the command alphabet supports a probability measure with a norm gap on  $L_0^2(\text{SU}(q))$ . For every fixed  $0 \leq \varepsilon < \rho/(2\sqrt{q^2 - 1})$ , the least classical width satisfies*

$$(3) \quad W_{N,\varepsilon} = \Theta_{q,\rho,\varepsilon,\mu}(N^{q-1}).$$

*The lower bound permits arbitrary hidden states, time-dependent rows and horizon-dependent design. The exact upper construction uses common command rows and an  $N$ -dependent final decoder. There are explicit finite algebraic alphabets satisfying the hypothesis for every  $q$ . The behavior has a fixed quantum realization of dimension  $q$ ; its classical label bits are  $(q - 1) \log_2 N + O(1)$ .*

The proof, including the alphabet and the fixed quantum device, is in Section 5. For  $q > 2$  the exponent  $q - 1$  differs from the ambient-sphere exponent  $(q^2 - 2)/2$ . The group-gap hypothesis here is qualitative; its existence follows from an external expansion theorem. It is not inferred merely from density of the generated subgroup.

A second application addresses effective constants. Section 6 uses the classical six  $V$ -gates, whose adjoint rotations have rational entries. The Lubotzky–Phillips–Sarnak bound gives a certified squared gap  $4/9$  on the sphere. For amplitude  $1/10$  the explicit consequence is

$$(4) \quad W_{N,\varepsilon} \geq \frac{(1/(10\sqrt{3}) - 2\varepsilon)^4}{221184} N.$$

This is a different alphabet from the earlier five-gate example, whose numerical gap is not evaluated here. The arithmetic spectral estimate is an external theorem, not a numerical truncation of spherical harmonics.

**1.2. Conventions and attribution.** All growth statements concern available persistent labels. The external epoch, the horizon, read-only row tables, their construction, arithmetic and exact atomic sampling are not charged. One query is selected after the command word; no independent joint answers are required. A finite random-bit implementation is a different resource problem.

| Ingredient                           | Role in the argument                                                                                              |
|--------------------------------------|-------------------------------------------------------------------------------------------------------------------|
| Gaussian score and conditional means | Classical identities; the one-sided quadratic entropy consequence is reproduced, not used as a priority claim.    |
| Group spectral gaps                  | External inputs, with a separate numerical Ramanujan certificate for the six-gate example.                        |
| Orbital occupation                   | The representation-level extension, using uniform small balls for all centroid directions.                        |
| Hermitian conjugation                | A uniform all-spectra estimate and matching projective synthesis give the $q - 1$ width exponent.                 |
| Quantum operations                   | Standard reset, conjugation and two-outcome measurement; the width lower bound concerns the classical competitor. |

The comparison with causal coding, Gaussian conditional-expectation entropy, state aggregation and probabilistic branching programs is made at the level of the optimized objects in Section 7. **Notation.**  $N$  is the command horizon;  $K_t$  is the available label count;  $W$  is its maximum.  $D$  is the real ambient dimension and  $s$  is the orbital small-ball exponent.  $q$  denotes quantum dimension, while  $q_t$  below denotes a conditional-centroid norm. Entropy and log use natural units;  $\log_2$  is reserved for label bits.

## 2. THE EXPERIMENT AND ITS POSITIVE REALIZATION

Let  $G$  be a compact group, let  $U : G \rightarrow O(V)$  be a continuous orthogonal representation on  $V = \mathbb{R}^D$ , and fix a finite command alphabet  $\mathcal{A} \subset G$ . A finite seed set  $\mathcal{X} \subset \mathbb{S}(V)$  is given initially. For  $w = (a_1, \dots, a_N)$  write  $U_w = U_{a_N} \cdots U_{a_1}$ . Relative to an orthonormal basis  $e_1, \dots, e_D$ , the prescribed numerical experiment is

$$(5) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho\langle e_j, U_w x \rangle}{2}, \quad b \in \{-1, 1\}, \quad j \in [D], \quad 0 < \rho \leq 1/10.$$

All seeds, words and queries are required, not only almost-sure words under one source law. The probabilities are between  $(1 - \rho)/2$  and  $(1 + \rho)/2$ .

**Definition 2.1** (Clocked atomic-row realization). A horizon- $N$  machine consists of finite sets  $\mathcal{S}_t$  with  $|\mathcal{S}_t| = K_t$ , a stochastic initialization  $E_x$  on  $\mathcal{S}_0$ , stochastic matrices  $T_{t,a} : \mathcal{S}_t \rightarrow \mathcal{S}_{t+1}$ , and columns  $d_j : \mathcal{S}_N \rightarrow [-1, 1]$ . Its mean response is

$$(6) \quad E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j.$$

It has error at most  $\varepsilon$  if this differs from  $\rho\langle e_j, U_w x \rangle$  by at most  $2\varepsilon$  for every  $(x, w, j)$ . Available labels, including padding, count. All rows, including unreachable ones, are normalized. Only the updated label persists. The seed, word prefix, old random choices and any data-dependent protocol information cannot be consulted again unless represented by that label. The external time, horizon, fixed program and exact sampling from its rows are free. The final binary answer may be sampled when  $j$  arrives; if retained, it uses a two-label final cut. Write  $W_{N,\varepsilon}$  for the minimum of  $\max(2, K_0, \dots, K_N)$ .

The state alphabets and matrices may be chosen anew for each  $N$ , but the command symbols and their experimental meanings are fixed. Nothing requires one autonomous device or one decoder to serve all stopping lengths. No adaptive choice of the command is optimized in this model. A complex unitary representation can be treated by its realification; all inner products in the entropy argument are real.

Fix one seed  $x$  and an independent command law at each epoch for the converse. Let  $Y_t = U_{a_t} \cdots U_{a_1} x$  and let  $S_t$  be the actual machine state under this test law. Define

$$(7) \quad Z_t = \mathbb{E}[Y_t \mid S_t], \quad q_t = \mathbb{E}\|Z_t\|, \quad v_t = \mathbb{E}\|Z_t\|^2.$$

These random vectors and their laws are analytical devices, not an additional runtime register or oracle.

**Lemma 2.2** (Quadratic budget and terminal calibration). *For the fresh command  $a$ , put  $X_t = U_a Z_t$ . Then*

$$(8) \quad Z_{t+1} = \mathbb{E}[X_t \mid S_{t+1}], \quad \Delta_t := \mathbb{E}\|X_t - Z_{t+1}\|^2 = v_t - v_{t+1}, \quad \sum_{t < N} \Delta_t \leq 1.$$

*The sequences  $q_t, v_t$  are nonincreasing and start at one. A machine with error at most  $\varepsilon$  satisfies*

$$(9) \quad q_t \geq q_N \geq \kappa := \rho/\sqrt{D} - 2\varepsilon \quad (0 \leq t \leq N).$$

*Proof.* The current command is independent of the past, and the new label is generated from  $(S_t, a)$  by a common row. Conditioning first on  $(S_t, a, S_{t+1})$  and then on  $S_{t+1}$  proves the first identity. The orthogonal projection identity for conditional expectation gives the second; Jensen and orthogonality give both monotonicities. The fixed seed has unit norm, even with randomized initialization. For calibration form  $d = (d_1, \dots, d_D)$  only in the proof, so  $\|d\| \leq \sqrt{D}$ . Conditioning on the complete word and using (5)–(6) gives  $\mathbb{E}\langle Y_N, d(S_N) \rangle \geq \rho - 2\sqrt{D}\varepsilon$ . On conditioning instead on  $S_N$ , this is at most  $\sqrt{D}q_N$ . This proves (9). It does not require a joint measurement of the  $D$  coordinates.  $\square$

For each fixed profile, the optimum actual error is attained: all stochastic rows and terminal columns form a finite product of compact sets and the objective is a maximum of finitely many continuous functions. Thus the subsequent lower bounds concern the actual optimization, not a sum of local error certificates.

### 3. AN ORBITAL ENTROPY OCCUPATION THEOREM

Lebesgue measure is used on  $V = \mathbb{R}^D$  and normalized Haar measure on  $G$ . For a function on  $V$ , set

$$(10) \quad \mathcal{U}_a f(z) = f(U_a^{-1}z), \quad P_t = \sum_a p_t(a) \mathcal{U}_a, \quad \Pi f(z) = \int_G f(U_g^{-1}z) dm_G(g).$$

Thus  $\mathcal{U}_a^* = \mathcal{U}_{a^{-1}}$ ,  $\Pi$  is an orthogonal projection, and  $P_t \Pi = \Pi P_t = \Pi$ . The probability law  $p_t$  need not be symmetric. Its required squared norm gap is

$$(11) \quad \|P_t f\|_2^2 \leq \|\Pi f\|_2^2 + (1 - g_t) \|f - \Pi f\|_2^2, \quad 0 \leq g_t \leq 1.$$

Invariance in this formula means  $G$ -invariance, not necessarily radial symmetry. In a reducible representation invariant functions can carry many parameters.

**Lemma 3.1** (Transfer of a group norm gap). *If right convolution  $R_{p_t} F(g) = \sum_a p_t(a) F(ga)$  on  $L^2(G)$  has mean-zero norm at most  $\sqrt{1 - g_t}$ , then (11) holds in every orthogonal representation on  $V$ .*

*Proof.* For each  $z$  apply the group inequality to  $F_z(g) = f(U_g^{-1}z)$ . Its mean is  $\Pi f(z)$  and  $R_{p_t} F_z(g) = P_t f(U_g^{-1}z)$ . Integrate the resulting inequality in  $z$ . Orthogonal changes of variables and Fubini identify the three integrals with those in (11). First take bounded compactly supported  $f$  and then use density. This proof does not replace the full group gap by a gap in the defining representation.  $\square$

**3.1. The conditional-mean cost.** Let  $G_D$  be a standard independent real Gaussian vector and let  $\gamma_\tau$  be the density of  $\tau G_D$ .

**Lemma 3.2** (A one-sided Gaussian coupling inequality). *For bounded  $X$  and a finite-valued variable  $J$ , put  $M = \mathbb{E}[X \mid J]$ . For every  $\tau > 0$ ,*

$$(12) \quad \mathbf{h}(X + \tau G_D) - \mathbf{h}(M + \tau G_D) \leq \frac{\mathbb{E}\|X - M\|^2}{2\tau^2}.$$

*Proof.* Write  $f = \text{Law}(M) * \gamma_\tau$ . Differentiation of the Gaussian mixture and the conditional covariance identity give

$$(13) \quad \nabla^2 \log f(y) = -\tau^{-2}I + \tau^{-4} \text{Cov}(M \mid M + \tau G_D = y) \succeq -\tau^{-2}I.$$

Hence  $\phi(x) = -\mathbb{E} \log f(x + \tau G_D)$  has Hessian at most  $\tau^{-2}I$ . Taylor's inequality at  $M$  yields  $\phi(X) \leq \phi(M) + \langle \nabla \phi(M), X - M \rangle + \|X - M\|^2 / (2\tau^2)$ . The conditional expectation of the linear term given  $J$  is zero. If  $g = \text{Law}(X) * \gamma_\tau$ , nonnegativity of  $D(g \parallel f)$  gives  $\mathbf{h}(g) \leq -\int g \log f = \mathbb{E}\phi(X)$ , whereas  $\mathbb{E}\phi(M) = \mathbf{h}(f)$ . Boundedness of  $X, M$  provides Gaussian bounds with finite second moments and justifies differentiation and integration. These identities prove (12).  $\square$

This elementary consequence of Gaussian posterior identities is used as an estimate, not as a claim of priority over the Gaussian estimation literature [1, 14]. The estimate is one-sided and can have a negative left side. Here  $J$  can be a finite register with no Gaussian observation model; the smoothing noise is added after conditioning.

**Lemma 3.3** (Entropy production away from invariant functions). *For any bounded-support Gaussian mixture density  $f$ ,*

$$(14) \quad \mathbf{h}(P_t f) - \mathbf{h}(f) \geq g_t \|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq 0.$$

*Proof.* Put  $f_a = \mathcal{U}_a f$  and  $h = P_t f$ . Orthogonality preserves entropy, so  $\mathbf{h}(h) - \mathbf{h}(f) = \sum_a p_t(a) D(f_a \parallel h)$ . For probability densities  $u, v$ ,  $D(u \parallel v) \geq \|\sqrt{u} - \sqrt{v}\|_2^2$ ; it follows, for example, from  $-\log x \geq 2(1 - \sqrt{x})$  and integration. The mean is the least-squares minimizer, and thus

$$\sum_a p_t(a) \|\sqrt{f_a} - \sqrt{h}\|_2^2 \geq \sum_a p_t(a) \|\sqrt{f_a} - P_t \sqrt{f}\|_2^2 = 1 - \|P_t \sqrt{f}\|_2^2.$$

Apply (11) and  $\|\sqrt{f}\|_2 = 1$ .  $\square$

No logarithmic Sobolev inequality or point-mass mixing assertion is used in this step.

**3.2. Sparsity away from invariant densities.** Suppose that the representation obeys the uniform orbital bound

$$(15) \quad m_G\{g : \|U_g u - v\| \leq r\} \leq A r^s \quad (u, v \in \mathbb{S}(V), 0 < r \leq 1),$$

where  $A \geq 1$  and  $s > 0$ . In particular the representation has no nonzero fixed vector. It is essential that  $u$  range over all possible centroid directions, not merely the initial seed orbit.

**Lemma 3.4** (Finite centroids cannot be almost invariant). *Suppose  $Z$  has at most  $k$  values in the unit ball and  $\mathbb{E}\|Z\| \geq \kappa$ , where  $0 < \kappa \leq 1$ . Set*

$$(16) \quad r = \left( \frac{\kappa}{16Ak} \right)^{1/s}, \quad \tau = \frac{\kappa r}{8\sqrt{2D}}, \quad f = \text{Law}(Z) * \gamma_\tau.$$

*Then  $\|\sqrt{f} - \Pi \sqrt{f}\|_2^2 \geq \kappa/16$ .*

*Proof.* Atoms of norm at least  $\kappa/2$  have total mass at least  $\kappa/2$ . Let  $\Omega$  be the union of radius- $r$  caps around their directions, and let  $C_\Omega$  be its cone. By Markov's inequality,  $\mathbb{P}(\|G_D\| \leq \sqrt{2D}) \geq 1/2$ . On this event, perturbing a high-norm atom by  $\tau G_D$  changes its direction by at most  $4\tau\sqrt{2D}/\kappa = r/2$ . Therefore  $\int_{C_\Omega} f \geq \kappa/4$ .

For any  $G$ -invariant  $u \in L^2(V)$ , Haar averaging and (15) give

$$\int_{C_\Omega} |u(z)|^2 dz = \int |u(z)|^2 \int_G \mathbf{1}_{C_\Omega}(U_g z) dm_G(g) dz \leq k A r^s \|u\|_2^2.$$

The point  $z = 0$  is Lebesgue-null. Taking  $u = \Pi\sqrt{f}$ , whose norm is at most one, bounds this integral by  $\kappa/16$ . The reverse triangle inequality in  $L^2(C_\Omega)$  now gives a norm difference at least  $\sqrt{\kappa/4} - \sqrt{\kappa/16} = \sqrt{\kappa}/4$ . Repeated directions and zero centroids cause no change.  $\square$

**Theorem 3.5** (Orbital occupation budget). *Under (11) and (15), let a finite hidden register track a unit-vector command process as in (7). If  $q_N \geq \kappa > 0$ , then, for every  $k \geq 1$ ,*

$$(17) \quad \sum_{\substack{0 \leq t < N \\ \bar{K}_t \leq k}} g_t \leq B_{D,A,s} \kappa^{-3-2/s} k^{2/s}, \quad B_{D,A,s} = 2048 D (16A)^{2/s}.$$

*The same inequality holds with  $K_t$  replaced by the number of positive-probability labels under the chosen test law. No bound is imposed on the other epochs.*

*Proof.* Fix  $k$  and the single scale (16) for the entire run. Write  $f_t = \text{Law}(Z_t) * \gamma_\tau$ . Isotropy of the Gaussian makes the density of  $U_a Z_t + \tau G_D$  equal to  $P_t f_t$ . By Lemmas 3.2 and 3.3,

$$\mathbf{h}(f_{t+1}) - \mathbf{h}(f_t) \geq g_t \|\sqrt{f_t} - \Pi\sqrt{f_t}\|_2^2 - \frac{\Delta_t}{2\tau^2}.$$

At an epoch with at most  $k$  labels, Lemma 3.4 bounds the norm term below by  $\kappa/16$ . Elsewhere it is nonnegative. The initial density is a translate of  $\gamma_\tau$ ; the terminal second moment is at most  $1 + D\tau^2$ . The Gaussian maximum-entropy bound and (8) yield

$$\frac{\kappa}{16} \sum_{K_t \leq k} g_t \leq \frac{D}{2} \log \left( 1 + \frac{1}{D\tau^2} \right) + \frac{1}{2\tau^2} \leq \frac{1}{\tau^2}.$$

Substitute (16). The same Gaussian scale is retained through all epochs; no repeated mixing-time charge is incurred.  $\square$

**Corollary 3.6** (Actual terminal error). *For a constant gap  $g > 0$ , let  $\mathcal{E}_N(\mathbf{K})$  be the minimum actual wordwise binary-TV error over a prescribed available profile, and put  $K = \max_t K_t$ . Then*

$$(18) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{D}} - \left( \frac{B_{D,A,s} K^{2/s}}{gN} \right)^{1/(3+2/s)} \right]_+.$$

*In particular,  $K = o(N^{s/2})$  implies  $\liminf \mathcal{E}_N \geq \rho/(2\sqrt{D})$ .*

*Proof.* If the actual error is below the calibration threshold, combine (9) with (17) and solve for it. Otherwise the displayed lower bound already holds. Attainment or a minimizing sequence gives the same conclusion for the optimum.  $\square$

Local simulation errors may cancel. Nothing in this corollary sums such errors or rules out cancellation; its objective is the actual final law.

## 4. UNIFORM GEOMETRY OF HERMITIAN CONJUGATION

Fix  $q \geq 2$  and let  $V = \text{Herm}_0(q)$  be the real space of traceless Hermitian  $q$  by  $q$  matrices, with inner product  $\text{tr}(AB)$ . Its dimension is  $D = q^2 - 1$ . Unitary conjugation is orthogonal on this space. The pure-state orbit has dimension  $2(q-1)$ , but normalized hidden centroids can have arbitrary spectra. We therefore prove a bound on *every* unit sphere orbit.

**4.1. A Grassmann small-ball estimate.** Let  $P_0$  be a rank- $k$  orthogonal projector in  $\mathbb{C}^q$ ,  $1 \leq k < q$ , and let  $P$  be a Haar-distributed rank- $k$  projector. Put  $m = k(q-k)$  and

$$(19) \quad b_{q,k} = \frac{1}{m!} \prod_{j=1}^k \frac{\Gamma(q-k+j)}{\Gamma(j)}.$$

**Lemma 4.1** (Projector balls). *For  $0 < R \leq 1$ ,*

$$(20) \quad \mathbb{P}(\|P - P_0\|_{\text{HS}} \leq R) \leq b_{q,k} R^{2k(q-k)}.$$

*Proof.* By invariance take  $P_0$  onto the first  $k$  coordinates. Apart from a null set, a Haar subspace is the graph of  $Z \in \mathbb{C}^{(q-k) \times k}$ . Its density with respect to complex Euclidean Lebesgue measure is

$$(21) \quad \pi^{-m} \prod_{j=1}^k \frac{\Gamma(q-k+j)}{\Gamma(j)} \det(I + Z^*Z)^{-q}.$$

For completeness, take a  $q$  by  $k$  matrix of independent standard complex Gaussian entries and split it into a square top block  $A$  and bottom block  $B$ . Its column space is Haar and  $Z = BA^{-1}$  almost surely. The change  $B = ZA$  has real Jacobian  $|\det A|^{2(q-k)}$ . Integrating  $A$  with weight  $\exp[-\text{tr} A^*(I + Z^*Z)A]$  gives the determinant factor  $\det(I + Z^*Z)^{-q}$ . Complex Gaussian Gram-Schmidt gives  $\mathbb{E}|\det A|^{2(q-k)} = \prod_{j=1}^k \Gamma(q-k+j)/\Gamma(j)$ , since its squared orthogonal lengths have gamma shapes  $1, \dots, k$ . The powers of  $\pi$  give (21).

If  $\theta_i$  are the principal angles, then  $\|P - P_0\|_{\text{HS}}^2 = 2 \sum_i \sin^2 \theta_i$  and  $\|Z\|_{\text{HS}}^2 = \sum_i \tan^2 \theta_i$ . On the event in (20) each  $\sin^2 \theta_i \leq R^2/2$ , whence

$$\|Z\|_{\text{HS}}^2 \leq \frac{R^2}{2 - R^2} \leq R^2.$$

The density (21) is bounded by its value at zero. Multiply this value by the volume  $\pi^m R^{2m}/m!$  of a real  $2m$ -dimensional ball. This proves the assertion.  $\square$

Define the explicit finite constant

$$(22) \quad A_q = \max_{1 \leq k < q} \left\{ \max(1, b_{q,k}) [9q(q-1)^2]^{k(q-k)} \right\}.$$

It is rational and at least one; no optimality is claimed.

**Theorem 4.2** (All-spectra orbital anti-concentration). *For all  $A, B \in \text{Herm}_0(q)$  of Hilbert-Schmidt norm one and all  $0 < r \leq 1$ ,*

$$(23) \quad m_{\text{SU}(q)} \{U : \|UAU^* - B\|_{\text{HS}} \leq r\} \leq A_q r^{2(q-1)}.$$

*In particular, the estimate is uniform at repeated eigenvalues and over mixed-state centroid directions. No lower bound on each eigenvalue gap is assumed.*

*Proof.* Let  $\lambda_1 \geq \dots \geq \lambda_q$  be the eigenvalues of  $A$ . Trace zero and  $\sum_i \lambda_i^2 = 1$  imply  $\lambda_1 - \lambda_q \geq q^{-1/2}$ . Hence some  $k$  has

$$(24) \quad \lambda_k - \lambda_{k+1} \geq \delta_q := \frac{1}{\sqrt{q}(q-1)}.$$

For two conjugates  $C, D$  of  $A$ , let  $P_C, P_D$  be their top- $k$  spectral projectors. Eigenvectors  $u_i$  of  $C$  and  $v_j$  of  $D$  obey

$$(\lambda_i - \lambda_j)\langle u_i, v_j \rangle = \langle u_i, (C - D)v_j \rangle.$$

Summing squares for  $i \leq k < j$  and using equal projector ranks gives

$$(25) \quad \|P_C - P_D\|_{\text{HS}}^2 = 2 \sum_{i \leq k < j} |\langle u_i, v_j \rangle|^2 \leq 2\delta_q^{-2} \|C - D\|_{\text{HS}}^2.$$

If the event in (23) is empty there is nothing to prove. Otherwise choose one conjugate  $D$  in that event. Every other  $C$  in the event has  $\|C - D\|_{\text{HS}} \leq 2r$ . The image  $P_C$  is a Haar rank- $k$  projector and lies within  $2\sqrt{2}\delta_q^{-1}r$  of  $P_D$ . Set  $c_q = 3\sqrt{q}(q-1)$ , which is larger than this coefficient. If  $c_q r \leq 1$ , Lemma 4.1 gives a bound  $b_{q,k}(c_q r)^{2k(q-k)}$ . Since  $k(q-k) \geq q-1$  and  $r \leq 1$ , this is at most the right side of (23). If  $c_q r > 1$ , then  $A_q r^{2(q-1)} \geq c_q^{2(q-1)} r^{2(q-1)} > 1$ , so the trivial probability bound suffices. Haar conjugation under  $\text{SU}(q)$  and under  $U(q)$  has the same law, completing the proof.  $\square$

The proof isolates one uniformly separated spectral cut rather than requiring a simple spectrum. This is why pure-state and highly mixed centroids are handled by the same constant. The smallest possible nontrivial Grassmann exponent is  $2(q-1)$ .

**Corollary 4.3** (Conjugation occupation). *For conjugation commands satisfying a group gap  $g_t$ , any hidden register with  $q_N \geq \kappa > 0$  obeys*

$$(26) \quad \sum_{K_t \leq k} g_t \leq C_q \kappa^{-3-1/(q-1)} k^{1/(q-1)}, \quad C_q = 2048(q^2 - 1)(16A_q)^{1/(q-1)}.$$

For a constant gap  $g > 0$  and wordwise error  $\varepsilon$  with  $\kappa = \rho/\sqrt{q^2 - 1} - 2\varepsilon > 0$ ,

$$(27) \quad W_{N,\varepsilon} \geq \left( \frac{g\kappa^{3+1/(q-1)}}{C_q} N \right)^{q-1}.$$

*Proof.* Apply Lemma 3.1, Theorem 4.2 and Theorem 3.5, then use Lemma 2.2.  $\square$

A group gap is stronger than a gap only on functions on the pure-state homogeneous quotient. The proof genuinely needs uniform control of the mixed-centroid directions, and does not silently replace this hypothesis by the weaker quotient gap.

## 5. SHARP MEMORY ON COMPLEX PROJECTIVE ORBITS

Write  $r_q = \sqrt{1 - 1/q}$  and associate to a rank-one orthogonal projector  $P$  the unit vector

$$(28) \quad Y(P) = \frac{P - I/q}{r_q} \in \text{Herm}_0(q), \quad \mathcal{K}_q = \text{conv}\{Y(P) : \text{rank } P = 1\}.$$

The body  $\mathcal{K}_q$  consists of normalized centered density matrices. It is invariant under conjugation and contains zero. Its extreme orbit is  $\mathbb{CP}^{q-1}$ . Fix an orthonormal real basis  $F_1, \dots, F_D$  of  $\text{Herm}_0(q)$  and use its coordinate queries in (5). One may take as seeds the  $q^2$  rank-one projectors onto  $e_i$ ,  $(e_i + e_j)/\sqrt{2}$  and  $(e_i + ie_j)/\sqrt{2}$ ,  $i < j$ . Their centered matrices affinely span  $\text{Herm}_0(q)$ . All seed and query alphabets are fixed when  $q$  is fixed.

**5.1. A projective enclosure with quadratic loss.** For rank-one projectors use the distance  $d(P, Q) = \sqrt{1 - \text{tr}(PQ)}$ , the sine of their principal angle.

**Lemma 5.1** (Finite projective synthesis). *For  $0 < h \leq 1$ , there is an  $h$ -net  $\mathcal{V}_h$  of rank-one projectors with at most*

$$(29) \quad q(2\lceil 2\sqrt{2(q-1)/h} \rceil + 1)^{2(q-1)}$$

*elements, and the entries of all these projectors can be chosen in  $\mathbb{Q} + i\mathbb{Q}$ . If  $qh^2 < 1$ , then*

$$(30) \quad (1 - qh^2)\mathcal{K}_q \subseteq \text{conv}\{Y(P) : P \in \mathcal{V}_h\} \subseteq \mathcal{K}_q.$$

*Proof.* Every complex line has a representative with a largest coordinate scaled to one and the real and imaginary parts of all other coordinates in  $[-1, 1]$ . In each of the  $q$  charts round these  $2(q-1)$  real coordinates to the grid of step  $1/M$ , where  $M = \lceil 2\sqrt{2(q-1)/h} \rceil$ . If  $v, w$  are the original and rounded representatives, their norms are at least one and  $\|v - w\| \leq \sqrt{2(q-1)}/(2M)$ . Normalization changes their distance by at most a factor two, and the sine distance is at most the distance of these normalized representatives. Thus the stated set is an  $h$ -net. The projector  $w w^* / \|w\|^2$  has rational real and imaginary entries, and the grid count is (29).

For a nonzero traceless Hermitian  $H$ , let  $\lambda_1$  and  $\lambda_q$  be its largest and smallest eigenvalues. A net projector within  $h$  of a top eigenline satisfies

$$\text{tr}(HP) \geq \lambda_1 - (\lambda_1 - \lambda_q)h^2 \geq (1 - qh^2)\lambda_1.$$

Indeed  $-\lambda_q \leq (q-1)\lambda_1$  by trace zero. The support function of  $\mathcal{K}_q$  at  $H$  is  $\lambda_1/r_q$ . The support-function criterion for convex containment proves (30). It applies to every direction, not just a finite set of tested queries.  $\square$

**Theorem 5.2** (A finite-alphabet exact upper machine). *For every finite unitary command alphabet and  $0 < \rho \leq 1/10$ , the experiment on (28) has an exact machine of width  $O_q(N^{q-1})$ . For each  $N$ , all command transition matrices can be chosen independent of the epoch. Each row uses at most  $q^2$  successors. The final decoder may depend on  $N$ .*

*Proof.* Take  $h = (8qN)^{-1/2}$  and  $\eta = 1 - 1/(8N)$  in Lemma 5.1. Let  $V$  be the resulting finite set of centered vectors, and put  $a_t = \eta^{-t}/4$ . A label  $i$  represents  $a_t Y(P_i)$  at epoch  $t$ . This is a proof description of a label; no matrix is stored in the register.

Since  $\rho/a_0 = 4\rho \leq 2/5 < \eta$  and  $0 \in \mathcal{K}_q$ , any seed  $\rho Y(P)$  is a convex combination of  $a_0 V$ . For each label  $i$  and each command  $U$ , the vector  $\eta U Y(P_i) U^*$  lies in  $\text{conv } V$ . Choose a convex representation and use its weights as the stochastic transition row. The choices depend on the command and label but not on  $t$ . Multiplying by  $a_{t+1}$  shows that the expected represented vector is updated by exact conjugation, since  $a_{t+1}\eta = a_t$ .

Induction gives expected vector  $\rho Y(U_w P U_w^*)$ . The terminal column for query  $j$  is  $a_N \text{tr}(F_j Y(P_i))$ . It is legal because  $|\text{tr}(F_j Y(P_i))| \leq 1$  and Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $a_N \leq 2/7$ . Sampling a binary answer with this mean proves every conditional probability in (5) exactly. Carathéodory's theorem in real dimension  $D = q^2 - 1$  permits  $q^2$  successors. The number in (29) is  $O_q(h^{-2(q-1)}) = O_q(N^{q-1})$ .  $\square$

The upper argument uses a quadratic support loss along the projective orbit. Applying a net on the full ambient sphere would instead give the larger exponent  $(q^2 - 2)/2$ .

**5.2. Fixed finite algebraic alphabets.** For  $1 \leq j < q$  let  $R_j, D_j \in \text{SU}(q)$  act as the identity outside the adjacent coordinate pair  $(j, j+1)$  and on that pair as

$$(31) \quad R = \frac{1}{5} \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}, \quad D = \begin{pmatrix} \zeta & 0 \\ 0 & \bar{\zeta} \end{pmatrix}, \quad \zeta = \frac{3 + 4i}{5}.$$

The alphabet has  $4(q-1) + 1$  symbols:  $\{I, R_j^{\pm 1}, D_j^{\pm 1} : 1 \leq j < q\}$ . Assign probability  $1/2$  to  $I$  and  $1/[8(q-1)]$  to each other symbol.

**Proposition 5.3** (Qualitative group expansion). *This command law has a norm gap on  $L_0^2(\text{SU}(q))$  for every fixed  $q$ . Its entries and probabilities are algebraic. No numerical gap value is asserted for this family.*

*Proof.* The number  $\zeta$  is not a root of unity:  $\zeta + \zeta^{-1} = 6/5$  is rational but not an algebraic integer. The powers of  $R_j$  and  $D_j$  therefore have closures containing two distinct one-parameter subgroups in the corresponding embedded  $\text{SU}(2)$ . Their Lie brackets generate that  $\mathfrak{su}(2)$ . The adjacent embedded Lie algebras generate  $\mathfrak{su}(q)$ : adjacent elementary off-diagonal directions produce all other off-diagonal directions by brackets, and their self-brackets produce the traceless diagonal directions. The closed generated subgroup is consequently  $\text{SU}(q)$ .

The adjoint entries are algebraic. The spectral-gap theorem of Benoist–de Saxcé [2, Theorem 1.2] applies to an adapted algebraic measure on this compact connected group with simple Lie algebra. Equivalently, one may use the algebraic unitary result of Bourgain–Gamburd [3]. The symmetric average has an upper gap; weight  $1/2$  at the identity makes its spectrum nonnegative. Its mean-zero operator norm is therefore strictly below one. This is the external full-group theorem, not a calculation in the defining  $q$ -dimensional representation.  $\square$

*Proof of Theorem 1.1.* Corollary 4.3 gives the lower order, for every fixed positive calibration  $\kappa$ . Theorem 5.2 gives the matching exact upper order. Proposition 5.3 supplies fixed finite alphabets. The quantum assertion follows from the next proposition. Taking binary logarithms gives the label-bit formula.  $\square$

**Proposition 5.4** (A fixed quantum realization). *The projective experiment has an exact quantum realization on  $\mathbb{C}^q$  using fixed seed resets, the prescribed unitary commands and fixed query measurements. It is independent of  $N$ .*

*Proof.* On seed  $P$  reset the density matrix to

$$\sigma_P = I/q + \rho Y(P) = (1 - \rho/r_q)I/q + (\rho/r_q)P.$$

This is positive and has trace one, since  $0 < \rho \leq 1/10 < r_q$ . Commands act by conjugation. For query  $j$ , use effects  $(I + F_j)/2, (I - F_j)/2$ . Hilbert–Schmidt normalization implies  $\|F_j\|_{\text{op}} \leq 1$ , so these are positive effects summing to  $I$ . Their outcome mean is  $\text{tr}(F_j \sigma_{U_w P U_w^*}) = \rho \text{tr}(F_j Y(U_w P U_w^*))$ . This is precisely (5). The seed reset is a channel, not a unitary; only one query is measured.  $\square$

The comparison is a fixed  $q$ -dimensional quantum register versus  $(q-1) \log_2 N + O(1)$  classical label bits. Dimension or entropy advantages for quantum models are prior phenomena [6, 17, 5]. The assertion here is the proved classical width order for this complete worst-word numerical behavior. It does not request jointly independent answers to all queries or optimize arbitrary adaptive experiments.

## 6. AN EFFECTIVE SIX-COMMAND RATIONAL EXAMPLE

The preceding group-gap application is qualitative. We now choose a separate arithmetic alphabet for which a classical theorem supplies a numerical infinite-dimensional norm bound. This does not evaluate the gap of the earlier five-command example.

Let  $R_x, R_y, R_z$  be rotations about the coordinate axes with cosine  $-3/5$  and sine  $4/5$ ; explicitly,

$$(32) \quad R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -3/5 & -4/5 \\ 0 & 4/5 & -3/5 \end{pmatrix}, \quad R_y = \begin{pmatrix} -3/5 & 0 & 4/5 \\ 0 & 1 & 0 \\ -4/5 & 0 & -3/5 \end{pmatrix}, \quad R_z = \begin{pmatrix} -3/5 & -4/5 & 0 \\ 4/5 & -3/5 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Use the fixed six-letter alphabet  $\mathcal{A}_V = \{R_x^{\pm 1}, R_y^{\pm 1}, R_z^{\pm 1}\}$  and its uniform law. These are the adjoint rotations of the classical norm-five quaternions  $1 \pm 2\mathbf{i}$ ,  $1 \pm 2\mathbf{j}$ ,  $1 \pm 2\mathbf{k}$ , normalized by  $\sqrt{5}$ .

**Proposition 6.1** (External arithmetic gap certificate). *For  $P_V f = (1/6) \sum_{R \in \mathcal{A}_V} f(R^{-1} \cdot)$  on  $L_0^2(\mathbb{S}^2)$ ,*

$$(33) \quad \|P_V\| \leq \frac{2\sqrt{5}}{6} = \frac{\sqrt{5}}{3}.$$

Consequently  $1 - \|P_V\|^2 \geq 4/9$ .

*Proof.* This is the  $p = 5$  specialization of the Lubotzky–Phillips–Sarnak spherical Hecke bound [10, 11]. In its unnormalized convention the  $p + 1$  norm- $p$  quaternion representatives act by a sum of rotations whose mean-zero norm is at most  $2\sqrt{p}$ . The representatives have positive odd real coordinate and even other coordinates when  $p \equiv 1 \pmod{4}$ ; at  $p = 5$  they are exactly the six displayed ones. The coauthor account [12, Section 3.2, the  $V$ -gate example] spells out these representatives and their Hecke interpretation. The unnormalized spherical norm convention is also stated in [13, Theorem 3(ii)]. Dividing by six gives (33). Passing from quaternions to adjoint rotations identifies  $\mathbb{S}^2$  as the homogeneous quotient; inverse signs do not affect this symmetric average. The arithmetic bound is invoked as an external theorem, not reproved by finite harmonic tests.  $\square$

Use six seeds  $\{\pm e_j : 1 \leq j \leq 3\}$ , amplitude  $\rho = 1/10$  and three final coordinate queries in (5).

**Theorem 6.2** (Numerical finite-horizon width certificate). *For  $0 \leq \varepsilon < 1/(20\sqrt{3})$  and every integer  $N \geq 1$ ,*

$$(34) \quad \frac{(1/(10\sqrt{3}) - 2\varepsilon)^4}{221184} N \leq W_{N,\varepsilon}(\mathcal{A}_V) \leq W_{N,0}(\mathcal{A}_V) < 150N.$$

*The upper machine has exact rational command and decoder rows, common command matrices, and an  $N$ -dependent decoder. At zero error every internal selected cut has separate positive minimum four, while*

$$(35) \quad W_{N,0} \geq \frac{N}{19\,906\,560\,000}.$$

*The constants are proof constants, not sharp asymptotic constants.*

*Proof.* For the standard  $\text{SO}(3)$  action the orbit of every unit vector is uniform on  $\mathbb{S}^2$ . A chordal cap of radius  $r \leq 1$  has probability  $r^2/4 \leq r^2$ , so take  $D = 3, s = 2, A = 1$  in Theorem 3.5. The sphere gap transfers to  $L^2(\mathbb{R}^3)$  by polar coordinates. Thus  $B_{3,1,2} = 98304$ , and the squared gap  $4/9$  gives the lower bound in (34). At  $\varepsilon = 0$  the fourth power of  $1/(10\sqrt{3})$  is  $1/90000$ , which yields (35).

Here is an explicit cardinality estimate for the upper construction. Take both rational stereographic charts

$$t \mapsto \frac{(2t_1, 2t_2, \pm(1 - \|t\|^2))}{1 + \|t\|^2}, \quad t \in [-1, 1]^2,$$

with a grid of step  $1/M$  and  $M = \lceil 2\sqrt{2N} \rceil$ . Every hemisphere is covered by its chart on the unit disk. Each chart is 2-Lipschitz, so its grid images form a sphere net of chordal radius at most  $\sqrt{2}/M \leq 1/(2\sqrt{N})$ . Its convex hull contains  $\eta$  times the unit ball, with  $\eta = 1 - 1/(8N)$ , by the support function identity  $u \cdot v = 1 - \|u - v\|^2/2$ . There are at most  $2(2M + 1)^2 \leq (82 + 48\sqrt{2})N < 150N$  labels. Use scales  $a_t = \eta^{-t}/4$ , initialization representing  $\rho x$ , rows representing  $\eta R u$  in this hull, and decoder  $a_N e_j \cdot u$ . The verification is the induction in Theorem 5.2. All data are rational; each nonempty rational convex system has rational weights, with at most four successors. The final decoder is bounded by  $2/7$ .

At a selected internal cut, fix any common command prefix. The six seed images affinely span  $\mathbb{R}^3$ , so the normalized continuation rank is four; future coordinate queries still separate these dimensions after any common suffix. For an upper factorization take a regular tetrahedron containing the radius- $\rho$  ball and having circumradius  $3\rho < 1$ . Its four vectors give legal continuations under all future rotations. One embeds this selected-cut factorization in a complete machine by allowing uncapped raw histories elsewhere. Therefore the separate minimum is exactly four. This does not give a four-state machine at all cuts simultaneously.  $\square$

For example, (35) exceeds four once  $N \geq 79\,626\,240\,001$ . The size of this number illustrates the conservative constants; the benefit is that no unspecified spectral constant is needed for this alphabet.

The associated qubit operations are  $(I - 2i\sigma_j)/\sqrt{5}$  and their inverses, with seed Bloch vector  $x/10$  and final Pauli query. They realize the numerical experiment exactly, independently of  $N$ . This quantum construction and the arithmetic gates are classical; (34) is the finite-register consequence. The earlier five-gate alphabet remains qualitatively gapped with a non-evaluated constant, and is retained unchanged in the supporting material.

## 7. OPERATIONAL AND THEOREM-LEVEL COMPARISONS

The comparisons below fix the minimized object before comparing results. They do not use a change of terminology as evidence of originality.

### 7.1. Ordered randomized programs.

**Proposition 7.1** (The layered-program interpretation). *For a fixed command alphabet, Definition 2.1 is equivalent to a nonuniform probabilistic ordered read-once layered program with cut-dependent widths and real terminal columns. For one selected column, randomized Boolean acceptance has probability  $(1 + m)/2$ , where  $m$  is the column's mean, without changing any command-layer width. A separate charged terminal layer needs at most two labels. Maximum width is not total program size, and neither measure prices the row descriptions.*

*Proof.* At layer  $t$ , the outgoing edge weights labelled by command  $a$  are exactly the row  $T_{t,a}(s, \cdot)$ . Summing path probabilities gives (6). Conversely the edge weights of a probabilistic layered program form those stochastic matrices. At the terminal label  $s$ , toss a Bernoulli coin of parameter  $(1 + d_j(s))/2$ . This implements Boolean acceptance with the claimed probability. Choosing a query selects one column; it does not request independent outcomes for all columns. Padding a layer by unreachable labels and assigning normalized unused rows proves the same assertion for varying widths.  $\square$

The equivalence permits arbitrary real edge probabilities and externally known layers. The Fourier-growth results for regular and width-three branching programs [15, 16, 9] have different structural assumptions and objectives. Here the external group average has a gap; the hidden transition matrices need not be regular or have a gap. In particular, a stochastic reset matrix is permitted. The all-spectra occupation inequality is a lower bound for the specified matrix-coefficient response, not a pseudorandom generator or a general lower bound for Boolean OBDDs.

**7.2. Zero-delay coding and state aggregation.** The structural coding results of Witsenhausen and Walrand–Varaiya, as formulated in [19, Theorems 1–2], reduce a Markov-source encoder to the current source and a posterior based on past transmitted messages. Wood–Linder–Yüksel prove stationary optimality and periodic finite-memory approximation for average distortion [19, Theorems 3–4]. A posterior is generally a point of a continuous simplex, not a finite alphabet. Those results optimize ongoing reproduction for a given stochastic source. Here a machine sees commands rather than the true orbit vector, and every command word must satisfy a final

numerical specification. Only its current label, not a free transcript of sent messages, is retained. Thus a sufficient belief state in the coding problem does not give a cardinality upper bound in the present problem. Conversely our width lower bound does not lower-bound the optimal average distortion of those coders.

Nonanticipative rate-distortion minimizes directed information over causal reproduction kernels under expected distortion constraints. For example, the finite-horizon Markov-source analysis in He–Charalambous–Stavrou [7, Sections II–III] derives a dynamic optimization of those kernels and an alternating computation. That objective is neither  $\max_t K_t$  nor  $\sum_t K_t$ . In particular, mutual information can be small for a channel whose exact finite positive realization needs many labels. A source-law rate-distortion optimization cannot be inserted in place of the wordwise specification without a separate reduction.

Geiger–Tammel [4, Theorem 9] characterize higher-order strong lumpability by an equality of conditional entropies for a stationary finite Markov chain and a deterministic lumping. Their entropy-rate preservation results concern the whole lumped process. We allow randomized, epoch-dependent maps, retain a command-driven terminal observable, and do not require preservation of the trajectory entropy rate or of a Markov partition. State aggregation is therefore an adjacent comparison, not a theorem claimed to have been subsumed. The common use of conditional expectations does not identify the optimization tasks.

**7.3. Conditional expectations and Gaussian entropy.** Atalik–Köse–Gastpar [1, Theorem 1 and Proposition 2] study  $M = \mathbb{E}[X \mid X + W]$  for Gaussian observation noise. In the identity observation case their inequality has the form  $h(M) \geq 2h(X) - h(X + W)$ , with a vector extension. Lemma 3.2 instead permits an arbitrary finite conditioning variable  $J$ , adds new independent noise *after* conditioning, and upper-bounds a difference of two smoothed entropies by the martingale coupling’s squared displacement. A discrete  $M$  is allowed here, whereas its unsmoothed differential entropy is not the quantity being compared. The two displayed inequalities are not direct substitutions of one another. The Gaussian score and posterior-covariance identities used in (13) are classical, and our short semiconcavity proof is not claimed as a new estimation identity. Polyanskiy–Wu’s Wasserstein entropy continuity [14] provides a further comparison; the quadratic cost here uses the particular conditional-mean coupling, not arbitrary transport. The argument needed for the occupation theorem is the amortization of that cost together with orbital sparsity.

**7.4. Positive realization and orbit geometry.** Positive realization and invariant convex sets have a long history [8, 18]. The occupation theorem does not require an internal state to be a point on an observed orbit or in the residual span. Such a restriction would miss hidden stochastic lifts. Classical sphere and projective covering exponents explain the net counts; the additional issue for conjugation is uniformity over spectra of all conditional centroids. Theorem 4.2 settles that issue through a separated spectral projector and the explicit Grassmann bound. Its exponent is matched by an exact projective, rather than ambient spherical, construction. This is the reason that  $q - 1$ , not  $(q^2 - 2)/2$ , appears in Theorem 1.1.

The deep group gaps are external inputs. Proposition 5.3 uses a qualitative theorem; Proposition 6.1 uses a numerical Hecke norm theorem for a different named alphabet. Finite diagonalization of a few harmonics is not a proof of either full gap. Neither density of a subgroup nor a gap in its defining finite-dimensional representation is silently promoted to a full  $L^2$  norm gap.

**7.5. Implementation and the remaining distinctions.** All exact theorems here count atomic nonuniform labels. Replacing each row by a rational approximation and then using a fixed-duration padded fair-bit comparison sampler, as in the retained predecessor, incurs additional control labels and terminal approximation error. The padding removes dependence of duration on private coin outcomes; it does not price the read-only threshold tables or prove uniform space complexity. No exact finite-coin compiler for arbitrary irrational rows is asserted.

The proved results are the representation-valued occupation inequality, the all-spectra conjugation estimate, the matched projective cardinality order, and the effective six-command consequence. They do not classify all compact representations, all finite alphabets, or arbitrary adaptive experimental design. The sufficient calibration threshold is not shown optimal, and signal approaching zero with the horizon requires retaining the explicit constants rather than invoking a fixed-signal asymptotic. Exact finite integer optima and leading constants remain different questions. The standalone article contains all proofs used for its new claims; preservation records and computation are not mathematical or priority certificates.

# GENERAL THETA FOUNDATIONS I: ENTROPY DISSIPATION AND SHARP FINITE-ALPHABET MEMORY

QIAN QI

ABSTRACT. Let a fixed finite family of orthogonal commands have an absolute spectral gap on the full mean-zero  $L^2$  space of the sphere. We prove that its wordwise numerical behavior over  $N$  commands requires and admits  $\Theta(N^{(d-1)/2})$  persistent classical labels, at zero error and at every fixed sufficiently small output error. The lower bound permits arbitrary hidden states, horizon-dependent design and unrelated rows at different epochs. It removes the logarithmic loss of a packet-mixing argument. The proof compares entropy production under random rotations with the entropy cost of conditional-mean compression after Gaussian smoothing; the latter is charged to one telescoping quadratic loss. A weighted occupation theorem also permits time-dependent command laws and unbounded widths at the other cuts. For five explicit rational three-dimensional commands, the classical width is consequently  $\Theta(N)$ , or  $\log_2 N + O(1)$  persistent label bits, while a fixed qubit realizes the same numerical probabilities. The external spectral-gap input is qualitative, not a numerical gap certificate. Our resource is nonuniform clocked atomic-row width. A separate padded fair-bit compiler has no update-duration side channel and does not identify this width with uniform computational space.

## 1. INTRODUCTION

A positive factorization at one time does not specify a stochastic machine that remains valid at all later times. This distinction becomes quantitative when a finite register must preserve an orthogonal orbit under every command word. At each isolated cut a fixed-dimensional simplex can encode the observable vector, yet its successive positive realizations need not be compatible. The problem is to determine the number of labels required by one complete causal realization, with all hidden directions allowed.

Fix  $U_a \in O(d)$  for  $a$  in a finite alphabet  $\mathcal{A}$ , seeds  $x \in X = \{\pm e_1, \dots, \pm e_d\}$  and signal  $0 < \rho \leq 1/10$ . The last command acts on the left:  $U_w = U_{a_N} \cdots U_{a_1}$ . A query  $j \in \{1, \dots, d\}$  is supplied only after the  $N$  commands. The required binary response is

$$(1) \quad \mathbb{P}(B = b \mid x, w, j) = \frac{1 + b\rho e_j^T U_w x}{2}, \quad b \in \{-1, 1\}.$$

All probabilities lie in  $[9/20, 11/20]$ . Equality, or the stated uniform error, is required on every word, not merely under a stationary input law. Let  $W_{N,\varepsilon}$  be the least maximum number of persistent labels with binary row total-variation error at most  $\varepsilon$ ; the complete machine convention is Definition 2.1.

For a probability vector  $p$  on  $\mathcal{A}$ , write

$$(2) \quad Pf(v) = \sum_a p(a) f(U_a^{-1}v), \quad \|P|_{L_0^2(\sigma)}\| \leq \lambda < 1,$$

*2020 Mathematics Subject Classification.* Primary 93B15, 68Q10; Secondary 60J05, 22D10, 94A17, 81P45.

*Key words and phrases.* Positive realization, spectral gap, entropy dissipation, probabilistic branching programs, finite alphabets, quantum memory.

where  $\sigma$  is normalized surface measure on  $\mathbb{S}^{d-1}$ . The inverse convention makes  $P$  also the density transfer operator. The same norm condition holds for its adjoint. It is a hypothesis on *all* spherical harmonics, not the spectrum of the defining  $d$ -dimensional representation.

**Theorem 1.1** (Sharp finite-alphabet width). *Suppose (2) holds and  $0 \leq \varepsilon < \rho/(2\sqrt{d})$ . Then, for constants depending only on  $d, \lambda, \rho, \varepsilon$ ,*

$$(3) \quad cN^{(d-1)/2} \leq W_{N,\varepsilon} \leq W_{N,0} \leq C_d N^{(d-1)/2} \quad (N \geq 1).$$

*The lower bound allows arbitrary hidden state continuations and cut-dependent stochastic rows. The upper realization has common command rows and an  $N$ -dependent terminal decoder. For rational commands, seeds and signal, its rows can all be rational and each update has at most  $d+1$  successors. If the identity is available and  $d\rho < 1$ , every isolated cut nevertheless has positive minimum  $d+1$ .*

The preceding finite-alphabet result [14] gave lower order  $(N/\log(N+1))^{(d-1)/2}$  and the same upper construction. Its converse waited  $O(\log k)$  command slots for the product distribution to become uniform to the resolution of a  $k$ -center quantizer. The proof here does not shorten that mixing time or assert one-step total-variation mixing of an atomic walk. It retains an entropy potential across *all* updates, so that repeated mixing need not be purchased afresh.

Put  $Y_t = U_{a_t} \cdots U_{a_1} x$  and  $Z_t = \mathbb{E}[Y_t \mid S_t]$ . The auxiliary Gaussian density  $f_t = \text{Law}(Z_t) * \gamma_\tau$  is used only in the proof. Randomizing a command increases its entropy by an angular Hellinger variance times the spectral gap. Replacing the resulting vector by a conditional mean decreases entropy by at most

$$\frac{\mathbb{E}\|Z_t\|^2 - \mathbb{E}\|Z_{t+1}\|^2}{2\tau^2}.$$

This cost telescopes. If  $Z_t$  has only  $k$  possible values but has nonvanishing mean norm, smoothing at scale  $\tau \asymp k^{-1/(d-1)}$  still leaves a definite angular Hellinger variance. These statements combine to give an  $O(k^{2/(d-1)})$  occupation bound, with no logarithmic factor. No noise is added to the actual command experiment.

The five rational gates of [14] consequently have exact and fixed-error classical width  $\Theta(N)$ . Their one-qubit realization is unchanged. This is a separation in worst-case numerical behavior under externally supplied words: the classical label bits are  $\log_2 N + O(1)$ , not linear bit space. The gap for these gates is supplied by Bourgain–Gamburd [1]; we do not give a numerical gap value.

| Quantity                 | Meaning                                                                           |
|--------------------------|-----------------------------------------------------------------------------------|
| $K_t, W_{N,\varepsilon}$ | Available labels at a cut; smallest whole-run peak.                               |
| $q_t, v_t$               | $\mathbb{E}\ Z_t\ $ and $\mathbb{E}\ Z_t\ ^2$ , proof-side conditional moments.   |
| $h(f), \Pi$              | Differential entropy with natural logarithms; spherical averaging at each radius. |
| $g_t = 1 - \lambda_t^2$  | The squared-norm gap of the command law at epoch $t$ .                            |
| $\kappa$                 | A positive lower bound on retained terminal amplitude.                            |

The new results are the one-step entropy comparison, the gap-weighted occupation law and its sharp width consequences. Rational spherical synthesis and the qubit operations are inherited and reproved. Spectral gaps, Gaussian score identities, Hellinger comparison and spherical quantization are classical inputs. Appendix A repairs the implementation timing convention; it is not counted as a new sampling algorithm. Section 7 gives the corresponding theorem comparisons. The prior packet, monomial and cyclic results remain intact in the supporting article rather than being silently weakened or used under altered hypotheses.

## 2. THE EXPERIMENT AND ITS REGISTERS

**Definition 2.1** (Clocked stochastic realization). For a prescribed horizon  $N$ , a machine consists of finite alphabets  $[K_t]$ ,  $0 \leq t \leq N$ , initial distributions  $E_x$ , row-stochastic matrices  $T_{t,a}$  of size  $K_t \times K_{t+1}$ , and columns  $d_j \in [-1, 1]^{K_N}$ . Its response mean is  $E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j$ . Its error is one half the maximum absolute discrepancy from  $\rho e_j^T U_w x$  over the finite set of seeds, words and queries. Its peak is  $\max_t K_t$ , also including two labels if the final binary answer is retained at a charged cut. The minimum peak at error  $\varepsilon$  is  $W_{N,\varepsilon}$ .

The seed and query are each supplied once. The current command is consumed in its update. Only the updated register survives; a retained seed, input transcript, random seed, or data-dependent scheduling variable would be part of that register. Available, not merely reachable, labels are counted; padding therefore gives a larger admissible profile. Every unused row is normalized. The epoch, horizon, row tables, their construction, lookup and arithmetic, and exact atomic stochastic sampling are free. A machine may be redesigned for every  $N$  and need not use common rows. This is a nonuniform probabilistic ordered read-once width, not total program size, autonomous state count or uniform computational space.

All converse distributions below are imposed on the external word, independently of private randomness. Wordwise correctness licenses this choice; the test law is not additional runtime information. The commands in this paper's new converse are independent, with a possibly different law at each epoch. No independence of the hidden past given its current state is assumed.

**Lemma 2.2** (Conditional moments and calibration). *Fix a unit seed  $x$ . Let the fresh command  $a_{t+1}$  be independent of the past and let private updates obey the stated Markov rule. Define*

$$Z_t = \mathbb{E}[Y_t | S_t], \quad q_t = \mathbb{E}\|Z_t\|, \quad v_t = \mathbb{E}\|Z_t\|^2, \quad Y_t = U_{a_t} \cdots U_{a_1} x.$$

*Then  $\|Z_t\| \leq 1$ ,  $q_t$  and  $v_t$  are nonincreasing, and*

$$(4) \quad Z_{t+1} = \mathbb{E}[U_{a_{t+1}} Z_t | S_{t+1}], \quad \Delta_t := v_t - v_{t+1} = \mathbb{E}\|U_{a_{t+1}} Z_t - Z_{t+1}\|^2.$$

*In particular  $\sum_{t < N} \Delta_t \leq 1$ . If the machine has wordwise error at most  $\varepsilon$ , then*

$$(5) \quad q_t \geq q_N \geq \kappa := \rho/\sqrt{d} - 2\varepsilon.$$

*Proof.* Conditioning on  $S_t, a_{t+1}$  and its randomized successor does not change the conditional mean of  $Y_t$ : the new command is independent of the past and the update uses that past only through  $S_t$ . The tower property gives (4). Conditional Jensen and the orthogonality of  $U_a$  give both monotonicities. The orthogonal projection identity for conditional expectation gives the equality for  $\Delta_t$ . Initially  $Z_0 = x$ , even when initialization randomizes the register.

In the proof only, combine the separate decoder columns as

$$D(S_N) = (d_1(S_N), \dots, d_d(S_N)), \quad \|D(S_N)\| \leq \sqrt{d}.$$

For every word its conditional mean is within  $2\sqrt{d}\varepsilon$  of  $\rho Y_N$ . Hence

$$\rho - 2\sqrt{d}\varepsilon \leq \mathbb{E}\langle Y_N, D(S_N) \rangle = \mathbb{E}\langle Z_N, D(S_N) \rangle \leq \sqrt{d}q_N.$$

This does not require jointly sampling multiple answers. The vector combines different permitted final query columns only in the proof.  $\square$

**Proposition 2.3** (The isolated-cut minimum). *If  $\text{Id} \in \mathcal{A}$  and  $d\rho < 1$ , the normalized residual rank and separate positive minimum at every internal cut equal  $d + 1$ .*

*Proof.* The residuals are affine functions of  $\rho U_w x$ . Idle prefixes from  $\pm e_j$  span  $\mathbb{R}^d$ , and idle suffixes with coordinate queries separate these coordinates. Normalization adds an independent constant direction, so the rank is  $d + 1$ . A regular simplex with inradius  $\rho$  has circumradius  $d\rho < 1$  and

contains every reachable predictive vector. Its vertices therefore define legal binary response channels after every orthogonal suffix. Decompose the selected-cut vector into those vertices. One may store the raw prefix before this cut and the raw suffix together with the simplex label after it. Those other state sets are finite and uncapped. Thus this is a factorization within a complete machine. Rank gives the matching lower bound. This proposition, inherited from [14], does not assert simultaneous attainment.  $\square$

### 3. ENTROPY COST OF A CONDITIONAL CENTROID

For  $\tau > 0$ , let  $\gamma_\tau$  be the centered Gaussian density on  $\mathbb{R}^d$  with covariance  $\tau^2 I$ . If  $X$  is bounded, write  $f_X = \text{Law}(X) * \gamma_\tau$  and  $h(f) = -\int_{\mathbb{R}^d} f \log f$ . All entropies and divergences in this section use natural logarithms. Gaussian mixtures with bounded centers have finite entropy and the Gaussian tail bounds needed below.

**Lemma 3.1** (Quadratic cost of barycentric compression). *Let  $X$  be a bounded random vector and  $J$  a finite random variable on the same probability space. Set  $M = \mathbb{E}[X \mid J]$ . Then*

$$(6) \quad h(f_X) - h(f_M) \leq \frac{\mathbb{E}\|X - M\|^2}{2\tau^2}.$$

*No sign assertion for the left side is required.*

*Proof.* Put  $f = f_M$ . Direct differentiation of the finite Gaussian mixture gives

$$(7) \quad \nabla^2 \log f(y) = -\tau^{-2} I + \tau^{-4} \text{Cov}(M \mid M + \tau G = y) \succeq -\tau^{-2} I,$$

where  $G$  is an independent standard Gaussian. This identity also follows by differentiating the log-sum of exponentials after factoring out  $\exp(-\|y\|^2/(2\tau^2))$ . Define  $\varphi(x) = -\mathbb{E}_G \log f(x + \tau G)$ . Boundedness of the centers justifies differentiation and gives  $\nabla^2 \varphi \preceq \tau^{-2} I$ . Therefore

$$\varphi(X) - \varphi(M) \leq \langle \nabla \varphi(M), X - M \rangle + \frac{\|X - M\|^2}{2\tau^2}.$$

The first term averages to zero conditional on  $J$ . On the other hand, nonnegativity of  $D(f_X \| f)$  gives

$$h(f_X) - h(f) \leq -\int (f_X - f) \log f = \mathbb{E}\varphi(X) - \mathbb{E}\varphi(M).$$

These inequalities prove the result. The Gaussian density used for convolution is a common mathematical kernel; no additional noisy state is assumed in the transducer.  $\square$

The Gaussian score/Hessian mechanism is classical. For comparison, Polyanskiy–Wu [2, Proposition 1 and Corollary 4] control smoothed entropy differences by a Wasserstein distance. Here the specified martingale coupling  $M = \mathbb{E}[X \mid J]$  cancels the linear Taylor term. The resulting one-sided *squared* error, rather than a square-root continuity estimate for unrelated measures, is what can be summed along a stochastic register. We use the explicit proof above, not an assumed entropy monotonicity under convex order.

**3.1. An entropy increment from a spherical gap.** Let  $\Pi$  be spherical averaging at each radius on  $L^2(\mathbb{R}^d)$ :

$$(\Pi u)(r\omega) = \int_{\mathbb{S}^{d-1}} u(r\theta) d\sigma(\theta).$$

It is the orthogonal projection onto radial functions. The angular gap (2), integrated in polar coordinates, gives

$$(8) \quad \|Pu\|_2^2 \leq \|\Pi u\|_2^2 + \lambda^2 \|u - \Pi u\|_2^2.$$

Here  $P$  acts on Euclidean functions by the same orthogonal pullbacks; it preserves radial functions and commutes with  $\Pi$ .

**Lemma 3.2** (Entropy increment and angular Hellinger variance). *For a Gaussian mixture  $f$  with bounded centers,*

$$(9) \quad \mathbf{h}(Pf) - \mathbf{h}(f) \geq (1 - \lambda^2) \|\sqrt{f} - \Pi\sqrt{f}\|_2^2.$$

*Without a strict gap the entropy increment is still nonnegative.*

*Proof.* Set  $f_a(y) = f(U_a^{-1}y)$  and  $g = \sum_a p(a)f_a = Pf$ . All  $f_a$  have the same entropy, and hence

$$\mathbf{h}(g) - \mathbf{h}(f) = \sum_a p(a) D(f_a \| g).$$

For probability densities  $u, v$ , Jensen's inequality gives  $D(u \| v) \geq -2 \log \int \sqrt{uv} \geq 2(1 - \int \sqrt{uv}) = \|\sqrt{u} - \sqrt{v}\|_2^2$ . Consequently the entropy increment is at least

$$\begin{aligned} \sum_a p(a) \|\sqrt{f_a} - \sqrt{g}\|_2^2 &= 1 - \|P\sqrt{f}\|_2^2 + \|P\sqrt{f} - \sqrt{g}\|_2^2 \\ &\geq 1 - \|P\sqrt{f}\|_2^2. \end{aligned}$$

As  $\|\sqrt{f}\|_2^2 = 1$ , (8) proves the assertion. The last statement also follows directly from entropy concavity. This argument uses the full  $L^2$  gap only on square roots of smoothed probability densities; it assumes no logarithmic Sobolev inequality and no one-step mixing of point masses.  $\square$

#### 4. SPARSE CENTROIDS CANNOT BE ANGULARLY UNIFORM

Write  $m = d - 1$ . Fix a cap constant  $A_d \geq 1$  such that

$$(10) \quad \sigma\{\theta : \|\theta - u\| \leq r\} \leq A_d r^m \quad (0 < r \leq 1, u \in \mathbb{S}^{d-1}).$$

For example, with  $|\mathbb{S}^j|$  denoting surface area, one can use

$$A_d = \max \left\{ 1, \frac{|\mathbb{S}^{m-1}|}{m|\mathbb{S}^m|} \left( \frac{\pi}{2} \right)^m \right\}.$$

Indeed a chordal radius  $r$  has angular radius  $2 \arcsin(r/2) \leq \pi r/2$ , and polar integration with  $\sin t \leq t$  proves the estimate. In dimension three,  $A_3 = 1$  is a convenient nonoptimal choice, since the exact cap mass is  $r^2/4$ .

**Lemma 4.1** (A scale-uniform sparse-mixture obstruction). *Suppose  $\|Z\| \leq 1$ ,  $Z$  has at most  $k$  values, and  $\mathbb{E}\|Z\| \geq \kappa$  for  $0 < \kappa \leq 1$ . Put*

$$(11) \quad r = \left( \frac{\kappa}{16A_d k} \right)^{1/m}, \quad \tau = \frac{\kappa r}{8\sqrt{2d}}, \quad f = \text{Law}(Z) * \gamma_\tau.$$

*Then*

$$(12) \quad \|\sqrt{f} - \Pi\sqrt{f}\|_2^2 \geq \frac{\kappa}{16}.$$

*The locations and masses of the atoms are arbitrary.*

*Proof.* Let  $L = \{\|Z\| \geq \kappa/2\}$ . Since  $\mathbb{E}\|Z\| \leq \kappa/2 + \mathbb{P}(L)$ , its probability is at least  $\kappa/2$ . Around each direction of a nonzero atom satisfying  $L$  place a spherical cap of chordal radius  $r$ . Their union  $\Omega$  satisfies  $\sigma(\Omega) \leq kA_d r^m = \kappa/16$ .

Let  $G$  be independent standard Gaussian. Markov's inequality gives  $\mathbb{P}(\|G\| \leq \sqrt{2d}) \geq 1/2$ . On this event and  $L$ ,

$$\|\tau G\| \leq \kappa r/8, \quad \left\| \frac{Z + \tau G}{\|Z + \tau G\|} - \frac{Z}{\|Z\|} \right\| \leq \frac{2\|\tau G\|}{\|Z\|} \leq r/2.$$

The denominator is nonzero here because  $r \leq 1$  and  $\|\tau G\| \leq \|Z\|/4$ . Thus the radial cone  $C_\Omega = \{s\theta : s > 0, \theta \in \Omega\}$  has  $\int_{C_\Omega} f \geq \kappa/4$ .

Write  $u = \Pi\sqrt{f}$ . This is radial, and  $\|u\|_2 \leq 1$ . Polar integration yields  $\int_{C_\Omega} u^2 = \sigma(\Omega)\|u\|_2^2 \leq \kappa/16$ . The triangle inequality in  $L^2(C_\Omega)$  now gives

$$\|\sqrt{f} - u\|_2 \geq \sqrt{\kappa/4} - \sqrt{\kappa/16} = \frac{\sqrt{\kappa}}{4}.$$

Squaring proves the assertion. Repeated atom directions and zero atoms only reduce the number of caps. No regularity or separation assumption on the centroid locations was used.  $\square$

The cap scale in this lemma is the classical  $k^{-1/m}$  quantization scale. To fix the comparison precisely, for a sphere probability measure  $\nu$  its  $k$ -center cosine distortion is

$$\inf_{u_1, \dots, u_k \in \mathbb{S}^m} \int \min_i (1 - \langle v, u_i \rangle) d\nu(v) = \frac{1}{2} \inf_{u_1, \dots, u_k \in \mathbb{S}^m} \int \min_i \|v - u_i\|^2 d\nu(v).$$

Repeated centers are permitted. For surface measure its order is  $k^{-2/m}$ ; the cap lower estimate and a covering upper estimate already prove that order. This is part of classical quadratic quantization, not a new geometric exponent; see Graf–Luschgy [3] and the manifold extension of Iacobelli [4, Theorem 1.4]. The quantity in (12) is different: it is an angular Hellinger obstruction for a *Gaussian-smoothed* finite register. Combined with the one-step entropy increment, it need not wait for a word product to approximate Haar measure at this scale.

## 5. A SHARP OCCUPATION LAW

The argument is useful in an inhomogeneous form. At epoch  $t$ , let the fresh command have a prescribed law  $p_t$ , independently across epochs, and let its angular operator satisfy

$$\|P_t|_{L_0^2(\sigma)}\| \leq \lambda_t \leq 1, \quad g_t = 1 - \lambda_t^2.$$

The alphabets and orthogonal matrices can also depend on  $t$  in this probabilistic statement. No strict gap is required at every epoch. Define the dimension-only constants

$$(13) \quad a_d = 3 + \frac{2}{d-1}, \quad B_d = 2048d(16A_d)^{2/(d-1)}.$$

**Theorem 5.1** (Gap-weighted occupation without a mixing-time loss). *For the hidden process of Lemma 2.2, suppose  $q_N \geq \kappa > 0$ . For every integer  $k \geq 1$ ,*

$$(14) \quad \sum_{\substack{0 \leq t < N \\ K_t \leq k}} g_t \leq B_d \kappa^{-a_d} k^{2/(d-1)}.$$

*The other cuts may have arbitrarily many labels. The inequality also holds when  $K_t$  is replaced by the number of positive-probability states under this independent-command test law.*

*Proof.* Fix  $k$  and choose one smoothing scale  $\tau$  by (11); keep it fixed throughout the run. Set  $f_t = \text{Law}(Z_t) * \gamma_\tau$  and  $\tilde{Z}_t = U_{a_{t+1}} Z_t$ . Orthogonal invariance of Gaussian noise and independence of the fresh command imply  $f_{\tilde{Z}_t} = P_t f_t$ . By (4),  $Z_{t+1} = \mathbb{E}[\tilde{Z}_t | S_{t+1}]$ . Lemma 3.1 therefore yields

$$(15) \quad h(f_{t+1}) - h(f_t) \geq h(P_t f_t) - h(f_t) - \frac{\Delta_t}{2\tau^2}.$$

Whenever  $K_t \leq k$ , Lemmas 3.2 and 4.1, together with  $q_t \geq q_N \geq \kappa$ , bound the entropy increment from randomizing the command below by  $g_t \kappa/16$ . At all other cuts that increment remains nonnegative.

Sum (15). The total quadratic loss is at most one. Furthermore, entropy concavity gives  $h(f_0) \geq \frac{d}{2} \log(2\pi e \tau^2)$ , while  $\mathbb{E}\|Z_N + \tau G\|^2 \leq 1 + d\tau^2$  and Gaussian maximal entropy give

$$h(f_N) \leq \frac{d}{2} \log(2\pi e(\tau^2 + 1/d)).$$

The latter bound follows directly by comparing  $f_N$  with the centered Gaussian of that covariance and using nonnegative relative entropy. It does not require  $Z_N$  to be centered. Consequently

$$(16) \quad \frac{\kappa}{16} \sum_{K_t \leq k} g_t \leq \frac{d}{2} \log \left( 1 + \frac{1}{d\tau^2} \right) + \frac{1}{2\tau^2} \leq \frac{1}{\tau^2}.$$

Since  $\tau^{-2} = 128d\kappa^{-2}(16A_d k/\kappa)^{2/(d-1)}$ , this is (14). Nothing in this summation restricts the intermediate hidden affine dimension, projected vertices, or the widths of the other registers. Under the test law, only positive-mass labels occur in the mixture  $f_t$ , proving the final assertion.  $\square$

For a fixed gap  $g = 1 - \lambda^2 > 0$ , (14) gives  $\#\{0 \leq t < N : K_t \leq k\} \leq B_d g^{-1} \kappa^{-a_d} k^{2/(d-1)}$ . Counting endpoints  $1, \dots, N$  instead changes this bound by at most one. Thus the earlier logarithmic loss in occupation, as well as in peak width, is removed. The proof does not assume a spectral gap for the stochastic state matrices; its gap belongs to the *external* orthogonal action on the sphere.

**Lemma 5.2** (Exact spherical synthesis, inherited upper bound). *For every  $N \geq 1$  and finite orthogonal command alphabet, the experiment (1) admits a common-row realization with at most  $C_d N^{(d-1)/2}$  labels. Rational commands, seeds and signal admit rational rows with at most  $d+1$  successors.*

*Proof.* This is the construction from [14]; we include it to make the matched theorem self-contained. Write  $m = d - 1$  and  $\eta = 1 - 1/(8N)$ . The two rational stereographic charts

$$t \mapsto \left( \frac{2t}{1 + \|t\|^2}, \pm \frac{1 - \|t\|^2}{1 + \|t\|^2} \right), \quad t \in [-1, 1]^m,$$

are 2-Lipschitz. Every sphere point has a preimage in the unit ball in one chart. On a grid of mesh  $1/M$ , with  $M = \lceil 2\sqrt{mN} \rceil$ , their images form a rational set  $V$  of at most  $2(2M+1)^m$  points. Every unit direction is within chordal distance  $\sqrt{m}/M$  of  $V$ . Hence  $\eta\mathbb{B}^d \subset P := \text{conv } V$  by the support-function criterion.

Associate label  $u \in V$  at time  $t$  with  $a_t u$ , where  $a_t = \eta^{-t}/4$ . On command  $a$  choose a convex representation of  $\eta U_a u$  in  $V$ . These are common command rows. Initialize the mean to  $\rho x$  in  $a_0 P$ , which is possible because  $\eta/4 \geq 7/32 > \rho$ . Use terminal mean  $a_N e_j^T u$ . Bernoulli's inequality gives  $\eta^N \geq 7/8$ , so  $a_N \leq 2/7 < 1$ . The identity  $a_{t+1} \mathbb{E}[u' \mid u, a] = a_t U_a u$  proves exactness on every word. For rational data, each convex feasibility problem has a rational basic solution with at most  $d+1$  nonzero coefficients. The state holds only the label. A charged final bit uses two labels and is absorbed in  $C_d$ . No efficient table-generation algorithm is inferred from finite feasibility.  $\square$

*Proof of Theorem 1.1.* Use the independent command law  $p$  from (2) and any fixed seed. Lemma 2.2 gives  $\kappa = \rho/\sqrt{d} - 2\varepsilon > 0$ . With  $K = \max_t K_t$ , Theorem 5.1 gives the explicit bound

$$(17) \quad K \geq \left( \frac{(1 - \lambda^2) \kappa^{a_d}}{B_d} N \right)^{(d-1)/2}.$$

The preceding lemma proves the exact upper bound. Proposition 2.3 proves the isolated-cut assertion.  $\square$

**Corollary 5.3** (An obstruction for actual terminal error). *For an available-label profile  $\mathbf{K}$ , let  $\mathcal{E}_N(\mathbf{K})$  be the least actual worst-row terminal error among all machines with that profile. For every integer  $k$  with  $I_k := \#\{0 \leq t < N : K_t \leq k\} > 0$ ,*

$$(18) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{d}} - \left( \frac{B_d k^{2/(d-1)}}{(1 - \lambda^2) I_k} \right)^{1/a_d} \right]_+.$$

In particular, peak  $o(N^{(d-1)/2})$  entails  $\liminf \mathcal{E}_N \geq \rho/(2\sqrt{d})$ .

*Proof.* The finite parameter domain of a fixed-profile machine is compact and the wordwise objective continuous, so the minimum exists. Apply (14) with  $\kappa = q_N$  when  $q_N > 0$ , and use  $q_N \geq \rho/\sqrt{d} - 2\mathcal{E}_N$ . If  $q_N = 0$ , the same conclusion follows directly from calibration. The last assertion uses  $I_K = N$ .  $\square$

This is an actual-error bound: it does not add local defects or rule out their cancellation. If a separately supplied diagram has an accumulated local deficiency certificate  $D$ , the classical composition argument produces a machine with final error at most  $D$ ; only then does (18) lower-bound that certificate. It need not equal the minimum terminal error.

## 6. A SHARP RATIONAL EXAMPLE AND ITS QUANTUM REALIZATION

Use the fixed five-letter alphabet  $\mathcal{A}_* = \{\text{Id}, R_x, R_x^{-1}, R_z, R_z^{-1}\}$ , where

$$(19) \quad R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -7/25 & -24/25 \\ 0 & 24/25 & -7/25 \end{pmatrix}, \quad R_z = \begin{pmatrix} -7/25 & -24/25 & 0 \\ 24/25 & -7/25 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

These are the rational commands from [14]. Take  $\rho = 1/10$ , six seeds  $\{\pm e_j : 1 \leq j \leq 3\}$  and three final coordinate queries. No alphabet grows with the horizon.

**Theorem 6.1** (Linear classical label complexity). *For every fixed  $0 \leq \varepsilon < 1/(20\sqrt{3})$ ,*

$$(20) \quad W_{N,\varepsilon}(\mathcal{A}_*) = \Theta_\varepsilon(N), \quad \lceil \log_2 W_{N,\varepsilon}(\mathcal{A}_*) \rceil = \log_2 N + O_\varepsilon(1).$$

*The exact upper machine may have rational common command rows. The separate positive minimum at each cut is four. If  $\lambda_* < 1$  is the norm-gap constant for the walk with probabilities  $(1/2, 1/8, 1/8, 1/8, 1/8)$ , every such machine has*

$$(21) \quad K \geq \frac{(1 - \lambda_*^2)(1/(10\sqrt{3}) - 2\varepsilon)^4}{98304} N.$$

*The existence of  $\lambda_* < 1$  is an external spectral-gap input; its numerical value is not evaluated here.*

*Proof.* Let  $\sigma_x, \sigma_y, \sigma_z$  be the Pauli matrices and define  $A_x = (3I - 4i\sigma_x)/5$ ,  $A_z = (3I - 4i\sigma_z)/5$  in  $\text{SU}(2)$ . Their adjoint actions are (19). Their eigenphases include  $(3 + 4i)/5$ , which is not a root of unity: its sum with its inverse is  $6/5$ , not an integer, whereas a rational algebraic integer is an integer. The closures of the respective cyclic subgroups therefore contain the two axial circles. The Lie algebra generated by  $i\sigma_x, i\sigma_z$  also contains their bracket, a nonzero multiple of  $i\sigma_y$ . The closed generated subgroup is  $\text{SU}(2)$ .

The generators have algebraic entries. Bourgain–Gamburd [1, Theorem 1] supplies the upper spectral gap for their symmetric averaging operator on  $L^2(\text{SU}(2))$ . Adding weight  $1/2$  at the identity makes its spectrum nonnegative and its mean-zero norm strictly less than one. Under the left action, lift a sphere function by  $f(v) \mapsto f(\text{Ad}_g e_3)$ . This is an isometry from the homogeneous quotient  $L^2(\mathbb{S}^2)$  into  $L^2(\text{SU}(2))$  and intertwines the left pullbacks. Thus the sphere operator has the same norm bound; inverse conventions are harmless for this symmetric walk.

Apply Theorem 1.1 and use  $A_3 = 1$  in (13), giving  $a_3 = 4$  and  $B_3 = 98304$ . This proves (21) and the matching upper order. Rational sparse rows follow from Lemma 5.2, and Proposition 2.3 gives four. Taking binary logarithms proves the bit statement, including the integer ceiling.  $\square$

The rationality and alphabet are explicit, but a numerical finite-horizon lower threshold requires an additional certified bound on  $\lambda_*$ . We provide neither such a certificate nor a claim that finite-dimensional matrix eigenvalues establish the infinite-dimensional gap. Formula (21) gives the full dependence on any supplied gap certificate. The new conclusion here is removal of the logarithmic factor from the classical label count, not a new construction of expanding generators.

**Proposition 6.2** (One qubit with reset, unitary commands and final query). *One qubit realizes (1) for (19) exactly, using a fixed finite collection of operations independent of  $N$ . Thus its quantum memory dimension is two, whereas its classical atomic label complexity and label bits satisfy (20) even at the stated fixed positive error. This is a numerical-behavior comparison, not a strict-cutpoint language-state separation.*

*Proof.* On seed  $x$  reset the qubit to  $\varrho_x = (I + \rho \sum_j x_j \sigma_j)/2$ . Its eigenvalues are positive because  $\rho < 1$ . Commands apply the unitaries  $I, A_x^{\pm 1}, A_z^{\pm 1}$ . The Bloch vector after the word is  $\rho U_w x$ . Measurement of  $\sigma_j$  has outcome  $b$  with probability  $(1 + b \rho e_j^T U_w x)/2$ . Only one final query is made. A seed reset is a completely positive operation; it is not being called a unitary measure-once transition. The classical statement is Theorem 6.1.  $\square$

The same qubit operations appeared in the preceding revision. What is strengthened is the matching classical cost. In particular this is one qubit versus  $\log_2 N + O(1)$  classical *label bits*, not one qubit versus linear bit space or an entropy lower bound for a chosen stationary input distribution.

## 7. COMPARISONS AND SCOPE

**7.1. Quantization, smoothing and the new accumulated estimate.** Classical quadratic quantization minimizes the expected squared distance to a finite codebook. The cosine loss on a sphere is exactly one half of the squared chordal distance. Graf–Luschgy [3] develops the general quantization framework, and Iacobelli [4, Theorem 1.4] proves the corresponding manifold asymptotics under explicit integrability hypotheses. On the compact sphere these give the familiar exponent  $2/(d-1)$ . Neither this geometric exponent nor the cap argument used here is a priority claim. Our lower bound concerns a sequence of *hidden conditional centroids*, not independently selected nearest neighbors in a static codebook.

Gaussian smoothing and entropy continuity are also established tools. The bound in [2, Corollary 4] applies to unrelated smoothed laws and is linear in an appropriate Wasserstein distance. Lemma 3.1 uses the particular conditional-mean coupling and a semiconvex Gaussian log density to remove the first-order term. We do not assert that this elementary Gaussian identity is absent from the literature. Its role here is to make the entire cost bounded by one quadratic variation budget, rather than by the sum of square roots of individual costs.

The entropy increment in Lemma 3.2 uses the standard relative-entropy/Hellinger comparison and an  $L^2$  spectral bound, not a logarithmic Sobolev assumption. Lemma 4.1 gives a uniform positive angular defect after smoothing at the register’s resolution. The conclusion that combines these ingredients is Theorem 5.1: a finite horizon with arbitrarily varying hidden implementations has a gap-weighted small-register occupation of order at most  $k^{2/(d-1)}$ . That inequality, rather than a new quantization exponent or expansion theorem, is the main assertion.

**7.2. Positive realization and branching programs.** After padding layer alphabets, the model is a probabilistic ordered read-once layered program, with command-dependent row-stochastic matrices and a bounded real output. The scalar decoder for one query can be turned into randomized Boolean acceptance by one Bernoulli row. The total number of layer nodes and transition-table size are not the maximum width. In particular the result is not a lower bound in a uniform algorithmic-space model.

Fourier-growth and pseudorandomness results for regular, permutation and width-three branching programs [10, 11, 12] use their stated transition assumptions and control Boolean-input Fourier coefficients. Their regularity is not implied by row stochasticity: a reset matrix with every row  $(1, 0, \dots, 0)$  does not preserve the uniform state law. Some bounds for unrestricted deterministic tables do extend to random tables by convexity, so randomness alone is not an

originality boundary. Here the assumed gap is on the external sphere action, whereas the arbitrary hidden matrices need have no gap or regularity. The converse uses the entropy of a smoothed conditional orbit mean, not an estimate on the Fourier mass of a Boolean acceptance function. We make no claim of an exhaustive branching-program priority classification.

Earlier positive-realization mechanisms and the packet theorem remain useful [13, 14]. In particular the full-word endpoint kernel must be allowed to distinguish different spellings of the same product. The present one-step proof uses actual independent command letters, not a product-sufficiency reduction. No previously corrected packet quantifier is relaxed.

**7.3. Which quantum memory is compared.** Quantum advantages for process simulation precede this work. Gu et al. [5] construct models with smaller stored entropy for classical stochastic processes. Thompson et al. [6] also treat *input-output* processes, not only autonomous outputs: their framework includes stationary input-dependent memory entropy and its worst-input counterpart. Our claim must not be distinguished from that work merely by the presence of input commands. The distinction here is finite-horizon worst-word numerical error, arbitrary horizon-specific classical tables, and maximum available label count; we do not minimize stationary memory entropy.

Ghafari et al. [7] demonstrate a memory-dimension advantage for stochastic process simulation. Thus dimension, as well as entropy, has established quantum-memory comparisons. Proposition 6.2 is an explicit driven family whose *classical* cardinality has a matched growth law in the horizon at fixed positive error. It is not a first claim of quantum dimension advantage. The recent world-model comparison [9] is also relevant; its process and update requirements are not replaced by our nonuniform one-query convention.

For strict cutpoints, Chen–Wu [8, Theorem 3.2] gives a classical PFA with at most  $n^2 + 1$  states for a general  $n$ -dimensional one-way quantum automaton. The conversion preserves a threshold sign while allowing a length-dependent shrinking numerical margin [8, Proposition 3.1]. It therefore does not preserve the fixed terminal correlation used here. The result in (20) does not contradict or improve that theorem in its own language metric.

**7.4. Conclusions.** The full-sphere spectral-gap class has matched exact and fixed-error width  $\Theta(N^{(d-1)/2})$ . The explicit three-dimensional gate family has linear classical label count and logarithmic classical label bits. The proof allows hidden directions, cut-dependent rows, and fixed positive error, and it does not repeat a mixing-time charge.

The constants in the occupation theorem are not optimized. Neither an exact leading asymptotic constant nor every finite integer optimum is identified. A numerical lower constant for the displayed gates still requires a certified spectral-gap value. Arbitrary compact actions without the assumed sphere gap, all irrational cyclic arithmetic, multiple jointly constrained queries and adaptive experimental design are different problems. The retained monomial and cyclic theorems keep their own hypotheses in the supporting article.

Finally, nonuniform atomic-row width and its padded finite-coin implementation are different resources. The latter has the additional control factor proved below. Both leave table construction and storage outside the counted register, and neither is represented as a uniform space bound. The complete predecessor development is preserved separately; it is not needed to validate the new proof or part of the editorial claim for this article.

## APPENDIX A. FIXED-DURATION FINITE-COIN IMPLEMENTATION

We make the timing repair explicit rather than assuming that duration is unobservable. The environment supplies a command at a ready boundary. Every completed update uses the same publicly specified number of microsteps, independent of the private bits, old label and command. No output or internal decision is visible during the update; only its fixed-time ready boundary is

visible. Threshold tables are nonuniform read-only data. The bit position, input latch, old label and control variables are counted. There is no uncharged microstep clock.

**Theorem A.1** (Padded sparse-row compiler). *Let a finite transducer have peak  $K$ , common command rows and at most  $L \geq 2$  successors per initialization, command or decoder row, with fixed seed, command and query alphabets. For  $\delta > 0$ , put*

$$b = \max \left\{ 1, \left\lceil \log_2 \frac{(N+2)(L-1)}{\delta} \right\rceil \right\}, \quad D = (L-1)b.$$

*It admits a fair-bit implementation with exactly  $D$  private fair-bit microsteps per macro update, terminal error increased by at most  $\delta$ , and at most  $C_{A,X,J,L}K(b+1)$  persistent labels. Its duration discloses no information about the private trajectory.*

*Proof.* For each categorical row, consider its conditional binary decision tree, with at most  $L-1$  internal nodes. Replace each conditional probability by a lower dyadic approximation with  $b$  bits, keeping probabilities zero and one exact. Coupling decisions bounds the row total variation by  $(L-1)2^{-b}$ . Zero-mass nodes are given arbitrary legal rows.

To draw a threshold  $m/2^b$ , compare  $b$  private fair bits with its stored binary digits. Until the first mismatch the sampled prefix is equal to the table prefix, so no prefix integer is needed. Store the bit position and the relation (equal, below or above); after a mismatch, continue consuming the remaining bits of this comparison without changing the relation. After  $b$  steps, move to the selected child of the categorical tree. Once a leaf has been selected, hold its new label and continue consuming dummy bits until exactly  $D$  steps have elapsed. Deterministic thresholds and trees of shorter depth are padded in the same way.

Active states retain the old label, current input, tree node, relation and counted progress; their number is at most a constant times  $K(b+1)$  for fixed alphabets and  $L$ . After leaf selection the old label is released; the sampler holds only the new label and counted progress. It does not hold two independent  $K$ -valued labels. Ready, initialization and query phases add only the same order. A final binary answer can be held inside the padding states. All timing information is the deterministic number  $D$ , so even a source observing ready times receives no private coin information from duration. This observation does not enlarge the main theorem into an adaptive-policy optimization result.

Each completed macro update has its rounded stochastic law regardless of padding. Stochastic contraction and a coupling of the at most  $N+2$  updates bound final error by  $(N+2)(L-1)2^{-b} \leq \delta$ . The construction changes no mathematical target to a cutpoint language.  $\square$

The comparison/tree construction is standard; the purpose is to price its control and remove the early-stopping side channel noted for the preceding self-paced compiler. It is not zero-error fair-bit sampling of arbitrary irrational probabilities.

**Corollary A.2** (Padded label-bit rate). *For every fixed positive tolerance in Theorem 1.1, the exact spherical upper machine has a padded fair-bit approximation with  $O(N^{(d-1)/2} \log(N+1))$  labels. In this separately defined nonuniform padded model, minimum persistent label bits obey*

$$\frac{d-1}{2} \log_2 N - O(1) \leq b_N^{\text{pad}} \leq \frac{d-1}{2} \log_2 N + O(\log \log(N+1)).$$

*For the five rational gates the leading coefficient is one.*

*Proof.* Lemma 5.2 gives common rows with  $L = d+1$  (enlarge  $L$  for the binary output if necessary). Compile them with  $\delta$  equal to the desired fixed tolerance, so  $b = O(\log(N+1))$ . This proves the upper label and bit bounds. At ready boundaries every padded machine induces an atomic transducer with no more labels than its total control alphabet. The sharp atomic lower bound therefore proves the lower bit bound. Tables, their generation, and arithmetic remain uncharged

in both nonuniform measures. No exact order for the padded label count is inferred from these leading-bit estimates.  $\square$

# GENERAL THETA FOUNDATIONS I: FINITE ALPHABETS, SPECTRAL GAPS, AND HIDDEN MEMORY

QIAN QI

**ABSTRACT.** We study the width of finite stochastic transducers that reproduce every conditional probability of a prescribed orthogonal command experiment. For a fixed finite alphabet whose action on the sphere has an  $L^2$  spectral gap, we prove lower and upper widths of orders  $(N/\log(N+1))^{(d-1)/2}$  and  $N^{(d-1)/2}$ , respectively. The upper realization is exact; the lower bound permits arbitrary hidden states, unrelated transition rows at different epochs, and fixed small output error. Five explicit rational three-dimensional commands therefore have classical width between  $cN/\log(N+1)$  and  $CN$ , although a single qubit realizes the same probabilities. This probability task is distinct from strict-cutpoint language equivalence. A second finite, noncommuting class, consisting of permutations and conjugations of resonant planar modes, has the matched order  $N^{1/3}$ . Its full group need not possess an irrational one-dimensional character. The common argument is a packet compression inequality formulated for the entire fresh command word, without assuming that its product is sufficient for the hidden machine. We also give a finite fair-bit compiler for sparse rows, with logarithmic rather than denominator-sized control overhead. The principal width is nonuniform clocked atomic-row width; the fair-bit interface is separately self-paced. The spectral-gap bounds determine a polynomial exponent, not a matched order up to constants.

## 1. INTRODUCTION

A small positive factorization at every observation cut does not, by itself, produce a small machine that realizes all cuts simultaneously. The additional requirement is causal compatibility: the same retained state must support each possible next input. We investigate this requirement for command experiments

$$(1) \quad \mathbb{P}(B = b \mid x, a_1 \cdots a_N, j) = \frac{1 + b\rho e_j^T U_{a_N} \cdots U_{a_1} x}{2}, \quad b \in \{-1, 1\}.$$

The command alphabet is fixed and finite. The seed is supplied once, and one coordinate query is supplied after the prescribed horizon. The command matrices act orthogonally; the realizing matrices act stochastically and may have arbitrary hidden directions.

The finite-alphabet restriction is substantive. An independent Haar rotation cannot be treated as one input when only a finite gate set is available. Nor can a whole word be replaced by its group product in the hidden transition law: equal products can have different intermediate computations. The present results retain each input slot and each full word throughout the converse.

Let  $m = d - 1$ . Suppose a probability distribution on the fixed alphabet induces an averaging operator  $P$  with

$$(2) \quad \|Pf\|_{L^2(\sigma)} \leq \lambda \|f\|_{L^2(\sigma)} \quad \text{when} \quad \int f d\sigma = 0, \quad \lambda < 1,$$

---

*Key words and phrases.* Positive realization, probabilistic branching programs, finite alphabet, spectral gap, quantum automata, stochastic transducers.

where  $\sigma$  is normalized spherical measure. For fixed positive signal and sufficiently small uniform error, Theorem 4.3 proves

$$(3) \quad c \left( \frac{N}{\log(N+1)} \right)^{m/2} \leq W_{N,\varepsilon} \leq W_{N,0} \leq CN^{m/2}.$$

In particular  $\log W_{N,\varepsilon} / \log N \rightarrow m/2$ . The logarithmic gap in (3) is part of the statement, not absorbed into a  $\Theta$  notation. The proof uses only a finite command distribution. A logarithmic number of actual commands makes its orbit distribution sufficiently close to spherical measure at the resolution imposed by the endpoint width.

Theorem 5.1 instantiates this criterion with five rational matrices in  $\text{SO}(3)$ . The spectral gap is an external theorem of Bourgain–Gamburd [1], not an assumption checked by numerics. Density and the algebraic hypotheses are verified for the stated gates. The experiment has separate positive minimum four at every internal cut, but its compatible hidden width grows almost linearly. A two-dimensional quantum memory realizes it exactly. Proposition 5.2 makes this comparison operational rather than terminological.

A different geometry gives a different order. In Theorem 6.1, finitely many orthogonal monomial commands permute planar modes, conjugate them, and rotate them by integer multiples of one badly approximable angle. Their exact and fixed-error widths are  $\Theta(N^{1/3})$ . The group generated by the displayed five-letter example is noncommuting, its real representation is irreducible, and no continuous one-dimensional character sees its irrational rotations. This is not an assertion that every finite noncommuting alphabet has the same exponent.

The methodological distinction is between mixing of the uncompressed orbit and irreversible loss at a finite register. The former supplies an orbit quantization scale; the latter converts that scale into a cumulative width constraint. All lower bounds allow new machines at each horizon and arbitrary changes of stochastic rows between epochs. The exact upper machines have common command rows for a fixed horizon, with a horizon-dependent decoder.

| Notation            | Meaning                                                              |
|---------------------|----------------------------------------------------------------------|
| $K_t, W$            | available labels at cut $t$ , and their maximum                      |
| $W_{N,\varepsilon}$ | least peak at uniform binary row-TV error $\varepsilon$              |
| $W, g(W)$ in §3     | fresh packet word, and its ordered group product                     |
| $\Gamma_k(\mu)$     | least $k$ -center orbit distortion, including the starting direction |
| $B_k$               | number of actual commands used by a test packet                      |
| $q_t$               | norm of the conditional orbit mean, averaged over hidden states      |

The use of  $W$  for a word is local to the packet lemma; width elsewhere is scalar. Classical positive realization, spherical covering, spectral gap, and strict-cutpoint simulation are identified at their points of use. The new finite-alphabet consequences depend on these stated inputs. The sharp binary rotation result of [10] is retained and its packet and resonant arguments are reproduced within the larger monomial construction. Historical results not needed for the present proofs remain in the separately preserved supporting article.

## 2. FINITE EXPERIMENTS AND PERSISTENT REGISTERS

Fix a finite alphabet  $\mathcal{A}$ , matrices  $U_a \in O(d)$ , a finite seed set  $X \subset \mathbb{S}^{d-1}$  and  $0 < \rho \leq 1/10$ . Unless otherwise stated,  $X = \{\pm e_1, \dots, \pm e_d\}$  and  $\text{Id} \in \mathcal{A}$ . We use the full specification (1); no distribution or fairness assumption is imposed on the external word.

**Definition 2.1** (Nonuniform clocked stochastic transducer). For horizon  $N$ , a transducer consists of finite state sets  $[K_t]$ , initial distributions  $E_x$ , stochastic matrices  $T_{t,a} \in \mathbb{R}_+^{K_t \times K_{t+1}}$ , and terminal columns  $d_j \in [-1, 1]^{K_N}$ . Its mean on a word is  $E_x T_{0,a_1} \cdots T_{N-1,a_N} d_j$ . Its error is half the

maximum absolute discrepancy from the mean in (1). The peak counts the available labels  $\max_t K_t$ , and also two terminal labels when the emitted answer is retained at a charged cut. The least peak with error at most  $\varepsilon$  is  $W_{N,\varepsilon}$ .

Only the updated register persists. The seed and the query appear once; the current command is consumed in its update. Private randomness does not persist outside the register. An input-dependent clock, a previous command, or an installation tag would be charged if retained. The epoch,  $N$ , complete row tables, their construction and arithmetic, and exact atomic sampling are free. Rows may vary with  $t$  and  $N$ . Unused rows are normalized, and padding counts as available labels. This is maximum layer width of a nonuniform probabilistic ordered read-once program, not uniform program space or total branching-program size. Section 7 specifies a different, finite-coin interface.

For comparison with the earlier compact-input theorem, a compact command space requires each matrix entry  $a \mapsto T_{t,a}(s, s')$  to be Borel. Such a row function is nonuniform program data, not a finitely represented real-input algorithm. None of the finite-alphabet theorems below requires that access. Every input to their machines is a symbol from a fixed finite set.

**Proposition 2.2** (Separate positive minimum). *If  $\rho d < 1$  and the identity is available, the normalized residual rank and the separate positive minimum at every cut are  $d + 1$ . A separate minimum places no cap on the other registers.*

*Proof.* Residual rows are affine in  $v = \rho U_w x$ . Idle prefixes from  $\pm e_j$  span  $\mathbb{R}^d$ , and an idle suffix followed by the coordinate queries separates the coordinates. Normalization adds the constant row, giving rank  $d + 1$ . A regular simplex centered at zero with circumradius  $d\rho$  has inradius  $\rho$ . It contains every reachable vector and all its vertices have norm less than one. Each vertex consequently defines a valid future binary channel after every orthogonal command word. At the selected cut decompose  $v$  into these vertices. Before this cut one may store the raw prefix; afterwards one may store a simplex label and the raw suffix. At  $l$  later inputs this costs at most  $(d + 1)|A|^l$  labels, and remains finite. It embeds the factorization in a complete machine rather than an amputated static matrix. Rank gives the converse.  $\square$

**Lemma 2.3** (Terminal correlation). *For a fixed unit seed  $x$ , put  $Y_t = U_{a_t} \cdots U_{a_1} x$  and  $q_t = \mathbb{E}[\|Y_t\| \mid S_t]$  under any external word law independent of the machine's private randomness. If the wordwise error is at most  $\varepsilon$ , then*

$$(4) \quad q_N \geq \kappa_d := \rho/\sqrt{d} - 2\varepsilon.$$

*Proof.* Combine the  $d$  decoder columns into  $D(S_N) \in [-1, 1]^d$ . Conditionally on a word, its mean differs from  $\rho Y_N$  by a vector of norm at most  $2\sqrt{d}\varepsilon$ . Thus  $\mathbb{E}\langle Y_N, D(S_N) \rangle \geq \rho - 2\sqrt{d}\varepsilon$ . Conditional expectation bounds the absolute value of this quantity by  $\sqrt{d}q_N$ . Two or more queries are not jointly sampled in this argument; their decoder columns are only combined in the proof.  $\square$

### 3. COMPRESSION OF FULL COMMAND WORDS

Let a compact group act orthogonally on a finite-dimensional real Hilbert space  $H$ . Complex unitary representations are covered by the real inner product. For a group probability measure  $\mu$ , define

$$(5) \quad \Gamma_k(\mu) = \inf_{v, u_1, \dots, u_k \in \mathbb{S}(H)} \int \min_{i \leq k} \{1 - \langle U_g v, u_i \rangle\} d\mu(g).$$

This continuous minimization has a minimum and lies in  $[0, 1]$ . The upper bound follows by including the direction of  $\int U_g v d\mu(g)$  as a center. An invariant direction may make the coefficient zero. The conclusions below remain valid but then give no positive loss from that packet.

**Lemma 3.1** (Full-word packet contraction). *Let  $Y \in H$  be integrable and  $S$  finite. Let a random packet word  $W$  be independent of  $\sigma(Y, S)$ , and let  $g(W)$  be its measurable ordered product. Suppose  $S'$  has at most  $k$  positive-mass values and, for every label  $r$ ,*

$$(6) \quad \mathbb{P}(S' = r \mid \sigma(Y, S, W)) = T_W(S, r) \quad a.s.,$$

where each  $T_w$  is a stochastic kernel. If  $\mu = g_* \text{Law}(W)$ , then

$$(7) \quad \mathbb{E} \|\mathbb{E}[U_{g(W)} Y \mid S']\| \leq (1 - \Gamma_k(\mu)) \mathbb{E} \|\mathbb{E}[Y \mid S]\|.$$

In particular  $T_w$  need not be constant on fibers of  $g$ .

*Proof.* Write  $p_s = \mathbb{P}(S = s)$ ,  $z_s = \mathbb{E}[Y \mid S = s]$ , and let  $\nu$  be the law of  $W$ . Independence and (6) imply

$$p'_r z'_r = \sum_s p_s \int T_w(s, r) U_{g(w)} z_s d\nu(w), \quad z'_r = \mathbb{E}[U_{g(W)} Y \mid S' = r].$$

For nonzero  $z'_r$  take  $u_r = z'_r / \|z'_r\|$ , with arbitrary unit choices for zero centroids. Summing inner products gives

$$\begin{aligned} \sum_r p'_r \|z'_r\| &= \sum_s p_s \int \sum_r T_w(s, r) \langle U_{g(w)} z_s, u_r \rangle d\nu(w) \\ &\leq \sum_{s: z_s \neq 0} p_s \|z_s\| \int \max_r \langle U_{g(w)} z_s / \|z_s\|, u_r \rangle d\nu(w) \\ &\leq (1 - \Gamma_k(\mu)) \sum_s p_s \|z_s\|. \end{aligned}$$

Only after removing the word-dependent assignment by a pointwise maximum do we push  $\nu$  forward to  $\mu$ . No product-sufficiency assertion is used. The old register and all internal packet cuts are unrestricted.  $\square$

*Remark 3.2* (Why the word matters). In a group with an involution  $r$ , the words  $ee$  and  $rr$  have the same product. A transducer can nevertheless record which first symbol occurred. Thus integration of the internal computation gives a kernel  $T_w$ , not necessarily a kernel  $T_{g(w)}$ . Also, independence of the product alone would be insufficient: an identity-product word correlated with  $Y$  could reveal  $Y$  through its spelling. The hypothesis concerns the entire fresh word. This repairs the word/product mismatch in the preceding formulation without restricting the class of machines or packet supports.

**Theorem 3.3** (Packet budget). *Start with a fixed unit vector. On disjoint intervals use packet words whose full laws are fixed in advance, each independent of the earlier process and of all private random choices. Fixed commands may fill the gaps. If  $k_i$  bounds the register at packet endpoint  $i$ , and a terminal correlation forces  $q_N \geq \kappa > 0$ , then*

$$(8) \quad \kappa \leq \prod_i (1 - \Gamma_{k_i}(\mu_i)), \quad \sum_i \Gamma_{k_i}(\mu_i) \leq \log(1/\kappa).$$

The full words and their products may be noncommuting, and the product map may have collisions.

*Proof.* The ordered internal stochastic matrices of a whole packet multiply to  $T_w$ . Their Markov property gives (6); word freshness gives the required independence. Apply Lemma 3.1 at successive boundaries. A fixed command followed by stochastic compression cannot increase  $q$ , by conditional Jensen. Initially  $q = 1$ . Multiplication proves the product, and  $1 - u \leq e^{-u}$  proves the sum. A factor zero precludes positive terminal correlation, as asserted.  $\square$

For a wordwise specification the test law may be chosen after the available-label profile is known. It does not become information given to the machine. In the next section packets are made of independent letters. In Section 6 they have correlated letters; both satisfy the same full-word hypothesis.

#### 4. FINITE SPECTRAL-GAP ALPHABETS

Let  $d \geq 2$ ,  $m = d - 1$ , and  $\sigma$  be normalized measure on  $\mathbb{S}^{d-1}$ . For a distribution  $p$  on the finite alphabet, put  $Pf(v) = \sum_a p(a)f(U_a v)$ . Our hypothesis is the absolute  $L^2$  gap

$$(9) \quad \|P|_{L^2_0(\sigma)}\| \leq \lambda < 1, \quad 0 < \lambda < 1.$$

Laziness makes an upper spectral gap absolute for symmetric walks. We assume (9) on the full mean-zero function space, not only on the defining  $d$ -dimensional representation. Density alone is not substituted for this analytic hypothesis.

**Lemma 4.1** (Uniform mixing for Lipschitz tests). *There is  $C_d$  such that every real 1-Lipschitz  $f$  with values in  $[-1, 1]$  satisfies*

$$(10) \quad \sup_v |P^B f(v) - \sigma f| \leq C_d \lambda^{2B/(m+2)}.$$

For  $d = 3$  one can take  $C_3 = 3$ .

*Proof.* Orthogonal actions preserve distances, so  $h = P^B f - \sigma f$  is 1-Lipschitz. Its  $L^2$  norm is at most  $\lambda^B$ , since  $\|f - \sigma f\|_2^2$  is a variance bounded by one. A chordal radius- $r$  ball has mass at least  $c_d r^m$  for  $0 < r \leq 1$ . Averaging  $|h(v)| \leq |h(u)| + r$  over this ball and using Cauchy–Schwarz gives

$$|h(v)| \leq r + c_d^{-1/2} r^{-m/2} \lambda^B.$$

Take  $r = \lambda^{2B/(m+2)}$ . The ball estimate follows from polar integration and  $\sin t \geq 2t/\pi$  on  $[0, \pi/2]$ . On  $\mathbb{S}^2$  the chordal cap mass is exactly  $r^2/4$ ; taking  $r = \lambda^{B/2}$  gives  $3\lambda^{B/2}$ .  $\square$

**Lemma 4.2** (Finite-word orbit distortion). *There are constants  $c_d > 0$  and integers  $B_k = O_{d,\lambda}(\log(k+1))$  such that the product law  $\mu_{B_k}$  of  $B_k$  independent command letters satisfies*

$$(11) \quad \Gamma_k(\mu_{B_k}) \geq c_d k^{-2/m}.$$

For  $d = 3$ , the explicit choices

$$(12) \quad B_k = \left\lceil \frac{2 \log(12k)}{-\log \lambda} \right\rceil, \quad \Gamma_k(\mu_{B_k}) \geq \frac{1}{4k}$$

are valid.

*Proof.* A chordal radius- $r$  cap has mass at most  $A_d r^m$ , with  $A_d \geq 1$ . For any  $k$  unit centers, choose  $r = (2A_d k)^{-1/m}$ . Outside their union, of mass at least one half, the loss  $1 - \max_i \langle v, u_i \rangle$  is at least  $r^2/2$ . Consequently the spherical average loss is at least  $a_d k^{-2/m}$ , where  $a_d = (2A_d)^{-2/m}/4$ . The function  $f(v) = \max_i \langle v, u_i \rangle$  is 1-Lipschitz and lies in  $[-1, 1]$ . Lemma 4.1 gives, uniformly in the centers and starting direction,

$$P^B f(v) \leq 1 - a_d k^{-2/m} + C_d \lambda^{2B/(m+2)}.$$

Choose  $B_k$  so the last term is at most  $a_d k^{-2/m}/2$ . This proves the first assertion. Powers of  $P$  and chronologically ordered products give the same law here, since the independent letters have a common distribution and their joint law is invariant under reversal.

On  $\mathbb{S}^2$  take  $r = \sqrt{2/k} \leq \sqrt{2}$ . The exact cap mass  $r^2/4$  gives spherical loss at least  $1/(2k)$ . Equation (12) makes  $3\lambda^{B_k/2} \leq 1/(4k)$ , proving the sharper constants. Notice that  $B_k$  counts ordinary inputs, not one Haar input.  $\square$

**Theorem 4.3** (Finite-alphabet width and occupation). *Assume (9),  $0 < \rho \leq 1/10$ , and  $0 \leq \varepsilon < \rho/(2\sqrt{d})$ . Then*

$$(13) \quad c_{d,\lambda,\rho,\varepsilon} \left( \frac{N}{\log(N+1)} \right)^{m/2} \leq W_{N,\varepsilon} \leq W_{N,0} \leq C_d N^{m/2}.$$

*In particular  $\lim_{N \rightarrow \infty} \log W_{N,\varepsilon} / \log N = m/2$ . Every available-label profile with this error satisfies*

$$(14) \quad \#\{1 \leq t \leq N : K_t \leq k\} \leq B_k - 1 + c_d^{-1} B_k k^{2/m} \log(1/\kappa_d).$$

*The other cuts may have arbitrarily large registers. For  $d = 3$  one may replace the second term by  $4B_k k \log(1/\kappa_3)$  using (12). The exact upper realization has common command rows and an  $N$ -dependent decoder.*

*Proof of the lower and occupation bounds.* Under the independent-letter law, every consecutive length- $B_k$  block is a fresh packet. Lemma 2.3 and Theorem 3.3 imply for a peak- $k$  machine

$$(15) \quad \lfloor N/B_k \rfloor c_d k^{-2/m} \leq \log(1/\kappa_d).$$

Thus  $N < B_k(1 + c_d^{-1} k^{2/m} \log(1/\kappa_d))$ . As  $B_k \leq C \log(k+1)$ , this implies the first inequality in (13). Explicitly, if  $k \geq N^{m/2}$  it is immediate; otherwise  $\log(k+1) \leq C_m \log(N+1)$  and rearrangement suffices. Constants absorb the finitely many small  $N$ .

For occupation, discard at most  $B_k - 1$  early endpoints and greedily select low-width endpoints at spacing at least  $B_k$ . Each selected interval removes at most  $B_k$  candidate endpoints. If  $l$  intervals are selected, their total loss is at least  $l c_d k^{-2/m}$ , irrespective of the internal widths. The packet budget bounds this by  $\log(1/\kappa_d)$  and proves (14). The initialization cut is not in this count. The argument remains valid for positive-mass states under the selected independent-letter law.  $\square$

**Lemma 4.4** (Rational spherical synthesis). *For every  $N \geq 1$  there is a rational finite set  $V_N \subset \mathbb{S}^{d-1}$  of cardinality at most  $C_d N^{m/2}$  such that*

$$\eta_N \mathbb{B}^d \subset \text{conv } V_N, \quad \eta_N = 1 - \frac{1}{8N}.$$

*For finitely many orthogonal commands, this gives the exact upper bound in (13). If the commands, seeds and  $\rho$  are rational, all transition, initialization and decoder entries may be chosen rational, with at most  $d+1$  successors in each command row.*

*Proof.* Use the two stereographic charts

$$t \mapsto \left( \frac{2t}{1 + \|t\|^2}, \pm \frac{1 - \|t\|^2}{1 + \|t\|^2} \right), \quad t \in [-1, 1]^m.$$

Every sphere point has a preimage in the unit ball in one chart. Each chart is 2-Lipschitz. A grid of mesh  $1/M$ , with  $M = \lceil 2\sqrt{mN} \rceil$ , is therefore within chordal distance  $\sqrt{m}/M$  of every sphere point. Its at most  $2(2M+1)^m$  images are rational. In every unit direction the support function of their convex hull is at least  $1 - m/(2M^2) \geq \eta_N$ .

Write  $P = \text{conv } V_N$ ,  $a_t = \eta_N^{-t}/4$ . From label  $u \in V_N$  on command  $a$ , choose coefficients expressing  $\eta_N U_a u$  as a convex combination of  $V_N$ . This is possible by ball containment. The coefficients depend on  $a, u, N$ , not on the epoch. Initialize to mean  $\rho x$  in  $a_0 P$ , since  $\rho \leq 1/10 < 7/32 \leq \eta_N/4$ . At the final cut use mean decoder  $a_N e_j^T u$ . Bernoulli's inequality gives  $\eta_N^N \geq 7/8$ , so  $a_N \leq 2/7 < 1$ . The conditional mean update is  $a_{t+1} \mathbb{E}[u' \mid u, a] = a_t U_a u$ , proving exactness by induction. Only the vertex label is retained.

For rational data, convex feasibility is a rational linear system. A basic feasible solution has at most  $d+1$  nonzero coefficients and is rational; apply this separately to the finitely many rows and

seeds. An extra binary-output cut has two labels and does not change the bound. This proves the upper assertion of Theorem 4.3.  $\square$

The mixing and quantization inequalities are classical analytic and geometric mechanisms. Their use above is a finite-word, all-hidden-state compression bound. A logarithmic mixing time is explicitly paid. Neither an atomic Haar command nor a uniform-in- $d$  constant is used.

## 5. FIVE RATIONAL COMMANDS AND A QUBIT

Consider the fixed matrices

$$(16) \quad R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -7/25 & -24/25 \\ 0 & 24/25 & -7/25 \end{pmatrix}, \quad R_z = \begin{pmatrix} -7/25 & -24/25 & 0 \\ 24/25 & -7/25 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

and the five-letter alphabet  $\mathcal{A}_* = \{\text{Id}, R_x, R_x^{-1}, R_z, R_z^{-1}\}$ . Use the six seeds  $\{\pm e_j : 1 \leq j \leq 3\}$ , signal  $\rho = 1/10$ , and three terminal coordinate queries. Every specified probability lies in  $[9/20, 11/20]$  at every horizon. Both the alphabet and the matrices are independent of  $N$ .

**Theorem 5.1** (A finite noncommuting rational family). *For the experiment (16), every fixed  $0 \leq \varepsilon < 1/(20\sqrt{3})$  has*

$$(17) \quad c_\varepsilon \frac{N}{\log(N+1)} \leq W_{N,\varepsilon}(\mathcal{A}_*) \leq W_{N,0}(\mathcal{A}_*) \leq CN.$$

*The exact upper machine can have rational entries and common command rows. Every separate positive minimum is four. If  $\lambda < 1$  is the sphere gap constant for the lazy walk with weights  $1/2, 1/8, 1/8, 1/8, 1/8$ , then a peak- $K$  machine necessarily obeys*

$$(18) \quad N < B_K \{1 + 4K \log(1/\kappa_3)\}, \quad B_K = \left\lceil \frac{2 \log(12K)}{-\log \lambda} \right\rceil, \quad \kappa_3 = \frac{1}{10\sqrt{3}} - 2\varepsilon.$$

*No numerical value of the spectral gap is asserted.*

*Proof.* Let  $\sigma_x, \sigma_y, \sigma_z$  denote the Pauli matrices and put  $A_x = (3I - 4i\sigma_x)/5$ ,  $A_z = (3I - 4i\sigma_z)/5$  in  $\text{SU}(2)$ . Their adjoint actions on the traceless Hermitian matrices are precisely  $R_x, R_z$ . Their eigenvalues include  $(3 + 4i)/5$ . This number is not a root of unity: otherwise its sum with its inverse,  $6/5$ , would be a rational algebraic integer, hence an integer. Their powers are therefore dense in the respective one-parameter axial subgroups. The Lie algebra generated by  $i\sigma_x, i\sigma_z$  contains their bracket, a nonzero multiple of  $i\sigma_y$ , so the closed subgroup they generate is all of  $\text{SU}(2)$ . In particular the generators do not commute.

The matrices have algebraic entries. Bourgain–Gamburd’s spectral-gap theorem [1, Theorem 1] applies to their symmetric averaging operator on  $L^2(\text{SU}(2))$ . Adding probability  $1/2$  at the identity makes its spectrum nonnegative and its mean-zero norm strictly below one. The action on the sphere is a homogeneous quotient: lifting  $f(v)$  to  $f(gv_0)$  embeds  $L^2(\mathbb{S}^2)$  isometrically into  $L^2(\text{SU}(2))$  and intertwines the averaging operators. Hence the same gap holds on the sphere.

Apply Theorem 4.3, with the explicit constants in (12). Rational synthesis follows from Lemma 4.4. Proposition 2.2 gives four at each separate cut, since  $3\rho < 1$ . The spectral-gap theorem is the substantive external input; no finite collection of eigenvalue computations is used as its proof.  $\square$

This theorem has a different arithmetic content from the binary example with rational rotation entries. One rotation may have exceptionally slow circle recurrences. Two noncommuting algebraic axes instead invoke a spectral gap on the entire sphere. We do not infer that either individual rotation angle is badly approximable.

**Proposition 5.2** (Quantum probabilities versus threshold languages). *The experiment in Theorem 5.1 has an exact single-qubit realization with a finite, horizon-independent collection of operations. A general one-way quantum automaton of dimension two realizes its probabilities on valid prepare–command–query words. For any fixed strict cutpoint, its threshold language has a PFA realization with at most five states by [2, Theorem 3.2]. Nevertheless any classical clocked transducer approximating these numerical probabilities at the stated tolerance has width bounded below by (17).*

*Proof.* For seed  $x$  prepare

$$\varrho_x = \frac{1}{2}(I + \rho(x_1\sigma_x + x_2\sigma_y + x_3\sigma_z)).$$

It is a density matrix because  $\|x\| = 1$  and  $\rho < 1$ . A command uses the corresponding unitary  $I, A_x^{\pm 1}, A_z^{\pm 1}$ . Their conjugations rotate the Bloch vector by (16). Measuring  $\sigma_j$  yields  $\text{tr}(\varrho_w(I + b\sigma_j)/2) = (1 + b\rho e_j^T U_w x)/2$ , exactly the required law. A query-dependent unitary before a fixed  $\sigma_z$  measurement implements all three queries; a seed symbol is a completely positive reset channel. Thus the operations define a dimension-two general quantum automaton on a finite alphabet, including all words outside the promised protocol with its usual automaton semantics.

The cited strict-cutpoint conversion concerns that entire language and therefore also its valid words. It preserves threshold signs, not numerical probabilities. In the conversion, the deviation from the classical cutpoint is multiplied by a positive length-dependent shrinking factor [2, Proposition 3.1]. Such attenuation is harmless for language equivalence and cannot supply the fixed-correlation requirement of Lemma 2.3. The last assertion is exactly Theorem 5.1; it even permits horizon-dependent and nonstationary classical simulators.  $\square$

The variable in (17) is input length, with quantum dimension fixed. The quadratic state-cost results of Chen–Wu [2, 3] instead vary quantum dimension under strict-cutpoint equivalence. Neither result is contradicted or strengthened in its own metric by changing to the other objective.

## 6. A MATCHED NONCOMMUTING FINITE CLASS

The preceding finite spectral-gap class determines a growth exponent, with a logarithmic order gap. There is also a finite noncommuting class with a matched order. Its orbit structure is different from a sphere.

Identify  $\mathbb{R}^{2r}$  with  $\mathbb{C}^r$ , fix an irrational  $\alpha$ , and put  $\zeta = e^{2\pi i\alpha}$ . A *resonant monomial command* has the form

$$(19) \quad (U_a z)_j = \zeta^{n_{a,j}} \begin{cases} z_{\pi_a^{-1}(j)}, & \epsilon_{a,j} = 1, \\ \overline{z_{\pi_a^{-1}(j)}}, & \epsilon_{a,j} = -1, \end{cases}$$

where  $\pi_a$  is a permutation,  $n_{a,j}$  is an integer, and  $\epsilon_{a,j} \in \{-1, 1\}$ . Fix finitely many such commands, and let  $M = \max(1, \max_{a,j} |n_{a,j}|)$ . Include the identity and the command  $A$  that multiplies the first coordinate by  $\zeta$  and fixes the rest. Take the  $4r$  seeds  $(\pm 1 \pm i)e_j$ , signal  $0 < \rho \leq 1/(10r)$ , and one of the  $2r$  real coordinate queries. The specified mean is the corresponding coordinate of  $\rho U_w x$ .

**Theorem 6.1** (Sharp monomial width). *If  $b_\alpha := \inf_{l \geq 1} l \|l\alpha\|_{\mathbb{R}/\mathbb{Z}} > 0$ , then for each fixed  $0 \leq \varepsilon < \rho/2$ ,*

$$(20) \quad W_{N,\varepsilon}^{\text{mon}} = \Theta_{r,A,\alpha,\rho,\varepsilon}(N^{1/3}).$$

*The exact upper machine has common command rows and at most four successors in any such row. Its final decoder may depend on  $N$ . Every separate exact positive minimum is  $2r + 1$ .*

*Lower bound.* Restrict to seed  $(1+i)e_1$ , commands  $\text{Id}, A$ , and the first two real queries. The conditional target is the planar phase  $\rho(1+i)\zeta^{L_N}$ . Combining its two mean columns shows that  $q_N \geq \kappa = \rho - 2\varepsilon$ , as in Lemma 2.3 with the sharper planar normalization.

For a proposed peak  $k$ , put  $B = 2k - 1$  and choose the length- $B$  word  $A^J \text{Id}^{B-J}$  with  $J$  uniform on  $\{0, \dots, B\}$ . Its  $2k$  circle points are separated by  $s_B = \min_{1 \leq l \leq B} \|l\alpha\|$ . Each open arc of radius  $s_B/2$  contains at most one of these points. Any  $k$  centers therefore leave at least half of them at distance at least  $s_B/2$ . The average loss is at least  $\frac{1}{2}(1 - \cos(\pi s_B)) = \sin^2(\pi s_B/2) \geq s_B^2$ . The full-word lemma applies although the packet's letters are correlated. Consecutive independent packets imply

$$\lfloor N/B \rfloor \frac{b_\alpha^2}{B^2} \leq \log(1/\kappa), \quad N < B + b_\alpha^{-2} B^3 \log(1/\kappa).$$

This proves the lower order against every hidden realization. No character of the full command group was used, only a sublanguage.  $\square$

*Sparse exact upper construction.* Take a convergent  $p_0/q_0$  of  $\alpha$ , put  $q = 2q_0$  and  $\delta = 2\pi(\alpha - p_0/q_0)$ . Choose the first convergent for which

$$(21) \quad q \geq \max\{8M, 8, (160MN)^{1/3}\}.$$

Then  $|\delta| < 8\pi/q^2$  and  $|n\delta| < \pi/q$  for  $|n| \leq M$ . Set  $a = \pi/q$ , and for each needed integer  $n$  put

$$\lambda_n = \frac{\cos(a - |n\delta|)}{\cos a}, \quad \omega_n = \frac{\sin |n\delta|}{\lambda_n \sin(2a)}, \quad \Lambda = \max_{|n| \leq M} \lambda_n.$$

These numbers obey  $1 \leq \lambda_n \leq \Lambda$  and  $0 \leq \omega_n \leq 1$ . Let  $u_l = e^{2\pi i l/q}$ , indices modulo  $q$ . The two-point law on labels  $l + 2np_0$  and  $l + 2np_0 + \text{sgn}(n\delta)$ , of weights  $1 - \omega_n, \omega_n$ , has mean  $\zeta^n u_l / \lambda_n$ . For  $n = 0$  interpret it as the single label  $l$ . This is the intersection of a polygon edge with the rotated ray.

The register is a pair  $(j, l)$ , comprising one mode and one polygon label. Command  $a$  sends the mode to  $j' = \pi_a(j)$  and, if needed, replaces  $l$  by  $-l$  to conjugate. Draw the just described edge label for  $n = n_{a,j'}$ . With probability  $(1 + \lambda_n/\Lambda)/2$  retain it; otherwise replace it by its antipode, label  $l + q/2$ . The expected complex label is exactly the commanded one divided by  $\Lambda$ . At most four labels occur. This antipodal step prices a common radial factor without a free zero state or a dense uniform redraw.

Associate  $a_t u_l e_j$  with label  $(j, l)$ , where  $a_t = \Lambda^t/4$ . The conditional mean update is exactly  $U_a$ . Moreover

$$\log \Lambda \leq M|\delta| \tan a \leq 16\pi^2 M/q^3 < 160M/q^3, \quad a_N \leq e/4 < 1.$$

The seed occupies one mode. Its planar vector has radius  $\rho\sqrt{2} \leq \sqrt{2}/10 < \cos(\pi/8)/4$ , hence lies in the initial polygon and can be initialized using at most three vertices. Decoder means are the real coordinates of  $a_N u_l e_j$ , with zeros on other modes. Induction gives the exact specified law on all words, not just the restricted lower-bound words. Only  $(j, l)$  persists.

Bad approximability is equivalent to bounded partial quotients, which bound the ratio of consecutive convergent denominators. Thus the first choice in (21) has  $q = O_{\alpha, M}(N^{1/3})$ , proving the upper order with  $rq$  labels.  $\square$

*Separate minima.* The seed vectors span  $\mathbb{R}^{2r}$ ; identity suffixes separate their coordinates, so normalized residual rank is  $2r + 1$ . All predictive vectors have norm  $\rho\sqrt{2}$ . A regular simplex with inradius  $\rho\sqrt{2}$  has circumradius  $2r\rho\sqrt{2} \leq \sqrt{2}/5 < 1$ . Its vertices define legal continuations under every orthogonal command. The selected-cut construction of Proposition 2.2 gives the matching positive minimum, with finite raw-word storage elsewhere.  $\square$

**Proposition 6.2** (A full group not seen by a character). *For every  $r \geq 2$ , at most five commands suffice to generate an instance of Theorem 6.1 whose compact closure is  $O(2)^r \rtimes S_r$ . Its real representation on  $\mathbb{R}^{2r}$  is irreducible. Every continuous one-dimensional unitary character is trivial on the connected torus  $SO(2)^r$ , hence cannot see  $A$ 's irrational phase.*

*Proof.* Use Id,  $A$ , conjugation of the first mode, the cyclic permutation of modes, and the transposition of the first two modes. The last two permutations generate  $S_r$ ; for  $r = 2$  duplicate commands are removed. Irrational powers of  $A$  fill one circle, and permutation conjugates fill all coordinate circles. Conjugations supply their reflections, proving the asserted closure.

An invariant real subspace under these circle actions decomposes into coordinate planes: averaging over all other circles projects onto a chosen plane. A nonzero projection contains that whole plane by rotation, and permutation invariance then supplies all planes. This proves irreducibility. Finally, conjugation of a coordinate circle element sends it to its inverse. In a one-dimensional character its value must therefore equal its inverse. Continuity on the connected circle forces that value to be one. Apply this in each coordinate.  $\square$

This example is genuinely noncommuting and is not an application of a character of its entire compact group. Its lower bound still uses a cyclic sublanguage, and its upper bound uses the monomial structure. It does not classify arbitrary finite dense subsets of  $SO(d)$ . The case  $r = 1$ ,  $\rho = 1/10$  and commands Id,  $A$  recovers the original sharp rotation experiment of [10] without changing its signal, seed set, error tolerance or hidden-state quantifier.

## 7. FINITE COINS WITH CHARGED CONTROL

The atomic model permits arbitrary exact row probabilities. We now separate a finite random-bit implementation. The environment supplies an input only at a ready boundary and waits until the update has finished. Fair bits are private. The row table may contain precomputed finite binary thresholds, but the bit position, current input, old label and control state are all charged. There is no free microstep clock.

**Theorem 7.1** (Sparse-row dyadic compiler). *Suppose a finite command transducer has peak  $K$ , at most  $L$  successors per row, fixed finite seed and query alphabets, and common command rows. For any  $\delta > 0$  it has a self-paced fair-bit implementation whose uniform terminal row-TV error increases by at most  $\delta$ , using*

$$(22) \quad C_{A,X,J,L}K(b+1) \text{ persistent labels,} \quad b = \max \left\{ 1, \left\lceil \log_2 \frac{C_L(N+2)}{\delta} \right\rceil \right\},$$

*and at most  $(L-1)b$  fair bits for a command update. The same bound holds for sparse initialization and the binary terminal decoder. Tables and the prescribed macroscopic final boundary remain nonuniform.*

*Proof.* A categorical row with at most  $L$  outcomes is a binary decision tree with at most  $L - 1$  internal nodes. At each node express the probability of choosing one subtree conditionally on reaching that node. A zero-mass node is unreachable and may use an arbitrary conditional row. Round each conditional probability down to a multiple of  $2^{-b}$ . Coupling the binary decisions shows that the row-TV discrepancy is at most  $(L - 1)2^{-b}$ , without needing the original probabilities to be rational. Initialization and binary decoding are treated in the same way.

Thresholds zero and one are deterministic. For  $0 < m < 2^b$ , to sample the dyadic Bernoulli threshold  $m/2^b$ , compare independent fair bits with the  $b$  binary digits of  $m$ , from most to least significant. At the first mismatch the comparison is decided; if all digits agree, return the prescribed strict-comparison outcome. No prefix integer is stored. The comparison retains only its position  $i \in \{1, \dots, b\}$ ; while all bits agree, their values are already the fixed threshold prefix.

A categorical tree additionally retains one of at most  $L - 1$  nodes. It must retain the old label and the current input until a leaf gives the new label. These are all included in (22), along with ready, seed and query phases. There is no second uncharged output index. The common-row assumption eliminates a retained epoch counter inside the sampler. An external end query selects the final decoder after the prescribed number of completed inputs.

TV contraction under stochastic kernels and induction on the actual word give at most  $C_L(N + 2)2^{-b}$  terminal discrepancy. This is at most  $\delta$  by the chosen  $b$ . The argument couples legal completed updates and therefore prices every command even when the bit comparison stops early. Its duration is at most  $(L - 1)b$  bits per update.  $\square$

**Corollary 7.2** (Leading label bits with finite coins). *For every fixed positive error below the thresholds of the preceding theorems, their explicit machines admit the following finite-coin peaks:*

$$\begin{aligned} O(N^{1/3} \log(N + 1)) & \quad \text{for the resonant monomial class,} \\ O(N^{(d-1)/2} \log(N + 1)) & \quad \text{for the spectral-gap class.} \end{aligned}$$

*Consequently the least persistent bits in this self-paced, nonuniform fair-bit model have leading coefficients  $1/3$  and  $(d - 1)/2$  in  $\log_2 N$ , respectively, with additive  $O(\log \log(N + 1))$  uncertainty.*

*Proof.* The monomial upper has at most four successors; the spherical upper has at most  $d + 1$ . Their initialization is sparse and their decoder binary. Compile the exact machine with tolerance equal to the fixed desired error. Formula (22) gives the upper peaks. Every such sampler, when observed at ready boundaries, is itself an atomic transducer with at most its total number of labels. Hence the atomic lower bounds apply, irrespective of its internal timing. Taking binary logarithms and using (13) and (20) proves the stated leading coefficients.  $\square$

This is not an exact finite-bit implementation of an irrational row at zero error. It is a fixed-error compiler with an explicitly charged input latch and bit counter. It does not make the row description or its construction free in an ordinary uniform-space model; those costs are outside both nonuniform measures. For the rational gates, exact rational atomic synthesis is additionally available, but exact rational sampling with unbounded rejection duration is a separate implementation choice.

## 8. OBJECTIVES, ANTECEDENTS, AND REMAINING DISTINCTIONS

**8.1. Quantum and probabilistic automata.** The prepare–rotate–query law is a numerical behavior, not just a language. Proposition 5.2 gives its exact quantum model and an explicit classical length-dependent obstruction. Chen–Wu’s revised paper [2] has a different title and sharper theorem than its April version: its stated cost is  $n^2 + 1$  under strict cutpoints. Their companion work [3] treats the simulation cost of reversible quantum models through prepare–test and sign geometry. These compare threshold languages as quantum dimension varies. A shrinking positive acceptance margin can preserve such a language at all lengths and fail every fixed numerical tolerance in the present task.

The September symmetry study [4] likewise distinguishes reachable–observable rank from operational threshold memory. Its strict-cutpoint objective is not wordwise preservation of numerical probabilities. Our sphere example already has fixed real predictive rank four, so a rank theorem alone cannot yield its diverging compatible width. The present comparison does not claim that quantum/classical state separation itself is new.

Lumbreras–Ma–Thompson–Gu [5] analyze a stationary world model with an irrational phase, repeated histories, value error and decision loss, and supply an exact qutrit realization. Their Theorems 28–30 concern that stationary decision task. Here the classical machine may be redesigned for every finite horizon and may change its rows at every cut; one externally prescribed

terminal probability is tested. Neither a stationary peripheral-spectrum argument nor a strict-cutpoint conversion supplies our finite nonuniform width bounds.

**8.2. Spectral and geometric inputs.** Bourgain–Gamburd [1] supplies the full spectral-gap input for Theorem 5.1. We do not prove a new expansion theorem or a new sphere-covering law. The gap converts finite command length into a uniform Lipschitz mixing scale; the full-word contraction then converts that scale into a hidden-register cost. This distinguishes the finite alphabet from the all-rotation-input theorem retained in [10]. The gap constant is fixed but not evaluated numerically. Constants may deteriorate with dimension, the generating set and the error margin.

The lower bound uses a probability law on external commands, not an adaptive policy implemented by the simulator. In the spectral-gap class the test letters are independent. In the monomial class they are correlated within width-dependent packets. Berkes–Borda [6] study the harmonic and Diophantine behavior of the uncompressed circle walk; compression into an endpoint register is an additional operation.

The transducer is a probabilistic ordered read-once branching program with real readout. For a binary alphabet its usual Boolean-input matrix Fourier coefficient is the ordered product of the matrices  $(T_{t,0} + (-1)^{s_t} T_{t,1})/2$ . This algebraic identity is not the packet converse. The Fourier-growth results for regular and width-three programs [7, 8, 9] have their stated hypotheses and objectives. An arbitrary stochastic row need not preserve the uniform state law. Conversely, bounds valid for all deterministic tables can sometimes pass by convexity to randomized rows. Private row choices should not be mistaken for a persistent shared seed available to the decoder.

**8.3. Inherited statements and preservation.** The sharp bounded-type binary theorem, nonuniform occupation, actual terminal-error bounds, the angular coefficient  $l^2 - 1$ , and the separate compact-input result of [10] remain in the unaltered supporting article. The corrected full-word lemma supplies the advertised general packet implication without a product-sufficiency restriction. For a compact command table, a Borel convex choice can be made by triangulating a finite polytope and using the first containing simplex in a fixed order; affine barycentric coordinates on finitely many closed simplices are Borel. No such infinite table is used by the finite-alphabet results.

The accumulated local deficiency certificate from the preceding work is not the minimum actual terminal error. Given a fixed profile in the sphere case, the present proof directly yields

$$(23) \quad \mathcal{E}_N(K) \geq \frac{1}{2} \left[ \frac{\rho}{\sqrt{d}} - \exp\{-c_d K^{-2/(d-1)} \lfloor N/B_K \rfloor\} \right]_+.$$

Indeed Lemma 2.3 holds for every candidate’s actual error, and the packet product bounds  $q_N$  above. This remains valid when intermediate approximation errors cancel. A sum of executable local garbling defects is only an upper certificate for a particular terminal error, by TV contraction; applying (23) to it does not turn that certificate into an intrinsic equality.

**8.4. Conclusion.** There are now two finite noncommuting classes with distinct quantitative laws. Spectral-gap actions on spheres have polynomial width exponent  $(d-1)/2$ , with the displayed logarithmic order gap. Resonant monomial actions have matched cube-root order and need not be detected by a character of the full group. Both conclusions allow arbitrary hidden states and layer-dependent stochastic rows. The explicit rational gates give a numerical-probability comparison with a single qubit, not a new strict-cutpoint state-cost theorem.

The logarithmic gap for spectral-gap alphabets, optimal finite constants, and classification of all irrational cyclic angles remain quantitative questions. General adaptive experimental design is a different task. The finite-coin corollary concerns a self-paced nonuniform sampler and does not

identify program-table space with label space. These distinctions leave the proved finite-alphabet results intact; they are not hypotheses silently replaced during implementation.

# GENERAL THETA FOUNDATIONS I: SHARP WIDTH OF HIDDEN ROTATION EXPERIMENTS

QIAN QI

**ABSTRACT.** We determine the order of the least hidden-state width of a uniformly positive binary-command rotation experiment. For every badly approximable angle and every fixed sufficiently small uniform output error, the minimum width is  $\Theta(N^{1/3})$ . The lower bound permits arbitrary stochastic transitions, cut-dependent state spaces, unobservable hidden directions, and a different machine for every horizon. It therefore matches the previous resonant-polygon construction without a vector-state restriction. The proof groups commands into independent packets whose rotation counts are separated. Compressing one packet into  $k$  labels loses a fixed multiple of  $k^{-2}$  of the conditional phase amplitude, while the packet uses  $2k - 1$  commands. Multiplying these losses yields both the sharp order and a nonuniform occupation bound. A representation-valued version gives an orbit-quantization budget for general compact groups; for the separate model with all  $\mathrm{SO}(d)$  rotations available as commands it yields the matched order  $N^{(d-1)/2}$ . We also bound the actual optimal terminal simulation error, independently of cancellation in local deficiency certificates. Throughout, width counts available persistent labels in a clocked atomic stochastic-row model; descriptions, arithmetic and exact real sampling are not charged. The fixed-alphabet rotation theorem and the compact-command extension have distinct input conventions.

## 1. INTRODUCTION

A small sufficient state at each separate experimental cut need not be compatible with small states at all cuts of one stochastic machine. The rotation experiment below makes this discrepancy quantitative while keeping the seed, command, query and answer alphabets fixed. Its separate positive minimum is three at every cut. Its simultaneous minimum grows with the number of commands, even when a fixed uniform approximation error is allowed.

Write  $R_\alpha$  for planar rotation through  $2\pi\alpha$ . A seed  $x \in \{-1, 1\}^2$  is followed by  $N$  binary commands and one coordinate query  $j \in \{1, 2\}$ . The answer  $B \in \{-1, 1\}$  must have mean

$$(1) \quad \mathbb{E}[B \mid x, c_1, \dots, c_N, j] = \frac{1}{10} e_j^T R_\alpha^{c_1 + \dots + c_N} x.$$

All answer probabilities belong to  $[(1 - \sqrt{2}/10)/2, (1 + \sqrt{2}/10)/2]$ , independently of  $N$ . Let  $W_{N,\varepsilon}(\alpha)$  denote the least peak number of persistent labels achieving total-variation error at most  $\varepsilon$  on every seed, word and query; Definition 2.1 is precise. Set

$$b_\alpha = \inf_{l \geq 1} l \|l\alpha\|_{\mathbb{R}/\mathbb{Z}}.$$

We call  $\alpha$  *badly approximable* when  $b_\alpha > 0$ ; equivalently its continued-fraction partial quotients are bounded.

*Key words and phrases.* Positive realization, probabilistic branching programs, causal memory, rotation, quantization, comparison of experiments.

**Theorem 1.1** (Sharp hidden width). *Let  $\alpha$  be badly approximable and  $0 \leq \varepsilon < 1/20$  be fixed. In the clocked atomic stochastic-row model,*

$$(2) \quad W_{N,\varepsilon}(\alpha) = \Theta_{\alpha,\varepsilon}(N^{1/3}).$$

*More explicitly, put  $\kappa = 1/10 - 2\varepsilon$ . Every realization of peak at most  $K$  satisfies*

$$(3) \quad N < (2K - 1) + \frac{(2K - 1)^3}{b_\alpha^2} \log \frac{1}{\kappa}.$$

*The upper bound is exact, uses two command matrices independent of the epoch, and has a decoder depending on  $N$ . At the golden angle  $\alpha = (\sqrt{5} - 1)/2$  and zero error,*

$$(4) \quad \max\{3, (N/168)^{1/3}\} \leq W_{N,0}(\alpha), \quad W_{N,0}(\alpha) < 2 \max\{5, (40N)^{1/3}\}.$$

*In fact  $W_{N,0} \geq 3$  and  $W_{N,0} > (N/168)^{1/3}$  separately.*

None of the constants is optimized. The conclusion identifies the order of width, not the exact integer optimum or its leading constant. In persistent bits it gives  $(\log_2 N)/3 + O_{\alpha,\varepsilon}(1)$ . This is not a uniform space bound charging program description or exact real arithmetic.

The predecessor Fourier argument gives  $\Omega(N^{1/5})$  for the same unrestricted hidden-state class [15]. Its conditional phase amplitude is the starting point here. The improvement does not come from changing a trigonometric-kernel constant. Instead we choose correlated commands *inside* fresh independent packets. A packet of  $2k - 1$  commands produces  $2k$  separated phase increments. Whatever hidden mechanism is used inside it, a  $k$ -label endpoint loses a proportion of amplitude of order  $k^{-2}$ . Since a wordwise simulator must pass this input distribution, multiplication over disjoint packets gives the cube-root converse. This also controls the number of low-width cuts without bounding the remaining widths.

The underlying model is a nonuniform probabilistic ordered read-once branching program, with two terminal affine readouts. Section 7 compares the result with the Fourier-growth theorems of Reingold–Steinke–Vadhan, Steinke–Vadhan–Wan and Lee–Pyne–Vadhan [1, 2, 3]. Our packet argument is a hidden-compression estimate, not a theorem about pseudorandom generators or Boolean Fourier growth. The circle-walk literature [5] describes the uncompressed walk; conditional averaging in a small register is an additional operation.

| Notation                    | Meaning                                                                 |
|-----------------------------|-------------------------------------------------------------------------|
| $K_t, W_{N,\varepsilon}$    | Available labels at cut $t$ ; optimum peak.                             |
| $q_t$                       | Expected norm of a conditional past-orbit mean, used only in the proof. |
| $s_B(\alpha)$               | $\min_{1 \leq l \leq B} \ l\alpha\ _{\mathbb{R}/\mathbb{Z}}$ .          |
| $\Gamma_k(\mu)$             | Worst starting-direction $k$ -center orbit distortion.                  |
| $\mathcal{E}_N(\mathbf{K})$ | Minimum actual terminal row error for a profile.                        |
| $\mathcal{D}(E)$            | Accumulated local deficiency certificate of a diagram.                  |

Contribution and provenance. The packet contraction, sharp unrestricted order, nonuniform packet budget and compact-group applications are the new results. The conditional-amplitude variable is inherited from [15]; the resonant-polygon upper construction is inherited from [14] and is proved again here. Jensen’s inequality, sphere quantization, continued fractions and finite Blackwell garbling are classical tools. The earlier Fourier theorem is preserved, with its angular estimate sharpened in Appendix A. No accumulated archive is needed to verify the new proofs in this article.

## 2. THE EXPERIMENT AND ITS REALIZING MACHINES

State distributions are row vectors and  $\Delta_k = \{e \in \mathbb{R}^k : e \geq 0, e\mathbf{1} = 1\}$ .

**Definition 2.1** (Clocked stochastic realization). For a specified  $N$ , a realizing machine has finite state sets  $[K_t]$  for  $0 \leq t \leq N$ , initialization rows  $E_x \in \Delta_{K_0}$ , row-stochastic matrices  $T_{t,c} \in \mathbb{R}_+^{K_t \times K_{t+1}}$  for  $t < N$ ,  $c \in \{0, 1\}$ , and decoder means  $d_j \in [-1, 1]^{K_N}$ . Its conditional answer mean is

$$E_x T_{0,c_1} \cdots T_{N-1,c_N} d_j.$$

Its error is one half the maximum absolute difference from (1), over all seeds, command words and queries. The profile counts *available* labels, including padding. Its peak is  $\max_{0 \leq t \leq N} K_t$ , or the maximum of this number and two if a binary answer is retained at an additional output cut.  $W_{N,\varepsilon}(\alpha)$  is the least such peak at error at most  $\varepsilon$ .

Only the updated register persists. An earlier random seed, a transcript, an input-dependent clock or any retained protocol variable must be in that register. The current input is consumed in its update; seed and query are supplied just once. The epoch is external and the complete row table may depend on  $N$ . All rows, including unused rows, are normalized. Exact atomic stochastic rows and read-only tables are allowed; row construction, arithmetic and table length are not part of this width. A self-paced finite fair-bit compiler for rational rows has additional workspace and is a different resource statement [12].

The commands are externally specified inputs. No independence or fairness is part of the simulation task. A lower bound may impose any distribution on command words, including one chosen after the available profile is known. That distribution is used in the proof and is not a persistent seed supplied to the machine. When counting states under a chosen test law, zero-probability labels may be removed; the conclusions in terms of available labels remain valid.

**Proposition 2.2** (Separate positive minimum). *At every cut after initialization the exact normalized residual rank and the separate positive minimum of (1) are three. The latter permits arbitrary finite registers at the other cuts.*

*Proof.* The predictive vectors are  $R_\alpha^a x/10$ . Idle prefixes from the four seeds span a plane, and two coordinate queries after an idle suffix separate it. Normalization adds the constant row, giving rank three. The triangle with vertices  $(1/2, 0)$  and  $(-1/2, \pm 1/2)$  contains the seed disk of radius  $\sqrt{2}/10$ , since its side distances from the origin are  $1/2$  and  $1/(2\sqrt{5})$ . Its vertices have norm at most  $1/\sqrt{2}$ , so all rotated continuations give valid binary laws. At the chosen cut decompose the actual predictive vector in this triangle. Before it retain the finite raw history; afterwards retain the triangle label and the remaining active-command count. This is a complete finite machine attaining three at that cut. Rank gives the lower bound. This separate-cut construction is inherited from [13, 14].  $\square$

The statement does not require a hidden basis state to possess a predictive vector. Indeed the converse below never projects a hidden simplex, or bounds the number of vertices in such a projection.

## 3. ORBIT QUANTIZATION UNDER STOCHASTIC COMPRESSION

We first state the probabilistic argument in a real finite-dimensional Hilbert space  $H$ . A complex unitary representation is covered by taking its real inner product. Let  $\mathbb{S}(H)$  be the unit sphere and let  $\mu$  be a probability measure on a compact group acting orthogonally on  $H$ , with action  $U_g$ .

**Definition 3.1** (Orbit distortion). For  $k \geq 1$  set

$$(5) \quad \Gamma_k(\mu) = \inf_{v, u_1, \dots, u_k \in \mathbb{S}(H)} \int \min_{i \leq k} (1 - \langle U_g v, u_i \rangle) d\mu(g).$$

It depends only on the representation and the law of a command packet, not on a proposed stochastic realization. It lies in  $[0, 1]$ .

The upper bound one follows by using the direction of  $\int U_g v d\mu(g)$  as one of the centers, with any center if that integral vanishes. The infimum is attained by compactness and continuity. An invariant direction may make the coefficient zero; positivity is a geometric property to be established, not an automatic conclusion for all representations.

**Lemma 3.2** (One-packet contraction). *Let  $Y \in H$  be integrable, let  $S$  be a finite register, and let  $G$  be independent of  $(Y, S)$  with law  $\mu$ . Suppose the new register  $S'$  has at most  $k$  positive-probability values and its conditional law, given  $(Y, S, G)$ , depends only on  $(S, G)$ . Then*

$$(6) \quad \mathbb{E} \|\mathbb{E}[U_G Y \mid S']\| \leq (1 - \Gamma_k(\mu)) \mathbb{E} \|\mathbb{E}[Y \mid S]\|.$$

*Proof.* Write  $z_s = \mathbb{E}[Y \mid S = s]$ ,  $p_s = \mathbb{P}(S = s)$  and  $T_g(s, r) = \mathbb{P}(S' = r \mid S = s, G = g)$ . Conditional independence gives

$$p'_r z'_r = \sum_s p_s \int T_g(s, r) U_g z_s d\mu(g), \quad z'_r = \mathbb{E}[U_G Y \mid S' = r].$$

Choose  $u_r = z'_r / \|z'_r\|$  when the latter is nonzero and any unit vector otherwise. Thus

$$\begin{aligned} \sum_r p'_r \|z'_r\| &= \sum_s p_s \int \sum_r T_g(s, r) \langle U_g z_s, u_r \rangle d\mu(g) \\ &\leq \sum_{s: z_s \neq 0} p_s \|z_s\| \int \max_r \langle U_g(z_s / \|z_s\|), u_r \rangle d\mu(g) \\ &\leq (1 - \Gamma_k(\mu)) \sum_s p_s \|z_s\|. \end{aligned}$$

Zero centroids cause no loss of an identity: their inner product with any chosen direction is zero. The maximization only relaxes the actual possibly randomized assignment. In particular, neither the old register nor the computation inside the packet is required to have  $k$  states.  $\square$

**Theorem 3.3** (Representation-valued packet budget). *Let  $Y_0$  be a fixed unit vector. Each command packet is sampled independently of the earlier process, with its full word law fixed in advance. Write  $G_i$  for its product and  $\mu_i$  for the induced law. Between packets one may insert fixed commands. A finite stochastic register processes the commands in their prescribed order, with arbitrary cut-dependent rows. Let  $k_i$  bound its positive-probability states at the end of packet  $i$ . If a terminal function  $d(S_N)$  satisfies  $\|d\| \leq B$  and*

$$|\mathbb{E} \langle Y_N, d(S_N) \rangle| \geq B\kappa > 0,$$

then

$$(7) \quad \kappa \leq \prod_i (1 - \Gamma_{k_i}(\mu_i)), \quad \sum_i \Gamma_{k_i}(\mu_i) \leq \log(1/\kappa).$$

Here  $Y$  evolves by the same ordered representation products as the commands. The statement also applies to a complex scalar correlation with absolute value, using  $q_N \geq \kappa$  as its terminal hypothesis.

*Proof.* At each boundary put  $q = \mathbb{E}\|\mathbb{E}[Y \mid S]\|$ . A whole packet has one stochastic input/output kernel conditional on its starting state and its command word. Its internal rows and all internal hidden states are integrated into that kernel. The fresh packet is independent of the past, so Lemma 3.2 applies. A fixed command can only decrease  $q$ , by conditional Jensen and preservation of norm by its action. Initially  $q = 1$ . At the terminal cut,  $|\mathbb{E}\langle Y_N, d(S_N) \rangle| \leq Bq_N$ . Multiplication proves the first assertion;  $1 - u \leq e^{-u}$  proves the second. If a coefficient is one, positive terminal correlation is impossible, consistent with the first assertion.  $\square$

The products  $G_i$  need not commute. The packet endpoints need not be consecutive cuts. Most importantly, the commands *inside* a packet need not be independent. Only its independence from the earlier process is used in the conditional-mean identity. This is what permits a stronger converse than a fair one-command test.

**Proposition 3.4** (A small-ball criterion). *For  $r > 0$  define*

$$A_\mu(r) = \sup_{v, u \in \mathbb{S}(H)} \mu\{g : \|U_g v - u\| < r\}.$$

*Then*

$$(8) \quad \Gamma_k(\mu) \geq \frac{r^2}{2} (1 - kA_\mu(r))_+.$$

*If for every  $v$  the packet is uniform on  $m$  orbit points separated by Euclidean distance at least  $\sigma$ , then  $\Gamma_k(\mu) \geq (1 - k/m)_+ \sigma^2/8$ .*

*Proof.* Outside the union of  $k$  radius- $r$  balls the squared distance to each center is at least  $r^2$ . Use  $1 - \langle v, u \rangle = \|v - u\|^2/2$  and the union bound. For separated points, each open ball of radius  $\sigma/2$  contains at most one, so  $A_\mu(\sigma/2) \leq 1/m$ .  $\square$

#### 4. THE SHARP BOUND FOR BINARY ROTATION COMMANDS

Put  $\zeta = e^{2\pi i \alpha}$  and

$$(9) \quad s_B(\alpha) = \min_{1 \leq l \leq B} \|l\alpha\|_{\mathbb{R}/\mathbb{Z}}.$$

For irrational  $\alpha$  this number is positive at every finite  $B$ . Given an integer  $k \geq 1$ , set  $B = 2k - 1$  and choose  $J$  uniformly from  $\{0, \dots, B\}$ . The associated packet is the length- $B$  command word

$$(10) \quad 1^J 0^{B-J}.$$

The command count is uniform on  $2k$  possibilities; the physical packet still consists of  $B$  ordinary binary commands. Its random choice is not revealed as an additional input.

**Lemma 4.1** (Separated packets). *The circle action of the packet (10) has*

$$(11) \quad \Gamma_k(\mu_B) \geq s_B(\alpha)^2.$$

*Consequently it multiplies the conditional phase amplitude by at most  $1 - s_B(\alpha)^2$  if its endpoint register has at most  $k$  states.*

*Proof.* Write  $s = s_B(\alpha)$ . For any starting direction the  $2k$  phase points differ pairwise by at least  $s$  in normalized circle distance. Each open arc of radius  $s/2$  contains at most one of them. For any  $k$  center directions, at least  $k$  packet points are therefore at circle distance at least  $s/2$  from every center. Their loss  $1 - \cos(2\pi\theta)$  is at least  $1 - \cos(\pi s)$ . Since  $0 \leq s \leq 1/2$  and  $\sin(\pi s/2) \geq s$ ,

$$\frac{1}{2}(1 - \cos(\pi s)) = \sin^2(\pi s/2) \geq s^2.$$

Average over the  $2k$  points and minimize over centers and initial phase. Lemma 3.2 proves the last assertion. This argument concerns actual hidden-state centroids, not their observable lift vertices.  $\square$

**Lemma 4.2** (Terminal calibration for every test law). *Fix seed  $x = (1, 1)$ . Under any command-word distribution independent of the machine's private randomness, a realization with error  $\varepsilon < 1/20$  obeys*

$$(12) \quad q_N := \mathbb{E}|\mathbb{E}[\zeta^{L_N} \mid S_N]| \geq \kappa := 1/10 - 2\varepsilon.$$

*Proof.* Set  $d = d_1 + id_2$ , so  $|d| \leq \sqrt{2}$ . For each word the target conditional mean of  $d(S_N)$  is  $(1+i)\zeta^{L_N}/10$ . A binary row-TV error  $\varepsilon$  changes each coordinate mean by at most  $2\varepsilon$ , hence the complex mean by at most  $2\sqrt{2}\varepsilon$ . Multiply by  $\zeta^{-L_N}$  and average to get

$$|\mathbb{E}[\zeta^{-L_N} d(S_N)]| \geq \sqrt{2}(1/10 - 2\varepsilon).$$

Conditioning on  $S_N$  bounds the left side by  $\sqrt{2}q_N$ . Only correctness at the final prescribed length was used.  $\square$

**Theorem 4.3** (Finite packet and occupation bounds). *For an arbitrary irrational  $\alpha$ , a machine of error  $\varepsilon < 1/20$  and available-label profile  $(K_t)_{t=0}^N$  satisfies, for every  $k \geq 1$  and  $B = 2k - 1$ ,*

$$(13) \quad \#\{1 \leq t \leq N : K_t \leq k\} \leq B - 1 + \frac{B}{s_B(\alpha)^2} \log \frac{1}{\kappa}.$$

*In particular, a peak- $K$  machine has*

$$(14) \quad \left\lfloor \frac{N}{2K-1} \right\rfloor s_{2K-1}(\alpha)^2 \leq \log \frac{1}{\kappa}.$$

*More generally, for pairwise disjoint packets ending at cuts  $t_i$ , of lengths  $B_i = 2k_i - 1$ , with  $K_{t_i} \leq k_i$ , one has*

$$(15) \quad \prod_i (1 - s_{B_i}(\alpha)^2) \geq \kappa, \quad \sum_i s_{B_i}(\alpha)^2 \leq \log \frac{1}{\kappa}.$$

*Proof.* On the chosen disjoint intervals use independent packets (10); set all other commands to zero. Fresh packet independence, Lemma 4.1 and Theorem 3.3 apply. Lemma 4.2 supplies the final correlation for this particular test law. This proves (15), and consecutive length- $2K - 1$  packets prove (14).

For (13), disregard low-width endpoints before  $B$ , of which there are at most  $B - 1$ . Select the first remaining such endpoint  $t$ , take the interval  $(t - B, t]$ , and repeat at the first low endpoint at least  $B$  epochs later. The selected intervals are disjoint. Each selected endpoint removes at most  $B$  low endpoints, since there are only  $B$  integer epochs in  $[t, t + B - 1]$ . If  $m$  intervals are selected, the total number of low endpoints is at most  $B - 1 + Bm$ . The second inequality in (15) gives  $ms_B(\alpha)^2 \leq \log(1/\kappa)$ .

The choice of intervals uses only the available profile, not the realized state or past command. It defines a legitimate external test distribution for this machine. No width bound is used inside a selected packet or at any unselected cut.  $\square$

*Proof of the lower bound in Theorem 1.1.* For badly approximable  $\alpha$ ,  $s_B(\alpha) \geq b_\alpha/B$ . Equation (14) and  $N < B(\lfloor N/B \rfloor + 1)$  prove (3). Since  $2K - 1 \leq 2K$  and  $K \leq K^3$ ,

$$(16) \quad W_{N,\varepsilon}(\alpha) > \left( \frac{N}{2 + 8b_\alpha^{-2} \log(1/\kappa)} \right)^{1/3}.$$

The corresponding occupation bound is  $\#\{1 \leq t \leq N : K_t \leq k\} \leq 2k - 2 + 8b_\alpha^{-2} k^3 \log(1/\kappa)$ .

For the golden angle, let  $\alpha' = -(1 + \sqrt{5})/2$  and let  $p$  be nearest to  $l\alpha$ . Then

$$(l\alpha - p)(l\alpha' - p) = p^2 + lp - l^2 \in \mathbb{Z} \setminus \{0\}, \quad |l\alpha' - p| \leq \sqrt{5}l + 1/2 < 3l.$$

Thus  $b_\alpha \geq 1/3$ . At zero error,  $2 + 72 \log 10 < 168$ , proving the stated bound. The elementary inequality  $\log 10 < 83/36$  can, for example, be checked by the positive exponential series. The rank-three bound follows from Proposition 2.2.  $\square$

**4.1. Matching realization.** We reproduce the resonant upper construction from [14, 15] to make the match self-contained. Let  $p/q$  be a convergent of  $\alpha$  with  $q \geq \max\{5, (40N)^{1/3}\}$ . Put

$$a = \pi/q, \quad \delta = 2\pi(\alpha - p/q), \quad \lambda = \frac{\cos(a - |\delta|)}{\cos a}, \quad \omega = \frac{\sin |\delta|}{\lambda \sin(2a)}, \quad u_s = (\cos(2\pi s/q), \sin(2\pi s/q)).$$

Subscripts on  $u_s$  are modulo  $q$ . Convergence gives  $|\delta| < a$ , so  $\lambda \geq 1$  and  $0 \leq \omega \leq 1$ .

**Proposition 4.4** (Exact resonant upper bound). *The experiment has an exact  $q$ -state realization. Its two command matrices are independent of the epoch, although its decoder depends on  $N$ . For badly approximable  $\alpha$ , one may take  $q = O_\alpha(N^{1/3})$ .*

*Proof.* Associate to label  $s$  at time  $t$  the vector  $r_t u_s$ ,  $r_t = \lambda^t/4$ . Define

$$T_0(s, \cdot) = \lambda^{-1} \delta_s + (1 - \lambda^{-1}) \text{Unif}[q], \quad T_1(s, \cdot) = (1 - \omega) \delta_{s+p} + \omega \delta_{s+p+\text{sgn } \delta}.$$

When  $\delta = 0$  take  $\omega = 0$ . The chord between the two indicated active vertices meets the ray at angle  $2\pi(s/q + \alpha)$  at radius  $1/\lambda$ . Its second coordinate gives exactly the formula for  $\omega$ . Thus the expected next associated vector is  $r_t u_s$  for an idle command and  $R_\alpha r_t u_s$  for an active command. Furthermore

$$\log \lambda = \int_{a-|\delta|}^a \tan v \, dv \leq |\delta| \tan a < 4\pi^2/q^3 < 40/q^3,$$

since  $q \geq 5$ . Hence  $r_N \leq e/4 < 1$ . The initial polygon has inradius  $\cos(\pi/q)/4 > \sqrt{2}/10$ ; initialize by any convex decomposition of  $x/10$ . The final decoder has means  $r_N e_j^T u_s \in [-1, 1]$ . Induction proves exactness for all words. Bounded partial quotients bound consecutive convergent-denominator ratios. For the golden angle the first denominator above a threshold  $L \geq 5$  is less than  $2L$ , proving (4).  $\square$

**Corollary 4.5** (Hidden, vector and fixed-length common-row widths). *For a badly approximable angle, exact clocked hidden width, exact clocked vector-state width, and exact fixed-length width with common command matrices are all  $\Theta_\alpha(N^{1/3})$ .*

*Proof.* The first class contains the other two, while Proposition 4.4 belongs to their intersection. Apply the unrestricted lower bound.  $\square$

An unchanged decoder correct after every earlier stopping length is a stronger, anytime specification; no such assertion is used here.

**4.2. Other arithmetic.** If  $\|l\alpha\| \geq bl^{-\tau}$  for all  $l \geq 1$ , the same proof gives  $N < B + b^{-2}B^{2\tau+1} \log(1/\kappa)$  for  $B = 2K - 1$ . No matching claim is made under this weaker arithmetic hypothesis. For the irrational angle whose rotation has rational entries  $\zeta = (3 + 4i)/5$ , the nonzero Gaussian integer  $(3 + 4i)^l - 5^l$  gives  $s_B(\alpha) \geq 5^{-B}/(2\pi)$ . Consequently

$$N < B + 4\pi^2 B 25^B \log(1/\kappa), \quad B = 2K - 1.$$

The Gaussian integer is nonzero because otherwise  $6/5 = \zeta + \zeta^{-1}$  would be an algebraic integer. This is an explicit logarithmic converse, not a proof that this angle is badly approximable. The earlier rational counter realization and its finite-coin accounting remain unchanged.

## 5. COMPACT COMMAND GROUPS

Theorem 3.3 applies to any orthogonal or unitary representation, including noncommuting commands. The following two consequences distinguish a finite command alphabet from a genuinely compact command alphabet.

**Corollary 5.1** (Characters of compact groups). *Let a finite command alphabet in a compact group contain the identity and  $g$ , and let  $\chi$  be a continuous one-dimensional unitary character with  $\chi(g) = e^{2\pi i\alpha}$ ,  $\alpha$  irrational. Any wordwise finite-register experiment whose terminal specification forces a conditional  $\chi$ -amplitude at least  $\kappa > 0$  satisfies (13) and (15) on these commands. In particular, a badly approximable character angle forces  $\Omega(N^{1/3})$  hidden width.*

*Proof.* Use packets  $g^J e^{B-J}$ . Their character images are exactly those in Lemma 4.1. The other commands may be assigned probability zero by the test law. Apply Theorem 3.3 on  $\mathbb{C}$ .  $\square$

This includes higher-dimensional tori through their characters. It is a lower bound for a selected observed character, not a multiplicative claim about simultaneous independent outputs of several characters. The next result uses a different orbit geometry rather than a character.

Fix an integer  $d \geq 2$  and a unit vector  $v \in \mathbb{R}^d$ . Consider the separate experiment with commands  $g_t \in \text{SO}(d)$ , supplied as exact atomic matrices, and final coordinate query  $j \in \{1, \dots, d\}$ . Its specified mean is

$$(17) \quad \mathbb{E}[B \mid g_1, \dots, g_N, j] = \frac{1}{10} e_j^T g_N \cdots g_1 v.$$

A realizing finite-state machine has Borel stochastic rows  $T_{t,g}$ . Its width still counts only labels; access to this compact input and its row function is part of this model, not an implementation by finite binary input symbols. All terminal probabilities lie in  $[9/20, 11/20]$ .

**Lemma 5.2** (Sphere quantization). *For normalized surface measure on  $\mathbb{S}^{d-1}$  there are constants  $c_d, C_d > 0$  such that the orbit distortion of Haar measure on  $\text{SO}(d)$  satisfies*

$$\Gamma_k(\text{Haar}) \geq c_d k^{-2/(d-1)}.$$

*For every  $0 < \rho \leq 1/2$  there is a finite set  $V \subset \mathbb{S}^{d-1}$  of at most  $C_d \rho^{-(d-1)}$  points whose convex hull contains the Euclidean ball of radius  $\cos \rho$ .*

*Proof.* Haar rotation sends every unit vector to normalized surface measure. A Euclidean radius- $r$  cap,  $0 < r \leq 1$ , has angular radius  $2 \arcsin(r/2) \leq \pi r/2$ . Polar integration bounds its probability by  $A_d r^{d-1}$  for some  $A_d \geq 1$ : its integral is proportional to  $\int_0^{2 \arcsin(r/2)} \sin^{d-2} u \, du$ . Take  $r = (2A_d k)^{-1/(d-1)}$  in Proposition 3.4. The bound follows with  $c_d = (2A_d)^{-2/(d-1)}/4$ .

For the second assertion choose a maximal set with pairwise angular distance greater than  $\rho$ . The angular radius- $\rho/2$  caps are disjoint and each has surface mass at least  $a_d \rho^{d-1}$ , by the same polar integral and  $\sin u \geq 2u/\pi$  on  $[0, \pi/2]$ . Thus the set has at most  $a_d^{-1} \rho^{-(d-1)}$  points. Maximality makes it a  $\rho$ -net. Its support function in every unit direction is at least  $\cos \rho$ , proving the ball containment. These elementary estimates are the usual spherical quantization and covering mechanisms; their role here is sequential compression.  $\square$

**Theorem 5.3** (Sharp width for all rotation commands). *For fixed  $d \geq 2$  and  $0 \leq \varepsilon < 1/(20\sqrt{d})$ , the least hidden-state width for (17), in its compact-command model, satisfies*

$$(18) \quad W_{N,\varepsilon}^{\text{SO}(d)} = \Theta_{d,\varepsilon}(N^{(d-1)/2}).$$

*Writing  $\kappa_d = 1/(10\sqrt{d}) - 2\varepsilon$ , every profile obeys*

$$(19) \quad c_d \sum_{t=1}^N K_t^{-2/(d-1)} \leq \log(1/\kappa_d).$$

The exact upper construction has common command rows and an  $N$ -dependent terminal decoder.

*Proof.* Use independent Haar commands as the test law and set  $Y_t = g_t \cdots g_1 v$ . Combine the coordinate decoder means into a vector  $d(S_N)$  of norm at most  $\sqrt{d}$ . Wordwise approximation implies

$$\mathbb{E}\langle Y_N, d(S_N) \rangle \geq 1/10 - 2\sqrt{d}\varepsilon, \quad q_N \geq \kappa_d.$$

Theorem 3.3 and Lemma 5.2, one command per packet, give (19) and the lower bound.

For the upper bound take  $\rho = 1/(2\sqrt{N})$  and a net  $V$  as in Lemma 5.2. Put  $P = \text{conv } V$ ,  $\lambda = (\cos \rho)^{-1}$ , and  $r_t = \lambda^t/4$ . A label  $u \in V$  has associated vector  $r_t u$ . For any command  $g$ , the vector  $gu/\lambda$  lies in  $(\cos \rho)\mathbb{B}^d \subset P$ . Fix a Borel convex decomposition of every point of  $P$  into  $V$ , and use the coefficients of  $gu/\lambda$  as the command row from label  $u$ . Such decompositions may be chosen by a finite triangulation of  $P$  using its vertices, with ties between simplices resolved in a fixed order. The resulting rows are Borel, normalized, and independent of  $t$ .

The expected next associated vector is exactly  $g(r_t u)$ . Since  $-\log \cos \rho \leq \rho^2$  for  $\rho \leq 1/2$ ,  $r_N \leq e^{1/4}/4 < 1$ . Also  $v/10 \in r_0 P$ , since  $\cos(1/2)/4 > 1/10$ . Initialize by its chosen convex decomposition and decode with means  $r_N e_j^T u$ . This realizes (17) exactly and uses at most  $C_d(2\sqrt{N})^{d-1}$  labels (and two output labels, absorbed by the bound). No vectors are retained at runtime.  $\square$

For  $d \geq 3$  the commands here are noncommuting. For  $d = 2$  the order  $N^{1/2}$  concerns all circle rotations as inputs, while Theorem 1.1 has the smaller fixed alphabet  $\{I, R_\alpha\}$  and order  $N^{1/3}$ . These statements concern different command sets. The compact theorem is not a claim of that exponent for an arbitrary finite generating set, or an uncharged approximation of a real command by a finite word.

## 6. ACTUAL TERMINAL ERROR AND LOCAL DIAGRAM CERTIFICATES

For a prescribed profile  $\mathbf{K}$ , define  $\mathcal{E}_N(\mathbf{K})$  as the minimum uniform terminal row-TV error in Definition 2.1. The minimum exists: the row simplices, initialization rows and decoder intervals form a compact set, and the maximum of finitely many wordwise errors is continuous. Thus this is an intrinsic final simulation objective, not a sum of intermediate defects.

For  $t \geq 1$  put  $B_t = 2K_t - 1$ . Call  $(t - B_t, t]$  admissible when  $B_t \leq t$ . Let

$$(20) \quad \mathfrak{B}_\alpha(\mathbf{K}) = \max_{\substack{\text{pairwise disjoint} \\ \text{admissible intervals}}} \sum_i s_{B_{t_i}}(\alpha)^2.$$

This finite weighted-interval problem depends only on the profile and angle. Empty selections give zero. If  $F_0 = 0$ , its exact recurrence is

$$F_t = \begin{cases} \max\{F_{t-1}, F_{t-B_t} + s_{B_t}(\alpha)^2\}, & B_t \leq t, \\ F_{t-1}, & B_t > t. \end{cases} \quad \mathfrak{B}_\alpha(\mathbf{K}) = F_N.$$

The last chosen interval proves the recurrence. Computing the weights requires the stated angle representation; no bit-complexity claim for arbitrary exact real inputs is made.

**Theorem 6.1** (Final-error obstruction). *For every irrational  $\alpha$  and finite profile,*

$$(21) \quad \mathcal{E}_N(\mathbf{K}) \geq \frac{1}{2} \left[ \frac{1}{10} - \exp\{-\mathfrak{B}_\alpha(\mathbf{K})\} \right]_+.$$

*In particular, for peak at most  $K$  and  $B = 2K - 1$ ,*

$$(22) \quad \mathcal{E}_N(K) \geq \frac{1}{2} \left[ \frac{1}{10} - \exp\{-\lfloor N/B \rfloor s_B(\alpha)^2\} \right]_+.$$

*For a badly approximable angle, every sequence  $K = o(N^{1/3})$  has  $\liminf \mathcal{E}_N(K) \geq 1/20$ .*

*Proof.* Choose the disjoint intervals maximizing (20) and put independent separated packets on them, idle commands elsewhere. Every machine of that profile has terminal amplitude at most  $\exp\{-\mathfrak{B}_\alpha(\mathbf{K})\}$ , by Lemma 3.2 and Lemma 4.1. Terminal calibration gives  $1/10 - 2\varepsilon \leq q_N$  whenever its left side is positive. Rearrange and then minimize over machines. Consecutive equal-length packets prove (22); the estimate  $s_B \geq b_\alpha/B$  proves the asymptotic assertion.  $\square$

This conclusion is about the actual terminal error, so possible cancellation of intermediate approximation errors cannot evade it. It does not give the exact value of  $\mathcal{E}_N$  at every finite profile. In particular the limiting lower constant  $1/20$  is not claimed optimal.

**6.1. Transfer to executable diagrams.** For finite row-stochastic experiments  $E, F$  indexed by the same finite set of prefixes, use the classical one-sided deficiency

$$(23) \quad \delta(E, F) = \min_{T \text{ stochastic}} \max_h \text{TV}((ET)_h, F_h).$$

The common row  $T$  cannot depend on  $h$ . The zero-defect case is Blackwell garbling [10, 11]; composition contracts total variation.

Let  $E_t$  specify a proposed state distribution for each actual input prefix at cut  $t$ . For every next command, choose a common update approximating the corresponding child rows, and likewise choose each terminal query decoder. Let  $\epsilon_t$  be the worst row error of that update over prefixes and commands, and  $\epsilon_{\text{out}}$  the worst terminal decoder error. If the initial rows are exact, put

$$\mathcal{D}(E) = \sum_{t < N} \epsilon_t + \epsilon_{\text{out}}.$$

Minimizing each one-step error gives (23) at that step. This is an *accumulated local deficiency certificate*, not a formula for the optimal final error.

**Corollary 6.2** (Diagram obstruction). *Every such diagram of profile  $\mathbf{K}$  satisfies the right side of (21) as a lower bound on  $\mathcal{D}(E)$ .*

*Proof.* Execute the selected common kernels. At each fixed prefix, induction and TV contraction bound the discrepancy from  $E_t$  by the sum of preceding  $\epsilon_s$ . Append the common terminal decoder to obtain actual row error at most  $\mathcal{D}(E)$ . If this sum exceeds one, the trivial error bound one suffices. Thus  $\mathcal{D}(E) \geq \mathcal{E}_N(\mathbf{K})$ ; apply Theorem 6.1.  $\square$

The certificate can overestimate the achieved final error, since local errors may cancel. The corollary does not deny cancellation, minimize  $\mathcal{D}$  over all diagrams, or assert equality of the two objectives. The new lower bound already applies before any diagram is introduced.

## 7. COMPARISON OF MODELS AND CONCLUSIONS

**7.1. Probabilistic read-once branching programs.** After fixing the seed and padding layers to a common width, the product in Definition 2.1 is a stochastic ordered read-once branching program: layer  $t$  reads command  $c_t$  once and applies  $T_{t-1, c_t}$ . This is the randomized-transition extension of the standard nonuniform model in [1, Section 1.1]; see also [4]. Width is the maximum layer size, whereas total size counts all layers. Our theorem is a width theorem, not a succinct uniform program-size or bit-operation theorem.

For a chosen query  $j$ , appending an accepting Bernoulli row with probability  $(1 + d_j(s))/2$  turns the real readout into ordinary randomized acceptance with no larger width than  $\max(K, 2)$ . Combining the two means into  $d_1 + id_2$  does not enlarge the retained alphabet. This combination is an identity between mean functions, not a requirement to sample both query answers jointly. Thus real readouts and the word “transducer” do not by themselves separate our problem from branching programs.

For a fixed initial row  $p$  and terminal column  $d$ , put  $F(c) = pT_{0,c_1} \cdots T_{N-1,c_N}d$ . Its Boolean-input Fourier coefficient at  $A \subseteq [N]$  is exactly

$$(24) \quad \widehat{F}(A) = p \prod_{t=1}^N \frac{T_{t-1,0} + (-1)^{\mathbf{1}_{\{t \in A\}}} T_{t-1,1}}{2} d.$$

This follows by multiplying independent sums over input bits in their original order. It is a matrix-product Fourier coefficient, distinct from a harmonic of the conditional phase measure used in [15]. The present proof instead uses the nonlinear quantity  $\mathbb{E}|\mathbb{E}[\zeta^{L_t} | S_t]|$  at packet boundaries.

Reingold–Steinke–Vadhan [1, Theorem 1.4] bound Boolean level- $l$  Fourier mass by  $(2w^2)^l$  for regular width- $w$  programs. Steinke–Vadhan–Wan [2] establish width-three Fourier-growth bounds and use them for pseudorandomness. Lee–Pyne–Vadhan [3, Definitions 3–5 and Theorem 6] refine the regular-program bounds, including unbounded width and restrictions on accepting states; their Section 1.2.3 discusses generalized group products. These results concern Fourier growth or fooling classes of computations. They do not state the terminal-correlation packet inequality (6) or its nonuniform occupation consequence.

Regularity means preservation of a uniform layer distribution under a fair next input. It is not implied by row stochasticity: the matrix all of whose rows put mass one on a single label is legal here and destroys uniformity. Consequently a regular/permutation theorem cannot be invoked without its hypothesis. Conversely, some bounds for general deterministic programs extend to stochastic programs by resolving all private rows into a convex combination of deterministic tables and using convexity. We therefore make no claim that private randomness alone prevents use of the earlier literature. The extra statement proved here is the multiplicative loss forced by a separated command packet, for arbitrary starting conditional centroids and arbitrary endpoint assignments. It gives the matching growing-width law without a regularity assumption and without an estimate of the Fourier mass in (24).

**7.2. Circle walks and the choice of test law.** For independent Bernoulli commands of bias  $p$ , the uncompressed phase has harmonic multiplier

$$a_l = 1 - p + pe^{2\pi i l \alpha}, \quad |a_l|^2 = 1 - 4p(1-p)\sin^2(\pi l \alpha).$$

These are classical circle-walk quantities. Berkes–Borda [5] relate convergence and limit theorems for circle walks to rational approximation, including the transition along convergent denominators. That analysis concerns the uncompressed walk, not the information retained by an additional hidden register.

The earlier Fourier budget [15] combined this damping, common conditional-amplitude loss, and a positive finite-atom Fourier witness. It gave a fifth-root unrestricted converse. Our test law is different: its bits are correlated inside a packet so that the packet count is uniform, and different packets are independent. We are not asserting a cube-root occupation theorem for the fair-command law itself. Wordwise correctness allows the new law; Lemma 3.2 measures its compression directly. The packet costs  $O(k)$  commands and loses  $\Omega(k^{-2})$  amplitude, explaining the cube-root order. The angular averaging estimate remains valid with its sharp universal coefficient, proved in Appendix A; improving that coefficient’s quadratic order is not needed for the new result.

**7.3. Positive realization and experiment comparison.** Invariant convex sets, positive stochastic realizations, and irrational rotation obstructions for one repeated positive matrix belong to classical realization theory [6, 7, 8, 9]. The present lower bound permits unrelated matrices at every layer and a new machine for each horizon; it is not a peripheral-eigenvalue argument for a stationary realization. The upper construction is inherited from [14, 15] and has

been proved again in Proposition 4.4. What is new in the main theorem is its match against all hidden states, including under fixed row error.

Finite Blackwell garbling and one-sided deficiency are classical [10, 11]. Theorem 6.1 bounds the actual terminal optimization. Corollary 6.2 then bounds an accumulated local certificate; it does not identify that certificate with the optimized terminal distance. Orbit quantization, sphere-cap bounds and polytope nets in Section 5 are classical geometric mechanisms. Their representation-valued sequential loss is stated and proved explicitly in Theorem 3.3.

**7.4. Conclusions and precise boundaries.** The hidden and vector-state rotation widths have the same cube-root order for each badly approximable angle and fixed nonzero signal at sufficiently small fixed error. The finite constants are proof constants, not optimized thresholds or exact integer minima. The packet budget also controls selected low-width endpoints and actual terminal error. For compact rotation commands, a distinct matched sphere-dimension law follows from the same contraction theorem.

No sharp order is asserted for every irrational angle, for every finite noncommuting command set, or for a regime in which signal and permitted error vary with the horizon. Optimizing informative action choice is not the external-command problem studied here. Atomic computable-real rows are not finite fair-bit algorithms. No exact minimum dynamic Blackwell distance or independent analytic foundation for an unrelated model is inferred from these results. The original manuscript and its historical arguments remain separately available, with their hypotheses unchanged.

#### APPENDIX A. THE SHARP HOMOGENEOUS ANGULAR COEFFICIENT

The earlier Fourier proof remains useful when the external test law is required to have independent single commands. Its elementary angular estimate admits the following sharpened statement. This also resolves the coefficient issue in the preceding report without changing any previous published source.

**Lemma A.1** (Homogeneous angular averaging). *Let  $f_l(re^{i\theta}) = re^{il\theta}$  for  $r > 0$  and  $f_l(0) = 0$ . For every integrable complex  $Z$  and integer  $l \geq 1$ ,*

$$(25) \quad |\mathbb{E}f_l(Z) - f_l(\mathbb{E}Z)| \leq (l^2 - 1)(\mathbb{E}|Z| - |\mathbb{E}Z|).$$

*For  $l \geq 2$  the coefficient  $l^2 - 1$  cannot be decreased uniformly over all such mixtures. At  $l = 1$  both sides vanish.*

*Proof.* The case  $l = 1$  is linear. For  $l \geq 2$ , if  $\mathbb{E}Z = 0$ , the left side is at most  $\mathbb{E}|Z|$  and  $l^2 - 1 \geq 1$ . Otherwise rotate the variable so  $\mathbb{E}Z = \rho > 0$ , and write  $Z = re^{i\theta}$ . For  $u = e^{i\theta}$ ,

$$u^l - 1 - l(u - 1) = (u - 1) \sum_{j=0}^{l-1} (u^j - 1).$$

Since  $|u^j - 1| \leq j|u - 1|$ , the modulus of this remainder is at most  $l(l-1)(1 - \cos \theta)$ . Retaining this coefficient gives

$$|u^l - \cos \theta - il \sin \theta| \leq \{l(l-1) + (l-1)\}(1 - \cos \theta) = (l^2 - 1)(1 - \cos \theta).$$

Multiply by  $r$  and average. The identities  $\mathbb{E}(r \sin \theta) = 0$  and  $\mathbb{E}(r \cos \theta) = \rho$  prove (25). Rotation covariance restores the general case. For sharpness take  $Z = e^{i\theta}$  and  $e^{-i\theta}$  with equal probabilities, and let  $\theta \downarrow 0$ . The ratio is

$$\frac{|\cos(l\theta) - \cos \theta|}{1 - \cos \theta} \rightarrow l^2 - 1.$$

□

Thus a uniformly linear-in- $l$  replacement is impossible for unrestricted conditional mixtures. The improvement to cube-root width in this paper does not require such an estimate: it changes the test law to packets and measures the directly incurred geometric amplitude loss.

# GENERAL THETA FOUNDATIONS I: FOURIER BUDGETS FOR HIDDEN CAUSAL MEMORY

QIAN QI

**ABSTRACT.** We prove a polynomial memory lower bound for a uniformly positive rotation experiment whose separate positive minimum is three at every cut. The bound allows arbitrary hidden states, unrelated transition matrices at different epochs, and a new machine for each horizon. Its proof uses conditional past-phase moments rather than the number of vertices of a projected simplex section. A homogeneous angular inequality controls all Fourier moments by one cumulative loss of conditional phase amplitude; positivity of the Fejér kernel detects a register with few labels. For an angle satisfying  $\inf_{m \geq 1} m \|m\alpha\| > 0$ , the unrestricted width is at least a constant times  $N^{1/5}$ , improving the previous logarithmic lower bound, while an exact  $O_\alpha(N^{1/3})$  construction is retained. The lower bound persists under any fixed sufficiently small uniform output error. For the rational rotation  $(3 + 4i)/5$  it gives a logarithmic, rather than doubly logarithmic, lower bound. We formulate stochastic extension as finite Blackwell comparison and transfer the new obstruction to the accumulated deficiency of every proposed lift diagram. This rules out logarithmic-coordinate low-defect lift chains for the bounded-type family without imposing vector-state or equivariance restrictions. The exponents  $1/5$  and  $1/3$  are not identified, and the fixed-length and anytime autonomous specifications are kept distinct.

## 1. INTRODUCTION

An experiment can admit a small positive factorization at each separate cut while requiring substantially more states when the factorizations must be joined by common stochastic updates. For hidden realizations, a state need not carry an individually meaningful predictive vector. A projection of a  $K$ -coordinate simplex section can have exponentially many vertices. Consequently, a lower bound obtained only by counting the vertices of an observable polygon may lose an exponential factor in the memory parameter.

We study the following fixed-alphabet experiment. A seed  $x \in \{-1, 1\}^2$  is followed by  $N$  commands  $c_t \in \{0, 1\}$ , a query  $j \in \{1, 2\}$ , and a binary answer  $B$ . For  $\zeta = e^{2\pi i \alpha}$  and the corresponding planar rotation  $R_\alpha$ , the prescribed answer law is

$$(1) \quad \mathbb{P}(B = b \mid x, c_1, \dots, c_N, j) = \frac{1 + b e_j^T R_\alpha^{c_1 + \dots + c_N} x / 10}{2}.$$

All these probabilities lie in the fixed interval  $[(1 - \sqrt{2}/10)/2, (1 + \sqrt{2}/10)/2]$ . The alphabets, amplitude and support margin do not change with  $N$ . Exact realization means equality for every input word, not merely after averaging over commands.

The separate positive minimum of this experiment is three. The previous mean-support argument gave  $\Omega_\alpha(\log N)$  as an unrestricted hidden-state lower bound and  $\Theta_\alpha(N^{1/3})$  within a vector-state subclass at bounded-type angles [17]. We retain its exact upper construction but replace the hidden lower argument. The new method does not associate a predictive vector with each basis state. Instead, it studies the conditional expectation of a random past phase *under a*

*Date:* September 25, 2026. Revision 34.

*2020 Mathematics Subject Classification.* Primary 93B15, 60J10; Secondary 42A16, 52B05, 62B15.

*Key words and phrases.* Positive realization, hidden memory, stochastic transducers, Fourier moments, comparison of experiments, causal lifts.

*chosen test distribution on external words.* These conditional expectations are proof objects, not information made available to the executing machine.

Write

$$(2) \quad \beta_m(\alpha) = \min_{1 \leq l \leq m} \sin^2(\pi l \alpha), \quad b_\alpha = \inf_{l \geq 1} l \|l \alpha\|_{\mathbb{R}/\mathbb{Z}}.$$

For irrational  $\alpha$ , every  $\beta_m$  is positive. The assumption  $b_\alpha > 0$  is the usual badly-approximable, equivalently bounded-type, condition. Let  $W_{N,\varepsilon}(\alpha)$  be the least peak label count of a clocked stochastic realization with uniform row-total-variation error at most  $\varepsilon$ , and write  $W_N = W_{N,0}$ .

**Theorem 1.1** (Polynomial obstruction for all hidden realizations). *Let  $0 \leq \varepsilon < 1/20$  and put  $\kappa = 1/10 - 2\varepsilon$ . Every realizing profile  $(K_t)_{t=0}^N$  satisfies, for every integer  $k \geq 1$ ,*

$$(3) \quad \#\{0 \leq t < N : K_t \leq k\} \beta_{2k}(\alpha) \leq \frac{18k^3}{\kappa^2}.$$

*In particular, if  $b_\alpha > 0$ , then*

$$(4) \quad W_{N,\varepsilon}(\alpha) \geq \left( \frac{b_\alpha^2 \kappa^2 N}{18} \right)^{1/5}.$$

*For  $\alpha = (\sqrt{5} - 1)/2$ , exact realization therefore obeys*

$$(5) \quad \max\{3, (N/16200)^{1/5}\} \leq W_N(\alpha) < 2 \max\{5, (40N)^{1/3}\}.$$

*More generally the same cube-root upper order holds whenever the partial quotients of  $\alpha$  are bounded. For  $\zeta = (3 + 4i)/5$ ,*

$$(6) \quad N \leq 7200 W_N^3 25^{2W_N}, \quad W_N \geq \max\{3, \log_{5000}(N/7200)\}.$$

*All lower bounds allow arbitrary cut-dependent hidden-state continuations.*

The theorem excludes  $O(\log N)$  hidden width at bounded-type angles, including at any fixed row error below  $1/20$ . It does not prove that hidden and vector-state widths have the same order: the current exact bounds are  $\Omega_\alpha(N^{1/5})$  and  $O_\alpha(N^{1/3})$ . The cumulative version (3) also limits how often a small register may occur in an otherwise unrestricted profile.

The proof has three steps. Conditional phase amplitude decreases under a stochastic update. Its entire loss is at most one. A homogeneous angular inequality bounds the perturbation of the  $l$ th Fourier moment by  $2l^2$  times this same loss. Finally, the positive Fejér kernel forces a nonnegligible Fourier potential whenever the conditional phase measure has few atoms. Randomizing the two external commands damps those moments at the rates  $\sin^2(\pi l \alpha)$ . The resulting potential telescopes for time-dependent as well as stationary matrices.

Section 5 interprets a supplied lift diagram as a sequence of finite experiment comparisons. The one-step garbling criterion and deficiency dual are classical [3, 12]. Their composition produces an executable approximate transducer. Applying Theorem 1.1 yields a new lower bound on the total defect of *every* such diagram for (1), rather than only a four-point warning example. Section 6 compares this notion with equivariant polyhedral lifts and distinguishes fixed-length autonomy from the stronger anytime query task.

| Notation                             | Meaning                                                                  |
|--------------------------------------|--------------------------------------------------------------------------|
| $K_t, W_{N,\varepsilon}$             | Available labels at cut $t$ ; minimum peak at row error $\varepsilon$ .  |
| $z_t(s), q_t$                        | Conditional past-phase expectation; its mean absolute value.             |
| $\Phi_t^{(m)}$                       | Finite Fejér-weighted Fourier potential of the conditional phases.       |
| $\delta(E, F)$                       | One-sided finite deficiency: simulate $F$ by garbling $E$ .              |
| $\mathcal{D}(\mathcal{E})$           | Sum of optimized one-step and terminal defects for a fixed diagram.      |
| $A_N^{\text{fix}}, A_N^{\text{any}}$ | Autonomous state counts for one fixed length, or all lengths up to $N$ . |

## 2. THE FINITE STOCHASTIC MODEL

State distributions are row vectors. Let  $\Delta_k = \{e \in \mathbb{R}^k : e \geq 0, e\mathbf{1} = 1\}$ .

**Definition 2.1** (Clocked transducer and approximation). A transducer for a prescribed  $N$  has initialization rows  $E_x \in \Delta_{K_0}$ , row-stochastic matrices  $T_{t,c} \in \mathbb{R}_+^{K_t \times K_{t+1}}$  for  $0 \leq t < N$ ,  $c \in \{0, 1\}$ , and binary decoder means  $d_j \in [-1, 1]^{K_N}$  for  $j \in \{1, 2\}$ . Its mean after a word is

$$E_x T_{0,c_1} \cdots T_{N-1,c_N} d_j.$$

Its uniform row error is the maximum total variation between this binary law and (1), over all seeds, command words and queries. The available-label profile is  $(K_t)$  and its peak is  $\max_t K_t$ .  $W_{N,\varepsilon}$  minimizes this peak over transducers of row error at most  $\varepsilon$ . At error zero the defining product must equal the specified mean on every word.

Only the current state survives each update. All retained randomness, past inputs and protocol distinctions belong to that state. The seed and query are supplied once as atomic symbols. The command is an external input; it is not a hidden parameter chosen by the model. The epoch is an external clock, so different cuts can have different alphabets and rows. All rows, including unreachable rows, are normalized. Available labels are counted; padding is allowed. A retained final binary answer uses two labels at its own output cut. This does not enlarge any exact peak here, which is at least three.

Exact stochastic rows, their read-only descriptions, arithmetic, and row-construction time are not charged by this positive-realization width. A rational row can be compiled into fair-bit rejection sampling with extra phase, old-state, current-input and sampler-prefix storage, as in [15]. No equality between that implementation cost and the atomic width is asserted. Irrational rows below are exact mathematical kernels, not a finite fair-bit implementation claim.

**Proposition 2.2** (The separate positive minimum remains three). *For exact realization of (1), every internal cut has normalized residual rank three and separate positive minimum three. The separate minimum allows arbitrary finite registers at all other cuts.*

*Proof.* A prefix has a predictive vector  $R_\alpha^a x/10$ . Its complete future array is affine in that vector. Four idle prefixes span an affine plane, and two idle-suffix coordinate queries separate it. Normalization adds the constant direction, so the residual rank is three. The triangle with vertices

$$(1/2, 0), \quad (-1/2, 1/2), \quad (-1/2, -1/2)$$

contains the disk of radius  $\sqrt{2}/10$ . Indeed its supporting-line distances from zero are  $1/2, 1/(2\sqrt{5}), 1/(2\sqrt{5})$ , all larger than that radius. Its vertices have norm at most  $1/\sqrt{2}$ , so every rotated continuation from a vertex gives legal binary answers. At the selected cut decompose the actual predictive vector in this triangle. Before that cut store the finite raw history; after it store the chosen vertex label and remaining command count. This is a complete finite realization with three states at the selected cut. Rank proves minimality. The construction is inherited from [16, 17]; the new result concerns simultaneous, not separate, width.  $\square$

The lower argument below uses only the stochastic update rule and the correct terminal correlation. It does not project hidden basis states into this predictive plane. In particular, it covers the simplex-section lifts in [17], including lifts with unobservable directions.

## 3. A FOURIER BUDGET FOR A HIDDEN REGISTER

This section states the probabilistic argument independently of the particular seed amplitude. Let  $C_1, \dots, C_N$  be independent fair bits, put  $L_t = C_1 + \cdots + C_t$ , and let  $S_t$  be an arbitrary

finite-state process with

$$(7) \quad \mathbb{P}(S_{t+1} = s' \mid S_0, C_1, \dots, C_t, S_t, C_{t+1}) = T_{t, C_{t+1}}(S_t, s').$$

The new command is independent of the past. Initialization may be random. The matrices and state spaces may depend on  $t$  and  $N$ . Set  $Y_t = \zeta^{-L_t}$  and, on states of positive probability, define

$$(8) \quad p_t(s) = \mathbb{P}(S_t = s), \quad z_t(s) = \mathbb{E}[Y_t \mid S_t = s], \quad q_t = \sum_s p_t(s) |z_t(s)|.$$

Put  $z_t = 0$  on a zero-mass state. These are conditional expectations used in the proof, not registers or extra inputs to the transducer.

**Lemma 3.1** (One common amplitude loss). *The sequence  $q_t$  is nonincreasing, with  $q_0 = 1$ . If  $Z_{t+1} = \zeta^{-C_{t+1}} z_t(S_t)$ , then*

$$(9) \quad z_{t+1}(S_{t+1}) = \mathbb{E}[Z_{t+1} \mid S_{t+1}], \quad \ell_t := q_t - q_{t+1} \geq 0, \quad \sum_{t < N} \ell_t \leq 1.$$

If a complex function  $d(S_N)$  obeys  $|d| \leq B$  and  $|\mathbb{E}[Y_N d(S_N)]| \geq B\kappa$ , then  $q_t \geq \kappa$  for every  $t$ .

*Proof.* The stochastic update and the independence of the new command imply  $\mathbb{E}[Y_t \mid S_t, C_{t+1}, S_{t+1}] = z_t(S_t)$  on positive-mass events. The tower property gives the first identity. Conditional Jensen gives  $q_{t+1} \leq \mathbb{E}|Z_{t+1}| = q_t$ , hence the telescoping loss bound. Finally

$$|\mathbb{E}[Y_N d(S_N)]| = |\mathbb{E}[z_N(S_N) d(S_N)]| \leq Bq_N.$$

Monotonicity proves the last assertion. No conditional independence of past commands given the retained state is assumed.  $\square$

For an integer  $l \geq 1$  define the homogeneous angular function

$$(10) \quad f_l(re^{i\theta}) = re^{il\theta} \quad (r > 0), \quad f_l(0) = 0.$$

It is not necessary to differentiate this function at zero. The following inequality charges its failure to preserve averages to the *same* absolute-amplitude loss for every  $l$ .

**Lemma 3.2** (Homogeneous angular averaging). *For any integrable complex random variable  $Z$  and integer  $l \geq 1$ ,*

$$(11) \quad |\mathbb{E}f_l(Z) - f_l(\mathbb{E}Z)| \leq (l^2 + 1)(\mathbb{E}|Z| - |\mathbb{E}Z|).$$

*Proof.* If  $\mathbb{E}Z = 0$ , the left side is at most  $\mathbb{E}|Z|$ , and the result follows. Otherwise rotate so that  $\mathbb{E}Z = \rho > 0$ , and write  $Z = re^{i\theta}$ . Then  $\mathbb{E}(r \sin \theta) = 0$  and  $\mathbb{E}(r \cos \theta) = \rho$ . For  $u = e^{i\theta}$  the identity

$$u^l - 1 - l(u - 1) = (u - 1) \sum_{j=0}^{l-1} (u^j - 1)$$

and  $|u^j - 1| \leq j|u - 1|$  give

$$|u^l - 1 - il \sin \theta| \leq l^2(1 - \cos \theta).$$

Consequently

$$|e^{il\theta} - \cos \theta - il \sin \theta| \leq (l^2 + 1)(1 - \cos \theta).$$

Multiply by  $r$ , average, and use the two identities for sine and cosine. Rotation covariance of  $f_l$  restores the general case. Values with  $r = 0$  contribute zero. Thus the proof covers mixtures passing through zero.  $\square$

Let

$$(12) \quad m_{t,l} = \sum_s p_t(s) f_l(z_t(s)), \quad a_l = \frac{1 + \zeta^{-l}}{2}.$$

By radial homogeneity,  $|m_{t,l}| \leq q_t \leq 1$ .

**Lemma 3.3** (Moment recursion). *There are complex errors  $e_{t,l}$  such that*

$$(13) \quad m_{t+1,l} = a_l m_{t,l} + e_{t,l}, \quad |e_{t,l}| \leq (l^2 + 1) \ell_t \leq 2l^2 \ell_t.$$

*In particular*

$$(14) \quad |m_{t+1,l}|^2 \leq (1 - \sin^2(\pi l \alpha)) |m_{t,l}|^2 + 4l^2 \ell_t.$$

*Proof.* Apply Lemma 3.2 conditionally on  $S_{t+1}$  to  $Z_{t+1}$  in Lemma 3.1, then average. The total conditional amplitude deficit is exactly  $\ell_t$ . Rotation covariance and the fair command give  $\mathbb{E} f_l(Z_{t+1}) = a_l m_{t,l}$ . This proves the first line. Both  $|m_{t+1,l}|$  and  $|a_l m_{t,l}|$  are at most one, so the difference of their squares is at most  $2|e_{t,l}|$ . Use  $|a_l|^2 = 1 - \sin^2(\pi l \alpha)$ .  $\square$

Associate to cut  $t$  the positive measure on the circle

$$(15) \quad \nu_t = \sum_{s: z_t(s) \neq 0} p_t(s) |z_t(s)| \delta_{\arg z_t(s)}.$$

Its mass is  $q_t$ , it has at most  $K_t$  atoms, and its  $l$ th Fourier moment is  $m_{t,l}$ . Equal directions may be combined; doing so only reduces the number of atoms.

**Lemma 3.4** (A finite positive Fourier witness). *For a positive circle measure  $\nu$  of mass  $q$  with at most  $k$  atoms, put*

$$\Phi^{(M)}(\nu) = \sum_{l=1}^M \left(1 - \frac{l}{M+1}\right) |\hat{\nu}(l)|^2.$$

*Then*

$$(16) \quad q^2 + 2\Phi^{(M)}(\nu) \geq \frac{M+1}{k} q^2.$$

*In particular,  $\Phi^{(2k)}(\nu) \geq q^2/2$ .*

*Proof.* The Fejér kernel

$$F_M(\theta) = \frac{1}{M+1} \left| \sum_{j=0}^M e^{ij\theta} \right|^2 = 1 + 2 \sum_{l=1}^M \left(1 - \frac{l}{M+1}\right) \cos(l\theta)$$

is nonnegative and has value  $M+1$  at zero. If the atom weights are  $w_i$ , integrate  $F_M(\theta - \phi)$  against  $\nu \otimes \nu$ . Dropping the nonnegative off-diagonal terms gives at least  $(M+1) \sum_i w_i^2 \geq (M+1) q^2/k$ . Expanding the same integral gives the left side of (16). This is the elementary positive-kernel identity; its use here is to detect a finite hidden register.  $\square$

**Theorem 3.5** (Spectral occupation budget). *In the process (7), suppose  $q_N \geq \kappa > 0$ . For every integer  $k \geq 1$ , even if other cuts have arbitrarily many states,*

$$(17) \quad \#\{0 \leq t < N : K_t \leq k\} \beta_{2k}(\alpha) \leq \frac{18k^3}{\kappa^2}.$$

*The conclusion remains true with  $K_t$  replaced by the number of positive-probability states under this test distribution.*

*Proof.* Fix  $k$ , set  $M = 2k$ ,  $w_l = 1 - l/(M + 1)$ , and abbreviate  $\Phi_t = \Phi^{(M)}(\nu_t)$ . Multiply (14) by  $w_l$  and sum. This gives

$$\Phi_{t+1} \leq \Phi_t - \sum_{l=1}^M w_l \sin^2(\pi l \alpha) |m_{t,l}|^2 + 4\ell_t \sum_{l=1}^M w_l l^2.$$

Initially  $z_0 = 1$  on every positive-mass state, so  $m_{0,l} = 1$  and  $\Phi_0 = M/2 = k$ . Moreover

$$\sum_{l=1}^M w_l l^2 = \frac{M(M+1)(M+2)}{12} = \frac{k(k+1)(2k+1)}{3} \leq 2k^3.$$

Sum over all epochs, use  $\Phi_N \geq 0$  and  $\sum \ell_t \leq 1$ , and obtain

$$(18) \quad \sum_{t < N} \sum_{l=1}^{2k} w_l \sin^2(\pi l \alpha) |m_{t,l}|^2 \leq k + 8k^3 \leq 9k^3.$$

At any cut with at most  $k$  positive-mass states, Lemma 3.4 and  $q_t \geq q_N \geq \kappa$  imply  $\Phi_t \geq \kappa^2/2$ . The summand at such a cut is therefore at least  $\beta_{2k}(\alpha)\kappa^2/2$ . All other summands are nonnegative. Counting the small cuts proves (17). Nothing in the proof identifies the conditional past phase with a statewise future prediction, and no bound on vertices of a lift is used.  $\square$

The test law uses fresh independent commands but makes no such assumption about the commands in the specification: a wordwise simulator must pass every chosen test distribution. The conditional objects in (8) need not be computable from the finite state by an available runtime table; they are used only in the converse.

#### 4. CONSEQUENCES FOR THE ROTATION EXPERIMENT

We now apply the budget to the original wordwise specification, not to a statewise-intertwining subclass.

**Proposition 4.1** (Terminal calibration of the past phase). *A realization of (1) with uniform row-TV error at most  $\varepsilon < 1/20$  satisfies  $q_N \geq 1/10 - 2\varepsilon$  under the fair-command test law with fixed seed  $x = (1, 1)$ .*

*Proof.* Let  $d = d_1 + id_2$  be the complex conditional mean of the two possible answers from the final state. Its modulus is at most  $\sqrt{2}$ . For any fixed command word, exactness would give

$$\mathbb{E}[d(S_N) \mid C_1, \dots, C_N] = \frac{1+i}{10} \zeta^{L_N}.$$

A TV error  $\varepsilon$  for a binary answer changes its mean by at most  $2\varepsilon$ . The complex error in this display is therefore at most  $2\sqrt{2}\varepsilon$ . Multiply by  $Y_N = \zeta^{-L_N}$  and average. The reverse triangle inequality gives

$$|\mathbb{E}[Y_N d(S_N)]| \geq \sqrt{2}(1/10 - 2\varepsilon).$$

Apply Lemma 3.1. Only the final-length answer identities were used. There is no assumption of a correct answer at an earlier cut.  $\square$

*Proof of the lower assertions of Theorem 1.1.* Proposition 4.1 and Theorem 3.5 give (3). If every cut has at most  $K$  states, then  $N\beta_{2K}(\alpha) \leq 18K^3/\kappa^2$ . For  $b_\alpha > 0$ ,

$$|\sin(\pi l \alpha)| \geq 2\|l\alpha\|_{\mathbb{R}/\mathbb{Z}} \geq \frac{2b_\alpha}{l} \geq \frac{b_\alpha}{K} \quad (1 \leq l \leq 2K).$$

This proves (4).

For the golden angle set  $\alpha' = -(1 + \sqrt{5})/2$ . If  $p$  is an integer nearest  $l\alpha$ , then

$$(l\alpha - p)(l\alpha' - p) = p^2 + lp - l^2 \in \mathbb{Z} \setminus \{0\}, \quad |l\alpha' - p| \leq \sqrt{5}l + 1/2 < 3l.$$

Hence  $l\|\alpha\| > 1/3$  and  $b_\alpha \geq 1/3$ . With  $\kappa = 1/10$  this gives  $(N/16200)^{1/5}$ . The exact rank-three bound is Proposition 2.2.

For  $\zeta = (3 + 4i)/5$ , no positive power equals one: otherwise  $\zeta + \zeta^{-1} = 6/5$  would be a rational algebraic integer. Thus  $(3 + 4i)^l - 5^l$  is a nonzero Gaussian integer and has modulus at least one. It follows that

$$\sin^2(\pi l \alpha) = \frac{|\zeta^l - 1|^2}{4} \geq \frac{25^{-l}}{4}, \quad \beta_{2K}(\alpha) \geq \frac{25^{-2K}}{4}.$$

The profile bound gives  $N \leq 7200K^3 25^{2K}$  at zero error. Since  $K^3 \leq 8^K$  for integer  $K \geq 1$ , it also gives  $N \leq 7200 5000^K$ . This proves (6).  $\square$

The occupation conclusion contains more information than a peak bound. For example, at the golden angle and zero error there are at most  $16200k^5$  command epochs with at most  $k$  available labels, irrespective of the widths at the other epochs. The analogous rational-angle count is at most  $7200k^3 25^{2k}$ . These are proof bounds, not exact finite complexity tables.

**4.1. An exact upper construction retained from the preceding argument.** For completeness we give the construction needed for the upper side of (5); its role here is inherited [17]. A convergent  $p/q$  of  $\alpha$  satisfies  $|\alpha - p/q| < q^{-2}$ . Choose one with  $q \geq \max\{5, (40N)^{1/3}\}$  and put

$$a = \pi/q, \quad \delta = 2\pi(\alpha - p/q), \quad \lambda = \frac{\cos(a - |\delta|)}{\cos a}, \quad \omega = \frac{\sin |\delta|}{\lambda \sin(2a)}.$$

Here  $|\delta| < 2\pi/q^2 < a$ , so  $\lambda \geq 1$  and  $0 \leq \omega \leq 1$ . Write  $u_s = (\cos(2\pi s/q), \sin(2\pi s/q))$  for the regular polygon vertices, with subscripts modulo  $q$ .

**Proposition 4.2** (Resonant stochastic polygon). *There is a  $q$ -state exact realization of (1), with command matrices independent of the epoch and a horizon-dependent final decoder. For bounded partial quotients it gives  $W_N = O_\alpha(N^{1/3})$ . For the golden angle the upper bound in (5) holds.*

*Proof.* At cut  $t$  use the vector  $r_t u_s$  for label  $s$ , where  $r_t = \lambda^t/4$ . The idle row is

$$T_0(s, \cdot) = \lambda^{-1} \delta_s + (1 - \lambda^{-1}) \text{Unif}[q].$$

The active row is

$$T_1(s, \cdot) = (1 - \omega) \delta_{s+p} + \omega \delta_{s+p+\text{sgn } \delta}.$$

If  $\delta = 0$  use  $\omega = 0$  and omit the second term. The line joining  $u_{s+p}$  to its indicated neighbor intersects the ray at angle  $2\pi s/q + 2\pi\alpha$  at radius  $1/\lambda$ . Resolving its two coordinates, or using the sine rule, gives exactly the displayed  $\omega$ . Consequently the expected next vector is  $r_t u_s$  after an idle command and  $R_\alpha r_t u_s$  after an active command.

Since  $\tan(\pi/q) \leq 2\pi/q$  for  $q \geq 5$ ,

$$\log \lambda = \int_{a-|\delta|}^a \tan v \, dv \leq |\delta| \tan a < 4\pi^2/q^3 < 40/q^3.$$

Thus  $r_N \leq e/4 < 1$ . The polygon at  $t = 0$  has inradius  $\cos(\pi/q)/4 > \sqrt{2}/10$  and therefore contains all four seed vectors  $x/10$ . Initialize by a convex representation of the seed in that polygon. The final decoder uses mean  $r_N e_j^T u_s$ , which lies in  $[-1, 1]$ . Induction on the commands proves exactness for every word.

Consecutive convergent denominators have bounded ratios at bounded-type angles, yielding the claimed order. At the golden angle the denominators are Fibonacci numbers, and the first one not smaller than a threshold  $L \geq 5$  is strictly less than  $2L$ . This gives the stated numerical bound.  $\square$

For the rational rotation an elementary exact rational alternative retains a triangle label and the number of active commands. Initialize in the triangle from Proposition 2.2, increment the count only on the active command, and decode the rotated triangle vertex. It uses at most  $3(N+1)$  labels and rational rows. The preceding resonant construction uses exact real rows; a finite fair-bit implementation of those rows is not being asserted.

## 5. DEFICIENCY OF A STOCHASTIC LIFT DIAGRAM

We next turn the quantitative converse into an obstruction to approximate stochastic lifts of the main experiment. The local language is classical comparison of experiments [3, 12]; the new use is a uniform lower bound on a full diagram, derived from the Fourier budget.

**5.1. Finite garbling and its normalization.** Let  $E \in \mathbb{R}_+^{H \times K}$  and  $F \in \mathbb{R}_+^{H \times J}$  have stochastic rows, indexed by a common finite parameter set. With the convention  $\text{TV}(p, q) = \frac{1}{2} \sum_j |p_j - q_j|$ , define

$$(19) \quad \delta(E, F) = \min_{T \mathbf{1} = \mathbf{1}, T \geq 0} \max_{h \in H} \text{TV}((ET)_h, F_h).$$

The direction is fixed: the signal of  $E$  is to simulate the signal of  $F$ . This is a one-sided finite deficiency. It is not a distance unless both directions and appropriate equivalence classes are considered.

**Proposition 5.1** (Finite comparison formula). *The minimum in (19) is attained, and*

$$(20) \quad \delta(E, F) = \max_{\sum_h \text{osc}(Z_h) \leq 1} \left\{ \langle Z, F \rangle - \sum_{i=1}^K \max_{1 \leq j \leq J} (E^T Z)_{ij} \right\}.$$

Here  $\text{osc}(Z_h) = \max_j Z_{hj} - \min_j Z_{hj}$ ; adding a constant to a row of  $Z$  changes neither objective nor constraint. In particular,  $\delta(E, F) = 0$  if and only if  $F = ET$  for a stochastic  $T$ , equivalently if and only if the associated finite decision inequalities hold. For three finite experiments,

$$(21) \quad \delta(E, G) \leq \delta(E, F) + \delta(F, G).$$

*Proof.* The stochastic matrices form a compact polytope. If each row of  $A$  sums to zero, then

$$\max_h \frac{1}{2} \|A_h\|_1 = \max_{\sum_h \text{osc}(Z_h) \leq 1} \langle Z, A \rangle.$$

Indeed each row contributes at most  $\text{osc}(Z_h) \|A_h\|_1 / 2$ ; equality follows by using an indicator of the positive coordinates on a maximizing row. Subtract the minimum of each row of  $Z$ . The permitted  $Z$  then form the compact convex set specified by auxiliary variables  $u_h \geq 0$ ,  $0 \leq Z_{hj} \leq u_h$ ,  $\sum_h u_h \leq 1$ . Apply finite convex minimax to  $\langle Z, F - ET \rangle$ . Each row of  $T$  maximizes a linear form independently, giving  $\max_T \langle Z, ET \rangle = \sum_i \max_j (E^T Z)_{ij}$ . This proves (20), including the normalization of the dual budget. At zero error it is exactly the finite Blackwell garbling criterion, not a new comparison theorem.

For the triangle bound choose minimizing post-processings  $T$  and  $U$ . For every row, contraction of TV under  $U$  and the triangle inequality give

$$\text{TV}((ETU)_h, G_h) \leq \text{TV}((ET)_h, F_h) + \text{TV}((FU)_h, G_h).$$

Taking maxima proves (21). □

**5.2. One common transition for every prefix.** Let  $H_t$  be all seed/command prefixes of length  $t$  in (1). A finite proposed diagram  $\mathcal{E}$  assigns a row-stochastic matrix  $E_t \in \mathbb{R}_+^{H_t \times K_t}$  at every cut. These are proposed ideal hidden-state distributions. For  $c \in \{0, 1\}$  let  $E_{t+1}^{[c]}$  have rows  $E_{t+1}(hc, \cdot)$  indexed by  $H_t$ . Let  $Q_j$  have rows equal to the prescribed binary answer laws for query  $j$  and complete prefixes in  $H_N$ . Define

$$(22) \quad \begin{aligned} d_t(\mathcal{E}) &= \max_{c \in \{0,1\}} \delta(E_t, E_{t+1}^{[c]}), \\ d_{\text{out}}(\mathcal{E}) &= \max_{j \in \{1,2\}} \delta(E_N, Q_j), \\ \mathcal{D}(\mathcal{E}) &= \sum_{t < N} d_t(\mathcal{E}) + d_{\text{out}}(\mathcal{E}). \end{aligned}$$

A stochastic post-processing in each term is common to all prefixes; it cannot depend on an unrecorded history. Each fixed-diagram term is a finite linear program. The definition does not optimize over the unknown rows  $E_t$  and does not assert that local errors cannot cancel at the output.

**Theorem 5.2** (Executable composition and main-family defect). *For every diagram  $\mathcal{E}$  there is a clocked stochastic machine with its same profile and uniform output error at most  $\min\{1, \mathcal{D}(\mathcal{E})\}$ . If every  $K_t \leq K$ , then*

$$(23) \quad \mathcal{D}(\mathcal{E}) \geq \frac{1}{2} \left[ \frac{1}{10} - \sqrt{\frac{18K^3}{N\beta_{2K}(\alpha)}} \right]_+.$$

More generally, for  $J_k = \#\{t < N : K_t \leq k\} > 0$ , the same inequality holds with  $K^3/N$  replaced by  $k^3/J_k$ .

*Proof.* Initialize using  $E_0$  and use minimizing stochastic matrices in each term of (22). Denote the actual prefix-state law by  $\hat{E}_t(h)$ . Induction and TV contraction give

$$\max_{h \in H_t} \text{TV}(\hat{E}_t(h), E_t(h)) \leq \sum_{u < t} d_u(\mathcal{E}).$$

The selected terminal decoder adds at most  $d_{\text{out}}$ . This proves the constructive statement, including a common executable row at every step.

Write  $D = \mathcal{D}(\mathcal{E})$ . If  $D \geq 1/20$ , the lower bound is immediate. Otherwise the constructed machine has error at most  $D$ , so Theorem 1.1 applies with  $\kappa = 1/10 - 2D$ . It implies  $N\beta_{2K}(\alpha) \leq 18K^3/(1/10 - 2D)^2$ . Rearranging gives (23). The occupation form is identical, using (3) rather than its peak consequence.  $\square$

For badly approximable  $\alpha$ , the right side is at least

$$(24) \quad \frac{1}{2} \left[ \frac{1}{10} - \sqrt{\frac{18K^5}{b_\alpha^2 N}} \right]_+.$$

Thus no family of diagrams with  $K = o(N^{1/5})$  has total certified simulation defect tending to zero. In particular a static polygon lift using  $O(\log N)$  coordinates cannot be turned into a vanishing-defect stochastic diagram for this task at the same width. This conclusion requires a specified initialization and bounded terminal decoder as in (22); it is not a lower bound on static extension complexity. It permits every hidden choice of section and projection, not merely a selected regular-polygon extended formulation.

The additive quantity  $\mathcal{D}$  is a useful operational upper bound on terminal error, not a claimed exact formula for minimum terminal error. Approximation of intermediate lifts, terminal decoding and the complete wordwise task are thereby kept distinct. Theorem 5.2 provides the requested

connection between finite deficiency and the actual rotation family without relying on a separate toy example.

## 6. EQUIVARIANCE AND TWO AUTONOMOUS SPECIFICATIONS

An equivariant lift carries a group action on one extension, intertwining with the action on the base. In the orthant case this is represented by coordinate permutations after the usual normalization. Definitions 2.7–2.8 and Theorem 2.9 of the preprint of Gouveia–Parrilo–Thomas [7] relate symmetric cone lifts to symmetric slack factorizations. Symmetry can change extension size substantially [9]. In the regular-polygon case, equivariant LP lifts of prime-power order require linear size, whereas nonsymmetric LP lifts can have logarithmic size; the equivariant PSD theory has different bounds [4], including logarithmic-size lifts of regular  $2^n$ -gons.

Our stochastic diagrams do not impose a group representation, inverses, one common section, or a permutation action on hidden coordinates. Their maps may be noninvertible and epoch dependent. Hence the cited equivariant lower bounds do not apply directly, and static small lifts do not provide the stochastic maps needed here. The following elementary comparison makes one exact point of contact. It is a consequence of classical stochastic matrix spectral theory, not a new symmetric-lift bound.

**Proposition 6.1** (An exact cyclic stochastic lift). *Let  $\xi = e^{2\pi i/m}$ ,  $m \geq 2$ , and suppose stochastic rows  $E_0, \dots, E_{m-1} \in \Delta_K$ , a stochastic matrix  $T$ , and a complex column  $d$  satisfy*

$$E_j T = E_{j+1 \bmod m}, \quad E_j d = r \xi^j \quad (r \neq 0).$$

*Then  $K \geq m$ . The bound is attained by the  $m$ -cycle permutation matrix.*

*Proof.* The complex row  $w = m^{-1} \sum_{j=0}^{m-1} \xi^{-j} E_j$  has  $wd = r$ , so it is nonzero, and direct reindexing gives  $wT = \xi w$ . Thus  $\xi$  is an eigenvalue of  $T$ . Every unit-modulus eigenvalue of a finite stochastic matrix belongs to a recurrent irreducible class and is a root of unity of order dividing the period of that class. That period is at most the number of its states. For completeness, transient blocks have spectral radius less than one; in an irreducible recurrent block, equality in the triangle inequality for an eigenvector at its maximal modulus forces its phases to advance by the eigenvalue along every positive edge. Along every directed cycle the accumulated phase is one, so its order divides the greatest common divisor of the cycle lengths. The primitive  $m$ th root therefore requires at least  $m$  states. The permutation construction realizes equality.  $\square$

Proposition 6.1 assumes exact cyclic closure, including its last-to-first transition. The finite irrational experiment has no such closure. Its nonstationary lower bound comes instead from the finite Fourier occupation theorem, which needs no eigenvalue shared by successive matrices. This is why replacing the latter proof by a peripheral-spectrum argument would be invalid.

**6.1. Fixed length is not an anytime query.** Define  $A_N^{\text{fix}}$  by requiring one common state set, two common command matrices  $T_0, T_1$ , and one final decoder, but correctness only after exactly  $N$  commands. The entire machine may depend on  $N$ . Define  $A_N^{\text{any}}$  with the same data required to answer after every command length  $0, 1, \dots, N$ . A query is an atomic external input in both models. Counts refer to internal labels before emission; charging two additional absorbing answer labels increases the given upper bounds by at most two. No internal test of input length is required by either interface.

**Corollary 6.2** (Bounds with the query-time quantifier fixed). *For bounded-type  $\alpha$ ,*

$$\Omega_\alpha(N^{1/5}) \leq W_N(\alpha) \leq A_N^{\text{fix}}(\alpha) \leq O_\alpha(N^{1/3}).$$

*For irrational  $\alpha$ , the stronger anytime specification satisfies*

$$N + 1 \leq A_N^{\text{any}}(\alpha) \leq 3(N + 1).$$

*The anytime assertion is the inherited spectral comparison [17], not a linear lower bound for  $A_N^{\text{fix}}$ .*

*Proof.* The unrestricted lower bound applies to stationary matrices in particular. Proposition 4.2 uses the same command matrices at all epochs, so it gives the fixed-length autonomous upper bound without phase tags. Its final radius and decoder depend on  $N$ , as permitted.

For the anytime lower bound fix seed  $(1, 1)$ , use only active commands, and combine the two decoders into  $d$ . If a machine with  $K \leq N$  states were correct, then  $ET_1^j d = c\zeta^j$  for  $j = 0, \dots, K$ , where  $c = (1 + i)/10 \neq 0$ . Cayley–Hamilton, applied to these  $K + 1$  identities, forces the characteristic polynomial of  $T_1$  to vanish at  $\zeta$ . The unit-modulus eigenvalue property proved above contradicts irrationality. For the upper bound keep the triangle label of the seed and the number of active commands. The latter never exceeds  $N$  on a permitted word. Idle commands leave it unchanged; active commands increment it; the decoder rotates the stored triangle vertex by that count. Arbitrary normalized rows at count  $N$  complete the matrix on unused transitions. This machine answers correctly at every allowed length.  $\square$

## 7. RELATION TO PRIOR MECHANISMS AND REMAINING QUESTIONS

Positive realization has long distinguished observable linear dimension from positive-state dimension. Benvenuti–Farina [1, 2] give fixed-degree examples requiring large positive order and explain invariant-cone constructions. Heller [8] and the realization survey of Vidyasagar [14] provide the stochastic-process background. Accessible spaces, observable quotients and positive intertwining are also explicit in Monràs–Winter [11]. None of these mechanisms is renamed here as a new normal form. The specific assertion proved in Theorem 3.5 is a finite-horizon lower bound for unrelated stochastic updates, using a final correlation rather than one repeated transition or a statewise predictive coordinate.

For comparison, the recent work of Lumbreras–Ma–Thompson–Gu [10] studies irreducible finite-classical prediction and decision errors in a stationary world-model setting. Its Section IV.B uses repeated application of the same update along a Wait–Tick trajectory and the peripheral behavior of that update. Here the matrices may change at every epoch, and even the complete machine may change with the horizon. The phase/Jensen/Fejér proof gives a quantitative finite budget under those quantifiers. This distinction does not claim that all neighboring approximate-realization results have been exhausted.

Static polyhedral lift theory identifies extension size through slack factorizations [7]. Regular polygons admit small nonsymmetric extensions [5, 13]; respecting a group action can change this substantially [9, 4]. Section 6 states the exact model distinction. Our converse does not assume equivariance or extract an exposed face for each state. A hidden register instead produces at most  $K$  atoms in a measure of conditional *past* phases, even when its reachable simplex section has exponentially many projected vertices. The common amplitude-loss estimate is what makes those atoms useful through time.

The one-step equation  $ET = F$ , its decision inequalities, and one-sided TV deficiency belong to classical comparison of experiments [3, 12]; see also the modern formulation of the Blackwell–Sherman–Stein theorem in [6]. Proposition 5.1 includes a proof to fix the direction and factor of two, not to claim a new one-step duality. The additive composition of stochastic errors is likewise standard. The main-family lower bound (23), which applies to every proposed small-width diagram, is a consequence of the new all-hidden-state budget.

| Main-family diagram-defect inequality                               | New consequence combining the converse with executable composition.       |
| Cyclic spectral and anytime comparisons                             | Classical spectral mechanism and inherited stronger-task comparison.      |

**7.1. Conclusions.** For the fixed-alphabet uniformly positive rotation experiment, a hidden register of bounded-type angle requires polynomial, not merely logarithmic, width. The proof permits arbitrary hidden states and arbitrary clocked updates. The same occupation theorem survives a fixed uniform row error below  $1/20$  and obstructs every small-width stochastic lift diagram with vanishing total deficiency.

The exact hidden exponent is not determined: the present lower and upper orders are  $N^{1/5}$  and  $N^{1/3}$ . The vector-state order remains  $N^{1/3}$  under the inherited bounded-type hypotheses. Sharpening the homogeneous angular estimate, the finite Fourier witness, or the exact hidden construction are distinct possible routes to closing this gap. No optimal global lift-search algorithm is asserted by the finite comparison linear programs.

The model counts persistent classical labels, not construction time, read-only program size, or fair-bit sampling workspace. Fixed-length and anytime autonomous interfaces remain distinct. The historical geometric, analytic and operator-theoretic manuscripts in the broader program keep their independent proof obligations; no conclusion in this article asserts their closure. Earlier results are preserved separately without being used as evidence of priority or editorial significance.

# GENERAL THETA FOUNDATIONS I: COMPATIBLE POLYHEDRAL LIFTS AND QUANTITATIVE CAUSAL WIDTH

QIAN QI

**ABSTRACT.** An exact finite-horizon stochastic transducer determines a sequence of simplex-section extensions joined by stochastic maps. Static extension size does not certify those maps. We formulate the compatibility condition, give its linear dual for fixed extensions, and exhibit an affine map whose best stochastic extension has uniform error exactly  $1/4$ . For a fixed-alphabet rotation experiment of separate positive rank three, a mean-support budget improves the all-hidden-state lower bound to  $\sum_{t \leq N} 2^{-3Kt} \leq 320$  at the golden angle. A resonant polygon construction improves the exact upper width from order  $N^{1/2}$  to order  $N^{1/3}$ . More generally, for every irrational angle with bounded continued-fraction coefficients, the minimum width among vector-state realizations is of order  $N^{1/3}$ ; the lower bound covers all time-varying polygon chains, not only regular polygons. For general hidden realizations the resulting bounds are logarithmic and cube-root, and need not coincide. An elementary denominator argument gives an explicit doubly logarithmic lower bound for the rational rotation  $(3 + 4i)/5$ . Finally, requiring a single clock-free decoder to answer at any stopping length up to  $N$  gives linear autonomous state complexity. These results distinguish static lifts, compatible clocked lifts, vector-state realizations, and autonomous devices without identifying their different optimization problems.

## 1. INTRODUCTION

The state count of a positive realization is not determined by its linear rank. This is a classical fact. Benvenuti and Farina constructed transfer functions of fixed McMillan degree three with arbitrarily large minimum positive order [1]; subsequent work obtained matching realizations for their family [5, Example 2]. There is a second, different classical fact: a polygon with many vertices may have an extension with only logarithmically many facets [14, 6, 12]. The simultaneous finite-horizon problem lies between these observations. Its state register supplies an extension at each epoch, but also supplies stochastic maps joining the extensions for every allowed command. Neither independent positive factorizations nor independent small extensions impose this compatibility.

We study the complete binary-output experiment

$$(1) \quad C_{N,\alpha}(b \mid x, c_1, \dots, c_N, j) = \frac{1 + b e_j^T R_\alpha^{c_1 + \dots + c_N} x / 10}{2},$$

where  $x \in \{-1, 1\}^2$ ,  $c_t \in \{0, 1\}$ ,  $j \in \{1, 2\}$  and  $b \in \{-1, 1\}$ . Here  $R_\alpha$  is rotation through  $2\pi\alpha$ . All alphabets are fixed. All probabilities lie in the fixed interval

$$\left[ \frac{1 - \sqrt{2}/10}{2}, \frac{1 + \sqrt{2}/10}{2} \right].$$

*Key words and phrases.* Positive realization, stochastic transducers, compatible extensions, mean width, irrational rotation, finite-horizon realization.

Equality is required for every word, not just in expectation over an input prior. The separate positive minimum at every internal cut is three (Proposition 2.3). The question is the peak number of labels needed by one compatible machine.

**1.1. The quantitative distinction.** Write  $W_N(\alpha)$  for unrestricted clocked positive-realization width. Write  $V_N(\alpha)$  for its vector-state restriction, in which every state has a predictive vector and each stochastic command row intertwines those vectors, not merely their reachable affine combinations. These are defined in Section 2. Let  $A_N(\alpha)$  be the number of states in a clock-free machine with one fixed decoder that answers a terminating query at any command length from zero through  $N$ . The last task has a stronger query-time specification, which is part of its definition.

**Theorem 1.1** (Quantitative width distinctions). *Let  $\alpha$  be irrational, and suppose all its continued-fraction partial quotients are at most an integer  $A \geq 1$ . Let  $q_N$  be the first convergent denominator at least  $\max\{5, (40N)^{1/3}\}$ . For  $N \geq 1$ ,*

$$(2) \quad \max\left\{3, \frac{1}{3} \log_2 \frac{N}{160(A+1)}\right\} \leq W_N(\alpha) \leq V_N(\alpha) \leq q_N,$$

$$(3) \quad \max\left\{3, \left(\frac{N}{160(A+1)}\right)^{1/3}\right\} \leq V_N(\alpha) < (A+1) \max\{5, (40N)^{1/3}\}.$$

Thus  $V_N(\alpha) = \Theta_\alpha(N^{1/3})$ . In addition, for every infinite-order planar rotation, without the bounded-type assumption,

$$(4) \quad N+1 \leq A_N(\alpha) \leq 3(N+1)+2.$$

At the golden angle  $\alpha = (\sqrt{5}-1)/2$ , every exact hidden-state profile satisfies  $\sum_{t < N} 2^{-3K_t} \leq 320$ ; every vector-state profile satisfies  $\sum_{t < N} K_t^{-3} \leq 320$ .

The hidden-state lower bound is not replaced by the stronger vector-state bound. A section of a  $K$ -coordinate simplex can project to many more than  $K$  vertices. This distinction is indispensable: regular polygons have small static extensions, and an unproved restriction to vector states would discard precisely the possible hidden savings. Theorem 3.5 specifies the additional stochastic compatibility required of a sequence of extensions. Theorem 3.2 checks it by a finite linear program when the extensions and the proposed lifted affine maps have been supplied. It does not optimize over all extensions efficiently.

For the rational rotation  $R = (1/5) \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}$ , Theorem 6.2 gives the explicit necessary condition

$$N \leq 140 2^{2W_N} 5^{82^{W_N}}.$$

It requires neither quantifier elimination nor an unproved bounded-type property of  $\arg(3+4i)/(2\pi)$ . Its growth rate is deliberately separated from the sharper bounded-type statement.

**1.2. Mechanism and scope.** For an observable polygon  $P$ , use the mean support  $m(P) = (2\pi)^{-1} \int h_P$ , rather than its area. The one-step gain for  $\text{conv}(P \cup R_\alpha P)$  accumulates linearly along a finite orbit. Comparing that orbit hull with the optimal perimeter of an inscribed polygon gives a gain of order  $M^{-3}$  for at most  $M$  vertices and bounded-type angles. No squaring of a Hausdorff displacement is needed. The matching vector-state upper bound aligns regular polygons with convergents of the angle; their required radial expansion per step is then of order  $M^{-3}$  rather than  $M^{-2}$ .

All exact clocked counts use atomic stochastic rows, an external epoch, and known read-only tables. They do not count arithmetic or table construction. The new autonomous comparison removes the external epoch and fixes the decoder, but still uses the same atomic-row convention.

The old rational fair-bit compiler remains a separately priced implementation theorem [15]. No table-free bit-space claim is made.

| Anytime autonomous comparison     | Finite-horizon consequence of Cayley–Hamilton and the classical peripheral-spectrum constraint.         |

The complete earlier proofs, including the volume theorem and tagged profile composition, are preserved separately. They are not prerequisites for auditing the new argument, and their archive size is not part of its mathematical content.

## 2. MACHINES AND OBSERVABLE SECTIONS

We use row vectors for state distributions. Put  $\Delta_k = \{e \in \mathbb{R}^k : e \geq 0, e\mathbf{1} = 1\}$ ,  $S = [-1/10, 1/10]^2$ , and  $D = [-1, 1]^2$ .

**Definition 2.1** (Clocked realization). A realization of (1) consists of an initialization  $E_x \in \Delta_{K_0}$ , row-stochastic matrices  $T_{t,c} \in \mathbb{R}_+^{K_t \times K_{t+1}}$  for  $0 \leq t < N$ ,  $c \in \{0, 1\}$ , and decoder means  $d_j \in [-1, 1]^{K_N}$ , satisfying

$$(5) \quad E_x T_{0,c_1} \cdots T_{N-1,c_N} d_j = e_j^T R_\alpha^{\sum c_t} x / 10$$

for every input word and query. The decoder emits the binary law with this conditional mean. The available-label profile is  $(K_t)_{t=0}^N$ ; its peak is  $\max_t K_t$ , and its minimum is  $W_N(\alpha)$ . A final retained binary output can be implemented in two further output labels at its own cut and does not change this peak, which is at least three.

Only the current register persists. The seed, old commands, random coins, and protocol history are not supplied again. The seed and terminal query are atomic inputs; commands are external, rather than selected by an experimental policy. A row may depend on the external epoch and current command, but not on a future symbol. Every row, including an unreachable one, is normalized. Available-label counting permits padding and makes feasible profiles upward closed. The number of program bits, exact row arithmetic, and sampling cost are not part of this width. For comparison, a separate minimum at cut  $t$  imposes no bound at any other cut. It is not the peak of a simultaneously minimal machine.

**Definition 2.2** (Vector-state realization). A clocked realization is vector-state if there are vectors  $z_{t,s} \in D$  satisfying

$$(6) \quad \sum_s E_x(s) z_{0,s} = x / 10, \quad \sum_{s'} T_{t,c}(s, s') z_{t+1,s'} = R_\alpha^c z_{t,s}, \quad d_j(s) = e_j^T z_{N,s}.$$

The middle equality is required at every available state, not only after averaging over reachable distributions. The least peak in this subclass is  $V_N(\alpha)$ .

Such a machine is equivalent to a sequence of polygons  $P_t = \text{conv}\{z_{t,s}\}$  with

$$(7) \quad S \subset P_0, \quad P_t \subset D, \quad \text{conv}(P_t \cup R_\alpha P_t) \subset P_{t+1}.$$

The forward implication follows from (6); conversely, choose the vertices as states and the corresponding barycentric rows. Thus the minimum vertex count of a compatible chain is exactly the vector-state optimization. No such identification is imposed on  $W_N$ .

**Proposition 2.3** (Separate minimum). *Every internal cut of (1) has normalized residual rank three and separate positive minimum three, for every  $N$  and rotation.*

*Proof.* The four prefixes with all commands idle have predictive vectors  $x/10$  and span an affine plane. The two idle-suffix coordinate queries separate this plane. All residual arrays are affine functions of a two-dimensional predictive vector, so their normalized rank is exactly three. The vectors have Euclidean norm  $\sqrt{2}/10$ . The triangle with vertices

$$(1/2, 0), \quad (-1/2, 1/2), \quad (-1/2, -1/2)$$

contains the disk of this radius: its three supporting lines have distances  $1/2, 1/(2\sqrt{5}), 1/(2\sqrt{5})$  from zero, all greater than  $\sqrt{2}/10$ . Its vertices have norm at most  $1/\sqrt{2}$ . Consequently every vertex defines a legal entire future continuation under all rotations and both queries. Barycentric initialization at the selected cut gives a three-generator factorization of all its residuals. To embed it into a complete machine, store the raw prefix until the selected cut, sample that three-valued label, and then retain the label and the remaining finite command count. Other cuts are unrestricted. Rank supplies the matching lower bound. This is the inherited separate minimum calculation of [16], included to fix its quantifier.  $\square$

**Lemma 2.4** (Reachable-section lift). *Every realization determines affine sections  $Q_t = H_t \cap \Delta_{K_t}$  and linear maps  $\pi_t$  with  $P_t = \pi_t(Q_t)$  satisfying (7) and*

$$(8) \quad |\text{ext } P_t| \leq 2^{K_t}.$$

*For vector-state realizations one may instead use  $|\text{ext } P_t| \leq K_t$ .*

*Proof.* Let  $E_h$  denote the state distribution following an actual prefix, and set  $H_t = \text{aff}\{E_h\}$ . Define  $\pi_t(e)$  by the two terminal means obtained from  $e$  after idling all remaining commands. It maps the whole simplex into  $D$ . The identities

$$E_h T_{t,c} = E_{hc}, \quad \pi_{t+1}(E_h T_{t,c}) = R_\alpha^c \pi_t(E_h)$$

extend affinely across  $H_t$ . Stochasticity then gives  $Q_t T_{t,c} \subset Q_{t+1}$  and the required observable inclusions. The idle command implies  $P_t \subset P_{t+1}$ , hence every  $P_t$  contains  $S$ . In its affine hull  $Q_t$  has at most  $K_t$  coordinate inequalities. Distinct vertices have distinct active zero-coordinate sets: otherwise their difference is a two-sided feasible direction at either vertex. There are at most  $2^{K_t}$  such sets, and projection cannot increase the number of vertices. This is the standard face-count bound for extensions [6], not a special new combinatorial principle. For the vector-state class, use the polygon in (7).  $\square$

The restriction to  $H_t$  is essential. A hidden basis state need not have the observable intertwining identity. The proof therefore retains the section before projection, as in accessible-space and observable-quotient constructions [3, 10]. It is this lift that separates the two bounds in Lemma 2.4.

### 3. STATIC EXTENSIONS AND STOCHASTIC COMPATIBILITY

A polyhedral extension is a polytope followed by an affine projection. Its size is the number of inequalities, not the number of projected vertices. The distinction is classical [14, 6]. We first record exactly what simplex normalization does, and does not, provide.

**Proposition 3.1** (Normalization of bounded extensions). *Every positive-dimensional bounded polytope with  $f$  facets is affinely isomorphic to a section  $H \cap \Delta_f$ . Thus a bounded extension with  $f$  facets can be put in simplex-section form without increasing  $f$ . An affine map between two such sections need not extend to a stochastic map between their ambient simplices.*

*Proof.* Work in the affine hull and write an irredundant facet description  $\ell_i(u) = b_i - a_i \cdot u \geq 0$ ,  $1 \leq i \leq f$ . Boundedness implies that the normals positively span the dual space. Consequently there are strictly positive  $w_i$  with  $\sum_i w_i a_i = 0$ . For example, express each  $-a_i$  as a nonnegative combination of the normals and add these  $f$  dependences. The positive constant  $c = \sum_i w_i b_i$  can be evaluated at a relative interior point, where it is a sum of positive slacks. The affine map

$$u \mapsto (w_i \ell_i(u)/c)_{i=1}^f$$

is injective, has coordinate sum one, and sends the polytope onto the intersection of its affine image with  $\Delta_f$ . Injectivity follows because the normals span. A point polytope uses  $\Delta_1$ . The last assertion is proved quantitatively in Proposition 3.3 below.  $\square$

The projection of a normalized extension is defined on its affine section. It need not map the whole ambient simplex into the observation domain. Nor does normalization produce transition kernels. These two additional requirements are not part of static extension complexity.

**Theorem 3.2** (Stochastic extension criterion). *Let  $Q \subset \Delta_k$  be a polytope, let  $q^1, \dots, q^r$  affinely span  $Q$ , and let  $F : Q \rightarrow \Delta_l$  be affine. Put  $E_{hi} = q_i^h$  and  $B_{hj} = F(q^h)_j$ . A row-stochastic  $k$  by  $l$  matrix  $T$  satisfying  $eT = F(e)$  on  $Q$  exists if and only if, for every real  $r$  by  $l$  matrix  $Z$ ,*

$$(9) \quad \langle Z, B \rangle \leq \sum_{i=1}^k \max_{1 \leq j \leq l} (E^T Z)_{ij}.$$

*For fixed rational  $E, B$ , feasibility and a separating certificate are finite linear-programming problems.*

*Proof.* The desired set of image matrices is the compact convex polytope  $\mathcal{B} = \{ET : T \geq 0, T\mathbf{1} = \mathbf{1}\}$ . Its support function at  $Z$  is the right side of (9), since the rows of  $T$  are independent probability vectors. Finite-dimensional separation says  $B \in \mathcal{B}$  exactly when all the displayed inequalities hold. Equality on the spanning rows extends to  $Q$  by affinity. This is the ordinary support-function dual of a stochastic post-processing problem; it is not a new minimax interchange. The additional point is that the same test can be applied to each proposed inter-epoch lift.  $\square$

**Proposition 3.3** (An exact extension defect). *On*

$$Q = \{e \in \Delta_4 : e_1 + e_2 = e_3 + e_4 = 1/2\}$$

*the affine map  $F(e) = (2e_1, 2e_2)$  takes values in  $\Delta_2$ , but has no ambient stochastic extension. More precisely,*

$$(10) \quad \min_{T \geq 0, T\mathbf{1} = \mathbf{1}} \max_{e \in Q} \text{TV}(eT, F(e)) = \frac{1}{4}.$$

*Proof.* Write  $u_i = T_{i1} \in [0, 1]$ . At the four vertices  $e^{ij} = (e_i + e_j)/2$ ,  $i \in \{1, 2\}$ ,  $j \in \{3, 4\}$ , the desired first output probability is one for  $i = 1$  and zero for  $i = 2$ . For fixed  $j$ , the realized probabilities differ by  $(u_1 - u_2)/2 \leq 1/2$ . Their two errors must therefore sum to at least  $1/2$ , and one is at least  $1/4$ . Taking  $(u_1, u_2, u_3, u_4) = (1, 0, 1/2, 1/2)$  attains error  $1/4$  at the vertices. Convexity bounds the error everywhere else by the vertex maximum. This also gives a finite strict witness for (9).  $\square$

**Definition 3.4** (Compatible stochastic lift). For the mean dynamics in (1), a lift of profile  $(k_t)$  consists of nonempty sections  $Q_t = H_t \cap \Delta_{k_t}$ , affine observable maps  $\pi_t : Q_t \rightarrow D$ , seed lifts  $E_x \in Q_0$  with  $\pi_0(E_x) = x/10$ , and affine maps  $F_{t,c} : Q_t \rightarrow Q_{t+1}$  with

$$\pi_{t+1} F_{t,c} = R_\alpha^c \pi_t.$$

Each  $F_{t,c}$  must extend to an ambient row-stochastic matrix. For each final query  $j$ , the map  $e \mapsto (1 + e_j^T \pi_N(e))/2$  must extend to a  $[0, 1]$ -valued affine map on the whole simplex, equivalently to a binary stochastic decoder. The least possible peak coordinate count is denoted  $\text{cw}_N(\alpha)$ .

**Theorem 3.5** (Operational meaning of a compatible lift). *The complete feasible coordinate profiles of compatible stochastic lifts are exactly the feasible hidden-state profiles of (1). In particular,  $\text{cw}_N(\alpha) = W_N(\alpha)$ . For supplied finite sections and supplied affine lift maps, all stochastic extension requirements, including the final decoder requirements, can be tested by Theorem 3.2.*

*Proof.* A machine supplies the sections and idle-suffix maps of Lemma 2.4. Restrict its actual transition matrices to these sections; their observable identity holds there. The final decoder already extends to the whole simplex. Conversely choose the stochastic extensions and start at the specified seed lift. Induction keeps the running distribution in  $Q_t$  and its observable image equals the desired rotated seed. The final extended decoder then gives exactly (1). The stochastic maps at different cuts are used together, not selected afresh after seeing a hidden parameter. Affinely spanning points suffice for each extension test; convexity ensures legality throughout a section.  $\square$

The theorem defines the dynamic object and gives a local feasibility criterion when its geometry is fixed. It is not an efficient algorithm for searching over all lifts. Proposition 3.3 does not prove that every logarithmic extension of a regular polygon is incompatible with rotation; it proves that compatibility cannot be inferred merely from affine positivity on the section. In particular, we neither assume nor exclude a logarithmic hidden-state construction for (1). Static  $O(\log m)$  extensions of regular  $m$ -gons [6, 12] remain relevant candidates, but need the inter-epoch and readout extension tests.

#### 4. MEAN-SUPPORT GROWTH ALONG AN ORBIT

For a planar convex body  $P$ , let  $h_P(u) = \max_{z \in P} u \cdot z$  and

$$m(P) = \frac{1}{2\pi} \int_0^{2\pi} h_P(\cos \theta, \sin \theta) d\theta.$$

For polygons this is perimeter divided by  $2\pi$ , by Cauchy's perimeter formula. Define

$$\mathcal{G}_\alpha(P) = \text{conv}(P \cup R_\alpha P), \quad D_\alpha(P) = m(\mathcal{G}_\alpha(P)) - m(P).$$

The functional is monotone under inclusion and invariant under rotation. For a chain (7),

$$(11) \quad \sum_{t < N} D_\alpha(P_t) \leq m(P_N) - m(P_0) \leq \sqrt{2}.$$

The last bound uses  $P_N \subset [-1, 1]^2 \subset \sqrt{2}\mathbb{B}^2$ . It is deliberately larger than the exact endpoint allowance.

**Lemma 4.1** (Accumulation without squaring). *For any integer  $q \geq 2$  and  $P$ ,*

$$(12) \quad m\left(\text{conv} \bigcup_{k=0}^{q-1} R_\alpha^k P\right) - m(P) \leq (q-1)D_\alpha(P).$$

*Proof.* Write  $h_k(\theta) = h_P(\theta - 2\pi k\alpha)$ . Pointwise,  $\max_{k < q} h_k - h_0 \leq \sum_{k=1}^{q-1} (h_k - h_{k-1})_+$ . Each summand has the same integral as  $(h_1 - h_0)_+$ , whose normalized integral is  $D_\alpha(P)$ . Integrate the inequality.  $\square$

**Lemma 4.2** (Inscribed-polygon deficit). *Suppose  $a\mathbb{B}^2 \subset P$ , and  $P$  has at most  $M \geq 3$  vertices. Put  $r = \max_{z \in P} \|z\|_2$ . Then*

$$(13) \quad m(P) \leq r \frac{M}{\pi} \sin \frac{\pi}{M}.$$

*Proof.* Push each vertex radially to the circle of radius  $r$ . The resulting convex hull still contains zero and hence contains the old vertices and  $P$ . If its successive angular gaps are  $\theta_1, \dots, \theta_m$ ,  $m \leq M$ , its perimeter is  $2r \sum_i \sin(\theta_i/2)$ . Concavity of sine on  $[0, \pi]$ ,  $\sum_i \theta_i = 2\pi$ , and monotonicity of  $m \sin(\pi/m)$  give at most  $2rM \sin(\pi/M)$ . Monotonicity of mean support and Cauchy's formula prove the assertion. The radial hull contains zero because any positive affine dependence of the old vertices giving zero can be reweighted by their radii.  $\square$

**Lemma 4.3** (A denominator gives an orbit net). *If  $(p, q) = 1$  and  $|\alpha - p/q| < q^{-2}$ , the first  $q$  points of the rotation orbit of any unit vector form an angular  $3\pi/q$ -net.*

*Proof.* The multiples of  $p/q$  give the uniform grid of mesh  $1/q$  turns. The corresponding first  $q$  multiples of  $\alpha$  differ by less than  $1/q$  turns. Every point is within  $1/(2q)$  turns of the grid, proving the bound after multiplying by  $2\pi$ .  $\square$

**Theorem 4.4** (One-step quantitative mean-support gain). *Suppose  $a\mathbb{B}^2 \subset P$ ,  $|\text{ext } P| \leq M$ ,  $M \geq 3$ , and a reduced fraction  $p/q$  satisfies  $q \geq 8M$  and  $|\alpha - p/q| < q^{-2}$ . Then*

$$(14) \quad D_\alpha(P) \geq \frac{3a}{4M^2q}.$$

*Proof.* Take a vertex of maximum radius  $r$ . Its first  $q$  rotations and Lemma 4.3 imply

$$m\left(\text{conv} \bigcup_{k < q} R_\alpha^k P\right) \geq r \cos(3\pi/q).$$

Subtract (13). Since  $M \geq 3$  and  $q \geq 8M$ , Taylor's inequalities for sine and cosine give

$$\begin{aligned} \cos(3\pi/q) - \frac{M}{\pi} \sin(\pi/M) &\geq \frac{\pi^2}{M^2} \left( \frac{1}{6} - \frac{\pi^2}{120M^2} - \frac{9M^2}{2q^2} \right) \\ &\geq \frac{9}{M^2} \left( \frac{1}{6} - \frac{10}{1080} - \frac{9}{128} \right) = \frac{301}{384M^2} > \frac{3}{4M^2}. \end{aligned}$$

The inequalities use only  $9 < \pi^2 < 10$ . Apply Lemma 4.1, use  $r \geq a$  and  $q-1 < q$ . The gain is linear in the integrated support deficit; an area cap is not introduced.  $\square$

For an irrational  $\alpha \in (0, 1)$ , let  $p_k/q_k$  be its continued-fraction convergents, ignoring the initial repeated denominator one, and define

$$(15) \quad Q_\alpha(M) = \min\{q_k : q_k \geq 8M\}.$$

We use the elementary relations

$$(16) \quad (p_k, q_k) = 1, \quad |\alpha - p_k/q_k| < \frac{1}{q_k q_{k+1}} \leq \frac{1}{q_k^2}, \quad q_{k+1} = a_{k+1} q_k + q_{k-1}.$$

They follow by writing  $\alpha$  with its remaining continued-fraction complete quotient and using  $p_k q_{k-1} - p_{k-1} q_k = (-1)^{k-1}$ ; see also [9]. In particular, if  $a_k \leq A$  for all  $k \geq 1$ ,  $Q_\alpha(M) < 8(A+1)M$ .

**Theorem 4.5** (Profile budget and bounded-type width). *Every exact hidden-state realization of (1) satisfies*

$$(17) \quad \sum_{t < N} \frac{1}{2^{2K_t} Q_\alpha(2^{K_t})} \leq \frac{40\sqrt{2}}{3}.$$

If  $a_k \leq A$ , then

$$(18) \quad \sum_{t < N} 2^{-3K_t} \leq 160(A + 1).$$

For vector-state realizations the same statements hold with  $2^{K_t}$  replaced by  $K_t$ . Consequently  $W_N \geq \frac{1}{3} \log_2(N/[160(A + 1)])$  and  $V_N \geq (N/[160(A + 1)])^{1/3}$ .

*Proof.* Use Lemma 2.4 and Theorem 4.4 with  $a = 1/10$ ,  $M = 2^{K_t}$ ,  $q = Q_\alpha(M)$  in (11). This gives (17). Under the bounded-type assumption each gain is at least  $3/[320(A + 1)M^3]$ . The endpoint allowance gives

$$\sum_{t < N} M^{-3} \leq \frac{320(A + 1)\sqrt{2}}{3} < 160(A + 1).$$

In the vector-state class, use the other vertex bound in Lemma 2.4. A peak bound supplies the stated consequences.  $\square$

For the golden angle all partial quotients equal one. The explicit hidden lower bound exceeds three when  $N > 320 \cdot 2^9 = 163840$ . The earlier area estimate exceeded three only after  $24000000 \cdot 2^{18} = 6291456000000$  commands [16]. The new constant is still not a practically sharp finite-horizon classification. Its significance is the improved exponent in the profile budget and its matching vector-state construction below.

The same mean-support proof works in any dimension for a specified orthogonal command family once one supplies an orbit-covering estimate and an inscribed-polytope mean-support deficit. No higher-dimensional numerical exponent is asserted here. Unlike a volume argument, the potential is not tied to a determinant formula. A strictly contractive rotation instead has a finite invariant polygon; the divergent conclusion cannot simply be retained under contraction.

## 5. RESONANT POLYGONS AND EXACT SYNTHESIS

A regular polygon need not be enlarged by the worst possible angular misalignment. Choosing its order from a convergent changes the cost from quadratic to cubic in its number of vertices.

**Lemma 5.1** (Resonant containment and stochastic rows). *Let  $q \geq 5$ ,  $(p, q) = 1$ , and  $|\alpha - p/q| < q^{-2}$ . Put*

$$a_q = \pi/q, \quad \delta = 2\pi(\alpha - p/q), \quad \lambda = \frac{\cos(a_q - |\delta|)}{\cos a_q}, \quad w = \frac{\sin |\delta|}{\lambda \sin(2a_q)}.$$

Then  $1 \leq \lambda$ ,  $0 \leq w \leq 1$ , and

$$(19) \quad \log \lambda \leq 40/q^3.$$

For  $v_j = (\cos(2\pi j/q), \sin(2\pi j/q))$  and  $P_t = r_t \operatorname{conv}\{v_j : 0 \leq j < q\}$ ,  $r_{t+1} = \lambda r_t$ ,

$$P_t \cup R_\alpha P_t \subset P_{t+1}.$$

The two stochastic rows realizing the inclusions are

$$(20) \quad T_0(j, \cdot) = \lambda^{-1} \delta_j + (1 - \lambda^{-1}) \operatorname{Unif}[q],$$

$$(21) \quad T_1(j, \cdot) = (1 - w) \delta_{j+p} + w \delta_{j+p+\operatorname{sgn} \delta},$$

with indices modulo  $q$ ; when  $\delta = 0$ , take the pure shift.

*Proof.* Here  $|\delta| < 2\pi/q^2 \leq a_q$ . The point  $r_t v_{j+p}$  rotated by the residual angle  $\delta$  lies on the edge of  $P_{t+1}$  joining the two displayed vertices. The imaginary coordinate gives the coefficient  $w$ ; the real coordinate identity is

$$\lambda = \cos |\delta| + \tan(a_q) \sin |\delta|.$$

This proves both barycentric equality and  $0 \leq w \leq 1$  by edge containment. The idle row uses the zero barycenter of a regular polygon. Finally,

$$\log \lambda = \int_{a_q - |\delta|}^{a_q} \tan u \, du \leq |\delta| \tan a_q \leq (2\pi/q^2)(2\pi/q) < 40/q^3.$$

We used  $a_q \leq \pi/5 < \pi/4$ , where  $\tan u \leq 2u$ .  $\square$

**Theorem 5.2** (Cube-root synthesis). *Let  $q_N$  be the first convergent denominator of  $\alpha$  at least  $\max\{5, (40N)^{1/3}\}$ . There is an exact vector-state realization of (1) with  $q_N$  states at every command cut. When the partial quotients are bounded by  $A$ ,*

$$q_N < (A + 1) \max\{5, (40N)^{1/3}\}, \quad V_N(\alpha) = \Theta_\alpha(N^{1/3}).$$

*The command matrices can be the same at all epochs. The final decoder and the chosen polygon order are horizon-specific.*

*Proof.* Take  $q = q_N$ ,  $r_0 = 1/4$  and  $r_t = r_0 \lambda^t$ . The inradius of  $P_0$  is at least  $\cos(\pi/5)/4 > \sqrt{2}/10$ , so all seed vectors lie in  $P_0$ . By (19),  $r_N \leq e/4 < 3/4$ , hence all polygons lie inside  $D$ . Initialize by any convex representation of  $x/10$  in  $P_0$ , and use (20)–(21). Given final label  $s$  and query  $j$ , use binary mean  $r_N e_j^T v_s$ . The row identities imply by induction that the distribution's barycenter in  $P_t$  is exactly the rotated seed. This proves every conditional row of (1), not an approximation to the angle. For an explicit initialization, the ray through  $x$  meets one edge of  $P_0$ ; represent that boundary point by its two endpoints and mix with the uniform zero barycenter to obtain  $x/10$ . The continued-fraction recurrence bounds the first crossing denominator by  $(A + 1)$  times the threshold. Theorem 4.5 supplies the matching vector-state lower order.  $\square$

This proves (2)–(3). In the normalized label coordinates, both command matrices contract the observable barycenter by  $\lambda^{-1}$  at each command. Multiplying the final decoder by  $r_N$  compensates for exactly  $N$  contractions. Querying that same decoder earlier generally gives the wrong amplitude. Thus the stationary command rows in this construction are not a clock-free anytime realization, and do not contradict Section 7.

The construction uses direct vertex states; it does not exploit the logarithmic extensions of regular polygons. The matched order for  $V_N$  is a theorem about all vector-state chains, not evidence that  $W_N = V_N$ . The gap  $\Omega_\alpha(\log N) \leq W_N \leq O_\alpha(N^{1/3})$  remains the quantitative hidden-lift question. The new upper bound improves the previous  $O(N^{1/2})$  construction without asserting its own optimality in the unrestricted class.

**Corollary 5.3** (A contractive comparison). *Replace the active mean map by  $\rho R_\alpha$ ,  $0 < \rho < 1$ , and keep the idle map. A single horizon-independent vector-state device realizes all command lengths with any convergent order  $q \geq \max\{5, (40/(-\log \rho))^{1/3}\}$ . For bounded-type angles this uses  $O_\alpha(1 + (-\log \rho)^{-1/3})$  processing labels.*

*Proof.* Use one fixed polygon of radius  $1/4$ . The resonant estimate implies  $\rho \lambda \leq 1$ , so  $\rho R_\alpha P \subset P$  and the idle map preserves  $P$ . The active row is the boundary row of (21) mixed with uniform mass, with weight  $\rho \lambda$  on that row. A fixed decoder reads the same polygon at all times. This is a quantitative instance of the classical invariant polytope construction [3], not a new existence principle.  $\square$

## 6. AN EXPLICIT RATE FOR A RATIONAL ROTATION

Let  $\zeta = (3 + 4i)/5 = e^{2\pi i\alpha}$ ,  $0 < \alpha < 1/4$ . This is not a root of unity: otherwise  $\zeta + \zeta^{-1} = 6/5$  would be a rational algebraic integer and hence an integer. Thus  $\alpha$  is irrational. No bounded-type assertion about this angle is needed.

**Lemma 6.1** (Elementary denominator control). *For every integer  $r \geq 1$ ,*

$$\|r\alpha\|_{\mathbb{R}/\mathbb{Z}} \geq \frac{5^{-r}}{2\pi}.$$

*Consequently the denominator function of (15) satisfies  $Q_\alpha(M) < 7 \cdot 5^{8M}$  for every integer  $M \geq 3$ .*

*Proof.* The Gaussian integer  $(3 + 4i)^r - 5^r$  is nonzero, so its modulus is at least one. Therefore

$$5^{-r} \leq |\zeta^r - 1| \leq 2\pi \|r\alpha\|_{\mathbb{R}/\mathbb{Z}}.$$

If  $q = Q_\alpha(M)$  and  $r$  is its preceding convergent denominator, then  $r < 8M$  and (16) gives  $\|r\alpha\| < 1/q$ . Combine the two estimates and use  $2\pi < 7$ . The elementary bound is exponentially weak in  $M$ , but entirely explicit.  $\square$

**Theorem 6.2** (Rational-angle profile bounds). *For the rotation  $R = (1/5) \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}$ , every exact hidden-state profile obeys*

$$(22) \quad \sum_{t < N} 2^{-2K_t} 5^{-8 \cdot 2^{K_t}} \leq 140.$$

*In particular,*

$$(23) \quad N \leq 140 \cdot 2^{2W_N} 5^{8 \cdot 2^{W_N}}.$$

*For  $N > 140$  this implies*

$$W_N \geq \max \left\{ 3, \log_2 \left( \frac{1}{9} \log_5 \frac{N}{140} \right) \right\}.$$

*In the vector-state class,  $\sum_{t < N} K_t^{-2} 5^{-8K_t} \leq 140$  and, for  $N > 140$ ,  $V_N \geq \max\{3, \frac{1}{9} \log_5(N/140)\}$ . Both classes have an exact rational realization with peak  $3(N+1)$ .*

*Proof.* Insert Lemma 6.1 into (17). It gives

$$\sum_{t < N} M_t^{-2} 5^{-8M_t} \leq \frac{280\sqrt{2}}{3} < 140, \quad M_t = 2^{K_t}.$$

Each summand is decreasing in  $M_t$ , proving (23). For an integer  $W \geq 1$ ,  $2W \log_5 2 \leq 2^W$ ; hence  $2 \log_5(2^W) + 8 \cdot 2^W \leq 9 \cdot 2^W$ . Taking logarithms gives the stated hidden lower bound. For vector states use  $M_t = K_t$  and  $2 \log_5 V \leq V$  for integers  $V \geq 1$ .

For completeness, an exact rational upper machine stores  $(s, k)$ , where  $s$  is one of the three triangle vertices in Proposition 2.3 and  $k$  is the number of active commands. Initialize  $s$  by the rational barycentric coordinates of  $x/10$ . An idle command leaves  $(s, k)$  unchanged, and an active command increments  $k$ . At epoch  $t$  only  $0 \leq k \leq t$  is needed. Assign predictive vector  $R^k v_s$  to  $(s, k)$  and use its coordinate as the final binary mean. All assigned vectors have norm less than one, all transitions are rational, and the row identities hold on every state. The largest processing alphabet is  $3(N+1)$ ; a held binary answer needs only two labels in its separate terminal cut.  $\square$

The explicit inequalities replace the former quantifier-elimination-only exclusion for this angle. They do not assert its sharp asymptotic order. Sharper irrationality estimates for  $\alpha$  would improve the denominator function in the same profile theorem, but none is silently assumed here. The rational upper machine admits the separately priced fair-bit implementation of [15]; its atomic label optimum and its sampler workspace are different quantities.

## 7. REMOVING THE CLOCK: ONE DECODER AT EVERY STOPPING LENGTH

We now change the query-time specification explicitly. The commands still come from the same external alphabet, and there is still only one terminal query. It may, however, arrive after any number  $0 \leq n \leq N$  of commands, and the answer must have mean  $e_j^T R_\alpha^{\sum c_t} x/10$  at that length. The machine does not receive  $n$  as a separate input.

**Definition 7.1** (Anytime autonomous realization). An anytime autonomous machine has one finite set of available states, fixed command matrices  $T_0, T_1$ , fixed initialization rows, and one fixed decoder for each query. The same rows work for every command length from zero through  $N$ . Let  $A_N(\alpha)$  be the least total number of states, counting any states used to retain the emitted answer. The device may depend on the prescribed maximum  $N$ ; its rows may not depend on the actual stopping length. Tables and exact atomic sampling remain free, so this is not a succinct bit-space model.

**Lemma 7.2** (Finite positive peripheral spectrum). *Every eigenvalue of modulus one of a finite row-stochastic matrix is a root of unity.*

*Proof.* Let  $Tv = \lambda v$  and choose  $i$  with  $|v_i|$  maximal and positive. Equality in the triangle inequality for  $\lambda v_i = \sum_j T_{ij} v_j$  forces  $v_j = \lambda v_i$  for every positive successor of  $i$ . All these successors have the same maximal modulus. Iteration follows a positive directed path, which eventually contains a cycle of length  $l \geq 1$ . Along that cycle,  $v_j = \lambda^l v_j$  with  $v_j \neq 0$ . Thus  $\lambda^l = 1$ . This is the familiar peripheral-spectrum constraint for positive realizations; see [2, 3].  $\square$

**Theorem 7.3** (Linear autonomous state complexity). *For any infinite-order planar rotation and every  $N \geq 1$ ,*

$$(24) \quad N + 1 \leq A_N(\alpha) \leq 3(N + 1) + 2.$$

*The upper machine has rational rows when  $R_\alpha$  is rational. Thus  $A_N(\alpha) = \Theta(N)$ , whereas the fixed-length vector-state width is  $\Theta_\alpha(N^{1/3})$  for bounded-type angles.*

*Proof.* Suppose a machine has  $K \leq N$  total states. Fix one nonzero seed and use only active commands. Let  $d = d_1 + id_2$  be the complex column formed from its two fixed terminal means and let  $z \neq 0$  be the initial complex predictive vector. With  $T = T_1$  and  $\zeta = e^{2\pi i \alpha}$ , correctness says

$$ET^j d = z\zeta^j \quad (0 \leq j \leq N).$$

Write the characteristic polynomial of  $T$  as  $\chi(X) = \sum_{j=0}^K a_j X^j$ . Cayley–Hamilton and the first  $K + 1$  required lengths give

$$0 = E\chi(T)d = z \sum_{j=0}^K a_j \zeta^j = z\chi(\zeta).$$

Thus  $\zeta$  is an eigenvalue of  $T$ , contradicting Lemma 7.2. Hence  $K \geq N + 1$ . The argument needs only the finite length interval, not an infinite stationary specification or a minimality assumption.

For the upper bound use the labels  $(s, k)$ ,  $1 \leq s \leq 3$ ,  $0 \leq k \leq N$ , from the triangle-counter construction in Theorem 6.2, now all available in one state set. The idle matrix is the identity; the active matrix increments  $k$ , with arbitrary normalized rows after  $k = N$ . The decoder at  $(s, k)$  reads  $R_\alpha^k v_s$  and has no epoch argument. Its norm is less than one. Initialization is the seed's triangle decomposition. The same matrices and decoder therefore answer at every permitted length. Add two absorbing answer states if the output must persist after its emission. This proves the count and rationality.  $\square$

Equation (24) completes the proof of Theorem 1.1. It does not lower-bound an autonomous device required to answer only at one fixed length and allowed to be incorrect at all earlier lengths. That is another problem. In particular, the resonant construction in Section 5 already has stationary command rows, but its decoder compensates for exactly  $N$  normalizing contractions. The strengthened anytime requirement is what prevents that compensation from concealing the elapsed length. The finite-horizon comparison is a concrete use of classical spectral constraints, not a claim to discover the stationary rotation obstruction.

## 8. CLASSICAL COMPARISONS AND THE REMAINING LIFT PROBLEM

**8.1. Fixed degree and positive order.** The direct precedent for fixed degree three with unbounded positive order is Benvenuti–Farina [1], not merely the familiar stationary irrational-rotation obstruction. In the normalization reproduced by Czaja–Jaming–Matolcsi [5, Example 2, equation (3.1)], their family is

$$H_m(z) = \frac{1}{z-1} - \frac{4(5/2)^{m-2}}{z-2/5} + \frac{3 \cdot 5^{m-2}}{z-1/5}, \quad m \geq 4.$$

Its McMillan degree is three. The 1999 lower bound on positive order is  $m$ , and the later construction attains  $m$  [1, 5]. Those statements concern one repeated nonnegative matrix and an entire impulse response. They are not lower bounds against independently chosen stochastic matrices at every cut of a finite word experiment.

There is an equally direct precedent for the inadequacy of positive factorization without dynamics. Benvenuti–Farina [2, Section 3, Example 4 and Theorem 2] give a periodic Hankel matrix with a nonnegative factorization of inner size three but no three-dimensional positive realization; their minimality theorem includes a positive intertwining matrix. Thus neither the need for compatibility nor its failure in positive factorization is claimed as new here. For a finite prefix–suffix array, conditioning supplies a positive factorization at a cut, just as for a finite Hankel truncation. The issue in this article is one sequence of such factorizations under every command, allowing unrelated rows and a horizon-dependent machine. The profile budget proves a necessary inequality even in that enlarged class. It is not claimed to sharpen the known stationary lower bound for the family  $H_m$ .

Accessible spaces, observable quotients and invariant cones are classical [8, 3, 13, 10]. Lemma 2.4 is the finite-word version needed to avoid asserting an intertwining identity on hidden directions that the observations do not determine. The proof is included to expose that quantifier, not to claim invention of an accessible-space construction.

**8.2. Static and dynamic extensions.** Yannakakis’ factorization theorem relates extension size to nonnegative rank of a slack matrix [14]; see the explicit formulation in [6, Theorem 1]. The number of faces of an extension supplies the standard logarithmic lower estimate from projected vertices. Fiorini–Rothvoß–Tiwary [6, Theorem 2], building on Ben-Tal–Nemirovski [4], show that a regular  $m$ -gon has an  $O(\log m)$  extension. Vandaele–Gillis–Glineur [12] refine regular-polygon bounds using slack factorizations.

These theorems minimize a static inequality count. They do not require the lifted command maps or the observable decoder to extend to stochastic maps on the whole ambient simplex. Proposition 3.1 shows that bounded polytope extensions can be normalized without increasing their facet count; Proposition 3.3 shows why this normalization alone does not settle dynamical implementation. The extension test (9) is elementary convex separation. Its role is to make the missing condition exact and checkable for fixed lift data, not to claim a new general linear-programming theorem.

The substantive quantitative conclusion is therefore divided in two. For arbitrary hidden realizations, the new potential yields a logarithmic lower bound, while the resonant construction yields a cube-root upper bound. For vector-state realizations, the same potential has no exponential facet-to-vertex conversion, and the order is exactly  $N^{1/3}$ . An independent small static lift does not bridge this gap. Conversely, the map-defect example does not rule out small compatible lifts that have a different geometry.

**8.3. What is retained, and what is not inferred.** The older volume obstruction, rank-three two-cut example, exact tagged profile identity, online query constructions and physical saddle results remain in their original sources and in the supporting archives [15, 16]. In particular the tagged identity still requires exact final tag recovery and a common suffix interface. Nothing in the present paper extends it to noisy tags or overlapping supports. The earlier additive replacement update is a weighted reservoir construction; its sampling mechanism is credited to that literature [11, Appendix A.2], not used as a new claim here.

The finite proofs above are self-contained apart from the named classical background identities whose short arguments are also given. The source record distinguishes the original 1999 reference from the full author survey and later matching-order proof used to inspect its family. The original 1999 article and the original Yannakakis article have not been claimed to receive an exhaustive proof-by-proof priority audit. Their results are expressly credited; the full accessible comparisons [2, 5, 6, 12] supply the concrete theorem statements used here. No exhaustive originality clearance is inferred from this bibliography.

The main unresolved issue is the optimal hidden width between logarithmic and cube-root growth. The vector-state result is not substituted for that question. The rational-angle bound is explicit but much weaker; its sharp denominator-controlled rate is likewise not identified.

The autonomous theorem concerns one fixed decoder at all stopping lengths, not just removal of a clock from the original single-length specification. All counts continue to price persistent labels rather than read-only programs, arithmetic, or physical realization of irrational coins. These are different optimization problems, and the comparisons depend on preserving their definitions.

The program title identifies this manuscript within the preserved research series. It does not assert that finite positive-realization arguments replace independent Fourier, large-deviation, semigroup, or operator-domain proof obligations elsewhere in that series, nor does it assert a journal decision. The theorem chain established here is the one displayed in Theorem 1.1 and its supporting lift and profile statements.

# GENERAL THETA FOUNDATIONS I: CAUSAL WIDTH BEYOND CUTWISE POSITIVE RANK

QIAN QI

**ABSTRACT.** We compare the least memory at individual cuts with the least peak memory of one exact finite-horizon stochastic transducer. We construct a uniformly full-support family on fixed alphabets whose separate minimum is three at every internal cut, whereas its minimum simultaneous width tends to infinity. The lower bound allows arbitrary time-dependent stochastic rows and hidden continuations outside the observable affine space. Its mechanism is a volume budget for projections of reachable simplex sections: each command forces an enlargement, while bounded state number bounds the number of projected vertices. For a golden-angle rotation we obtain the explicit bound  $W_N \geq \frac{1}{6} \log_2(N/24000000)$ , alongside an exact  $4\lceil\sqrt{N} + 1\rceil$ -state construction. A rational rotation gives the same unbounded incompatibility with effective algebraic horizon thresholds and rational finite realizations. A separate composition theorem identifies feasible profiles under a verifiable retained tag as Minkowski sums; applied to the two-cut obstruction, it gives the exact frontier  $K_1, K_2 \geq 3m$ ,  $K_1 + K_2 \geq 7m$ . The finite-horizon volume inequality, rather than a stationary nonrealizability statement, is the central relation between local positive rank and causal memory.

## 1. INTRODUCTION

A stochastic response array can have small positive factorizations at every cut without admitting one machine that realizes those factorizations in succession. The issue is not only how many continuations enclose the observed rows. Every chosen continuation must also evolve by the same legal stochastic update as the other continuations at that time. We study the resulting difference between *separate* and *simultaneous* state complexity.

Our principal result gives an unbounded difference with fixed input and output alphabets. Fix  $a = 1/10$ , a planar rotation  $R$ , a seed  $x \in \{-1, 1\}^2$ , a word  $c = (c_1, \dots, c_N) \in \{0, 1\}^N$ , and a query  $j \in \{1, 2\}$ . The seed is read first, the commands are read in order, and the query is supplied last. The required binary response is

$$(1) \quad C_{N,R}(b \mid x, c, j) = \frac{1 + b e_j^T R^{c_1 + \dots + c_N} a x}{2}, \quad b \in \{-1, 1\}.$$

The same formula is required for every input word, not merely under a chosen distribution on words. Every entry lies between  $(1 - \sqrt{2}/10)/2$  and  $(1 + \sqrt{2}/10)/2$ .

At any one internal cut, three normalized continuations suffice and are necessary. This remains true when the cut is required to belong to a complete machine and all its other registers may be enlarged. Write  $W_N(R)$  for the least peak over machines satisfying all cuts at once.

**Theorem 1.1** (Fixed local rank and growing causal width). *Let  $\alpha = (\sqrt{5} - 1)/2$  and let  $R$  rotate by  $2\pi\alpha$ . Every internal cut of (1) has separate minimum three and ordinary normalized*

residual rank three. For  $N \geq 1$ ,

$$(2) \quad \max \left\{ 3, \frac{1}{6} \log_2 \frac{N}{24000000} \right\} \leq W_N(R) \leq \min \left\{ 3(N+1), 4 \lceil \sqrt{N+1} \rceil \right\}.$$

All lower bounds allow arbitrary randomized encoders, arbitrary hidden state continuations, and cut-dependent stochastic transition matrices. The upper bounds realize every conditional probability exactly.

For the rational rotation

$$(3) \quad R_0 = \frac{1}{5} \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix},$$

the same separate minima and upper bounds hold and  $W_N(R_0) \rightarrow \infty$ . For each proposed state bound, an excluded horizon can be computed by real algebraic optimization. The  $3(N+1)$ -state realization is rational.

The proof occupies Sections 3–5. The logarithmic lower bound and square-root upper bound are not asserted to be sharp. They show, with explicit constants in one family, that uniformly bounded separate positive ranks do not control simultaneous width even in the permissive clocked model. The rational version makes the qualitative phenomenon independent of transcendental input data.

The principal technical point is the treatment of nonminimal hidden representations. If a machine has  $K_t$  states, its hidden state vectors need not individually have an observable two-dimensional continuation. Projecting those individual states into a presumed invariant polygon would therefore restrict the competing class. Instead, let  $H_t$  be the affine span of the actually reachable state *distributions*, and intersect it with the probability simplex. Projecting  $H_t \cap \Delta_{K_t}$  gives a valid observable polytope with at most  $2^{K_t}$  vertices. Stochastic updates carry these sections forward. A command and an idle command then force a nested sequence of observable polytopes. A strictly positive volume increment, summed over time, provides the lower bound. This is a necessary argument for all hidden realizations, not a restriction to residual-state or affine-minimal machines.

A second result concerns exact finite profile composition. Theorem 6.1 proves that a verifiable retained tag makes feasible profiles add as sets. In particular, the earlier two-cut obstruction with frontier  $(3, 4)$ ,  $(4, 3)$  yields

$$K_1 \geq 3m, \quad K_2 \geq 3m, \quad K_1 + K_2 \geq 7m.$$

Its optimum peak is  $\lceil 7m/2 \rceil$ , whereas either cut separately has minimum  $3m$ . This closure law complements the temporal example: it identifies an exact growing Pareto frontier, while the rotation family keeps alphabets and all separate minima fixed. The tagged construction has structural output zeros; it is not called a full-support example.

**1.1. Classical mechanisms and the new comparison.** Invariant polyhedral cones and normalized convex sections are classical in positive realization [6, 1, 12]. Irrational rotation as an obstruction to a finite *stationary* positive realization is also classical: see [1, Example 4] and [8, Theorem 6, Example 2 and Lemma 7]. We do not claim either mechanism as a new discovery. Reachable subspaces and observable quotients are likewise established tools [8, Section 4].

The comparison proved here differs in its quantifiers. Every finite horizon has a finite exact realization; both the state spaces and the rows may change at every epoch. There is no common stationary matrix to which a peripheral-spectrum obstruction can be applied. Moreover, the least *positive* factorization at each cut, not just ordinary rank, is three. The cumulative volume bound and the explicit sequence of finite realizations concern this finite, time-dependent problem. Section 7 details the relation to positive realization, nonnegative factorization and residual

automata. The explicit bounds are claims of the present article; exhaustive priority clearance is not inferred from the bibliography.

## 2. COMPLETE ARRAYS AND CHARGED STATE PROFILES

**Definition 2.1** (Clocked stochastic transducer). Fix finite alphabets  $X, Y_1, \dots, Y_N, J, B$ . A complete terminal array is a probability distribution  $C(\cdot \mid x, y_1, \dots, y_N, j)$  on  $B$  for every word in the full Cartesian product. A realization has finite registers  $S_t = [K_t]$  for  $0 \leq t \leq N$ , an initialization row  $E(s \mid x)$ , transition rows  $T_{t,y}(s, s')$  from  $S_t$  to  $S_{t+1}$  for  $0 \leq t < N$ , and terminal rows  $D(b \mid s, j)$ , all nonnegative and normalized. It realizes  $C$  when

$$(4) \quad C(b \mid x, y_1, \dots, y_N, j) = \sum_{s_0, \dots, s_N} E(s_0 \mid x) \prod_{t=0}^{N-1} T_{t, y_{t+1}}(s_t, s_{t+1}) D(b \mid s_N, j).$$

The current input is read atomically, and only the next register survives its update. There is an initial singleton before  $x$  and, when the output is retained, a final  $|B|$ -label register. The full peak is  $\max(1, |B|, K_0, \dots, K_N)$ .

Inputs in this definition are externally supplied; they need not have a probability law. Equality is wordwise. A controller’s earlier randomness, input buffers, data-dependent scheduling information and previously emitted symbols cannot be read again unless retained in its register. The declared epoch  $t$  is a free external clock; the current query is consumed in the terminal update. All row tables are known program data, and sampling a stochastic row is atomic. Table size, arithmetic work, construction time and fair-bit sampling workspace are not included in  $K_t$ . A shared private seed is not an additional free input.

We count available labels. Unreachable labels may be removed, while padding by unused labels explains upward closure of feasible profiles. Every declared input row, including rows unused by the actual initial law, is a stochastic row. An autonomous implementation instead uses one state set and time-independent rows; phase tagging gives a sufficient sum-of-widths bound and is not identified with the clocked peak. These conventions separate the finite positive-realization problem from succinct streaming-program or bit-operation complexity.

Let  $\mathcal{F}(C) \subset \mathbb{N}^{N+1}$  be the upward-closed set of realizable profiles. For a prefix  $h = (x, y_1, \dots, y_t)$ , let  $R_h$  be its complete conditional array on all suffixes and terminal queries. At this cut the ambient continuation polytope is a product of output simplices. Define  $r_t = \text{rank}(R_h)_h$ , with columns indexed by suffix, query and output. Normalized rows give  $r_t = 1 + \dim \text{aff}\{R_h\}$ .

**Definition 2.2** (Separate minimum). The separate minimum  $\kappa_t(C)$  is the least  $k$  such that every  $R_h$  is a convex combination of  $k$  normalized continuation arrays on the same future alphabet. There is no compatibility requirement between the dictionaries selected at distinct cuts. The minimum peak of a compatible realization is denoted  $W(C)$ .

For finite alphabets,  $\kappa_t(C) = \min_{\mathbf{K} \in \mathcal{F}(C)} K_t$ : store the whole prefix before the chosen cut, implement its encoder at that cut, and afterwards store the selected label and future inputs until the terminal update. Thus a separate factorization can always be embedded in a complete

machine, at possibly large costs elsewhere. Ordinary row rank is a lower bound on  $\kappa_t$ . For a single terminal output alphabet this minimum is ordinary nonnegative rank after normalization. For a queried continuation array, every suffix/query block of a generator must normalize separately; nonnegative rank of the concatenated matrix need only be a lower bound. These are not the same as residual-only state counts [5, 3].

| Notation           | Meaning                                                    |
|--------------------|------------------------------------------------------------|
| $K_t, W(C)$        | available labels at a cut; least simultaneous peak         |
| $r_t, \kappa_t(C)$ | ordinary row rank; separate normalized positive minimum    |
| $E_h, H_t$         | reachable state distribution; its affine span              |
| $Q_t, P_t$         | reachable simplex section; observable projected section    |
| $S, D$             | compulsory seed hull; bounded observable domain            |
| $\delta_M$         | minimum one-step volume expansion for at most $M$ vertices |

The input-only model is already a subclass of finite causal experiments: a prescribed action alphabet may consist of one action at each stage. A lower bound in this class does not solve optimization over informative experimental actions. The present advance concerns arbitrary-horizon compatibility of exact responses under a specified interface.

### 3. REACHABLE SECTIONS AND A CUMULATIVE VOLUME BOUND

We first treat a general finite collection of linear mean updates. Let  $\mathcal{L}$  be a finite set of linear maps of  $\mathbb{R}^d$ , containing  $I_d$ . A finite seed alphabet has associated vectors  $z(x)$ , whose convex hull  $S$  has nonempty interior. Assume that every product of at most  $N$  allowed maps sends the seed vectors into  $D = [-1, 1]^d$ . After reading  $x$  and  $N$  commands  $L_1, \dots, L_N \in \mathcal{L}$ , a terminal query  $j \in [d]$  requires a binary output of mean  $e_j^T L_N \cdots L_1 z(x)$ . Denote this complete array by  $C_N$ .

**Lemma 3.1** (The reachable-section lift). *Every realization of  $C_N$  with profile  $(K_t)_{t=0}^N$  determines full-dimensional polytopes  $P_t \subset D$  such that*

$$(5) \quad S \subset P_t, \quad |\text{ext } P_t| \leq 2^{K_t}, \quad LP_t \subset P_{t+1} \quad (L \in \mathcal{L}, t < N).$$

*The conclusion permits arbitrary hidden states and does not require individual state continuations to belong to the residual affine span.*

*Proof.* For each actual prefix  $h$  at cut  $t$ , let  $E_h \in \Delta_{K_t}$  be its hidden state distribution. Put

$$H_t = \text{aff}\{E_h : h \text{ a prefix at } t\}, \quad Q_t = H_t \cap \Delta_{K_t}.$$

For any state distribution  $e \in \Delta_{K_t}$ , run the remaining commands all equal to  $I_d$ . The vector of its  $d$  terminal means is a linear function  $\pi_t(e)$  and belongs to  $D$ . Correctness on actual prefixes gives  $\pi_t(E_h) = z_h$ , the specified predictive vector. Set  $P_t = \pi_t(Q_t)$ .

Write  $T_{t,L}$  for the realizing transition matrix of command  $L$ . The identity  $E_h T_{t,L} = E_{hL}$  implies  $H_t T_{t,L} \subset H_{t+1}$ . Stochasticity also implies  $\Delta_{K_t} T_{t,L} \subset \Delta_{K_{t+1}}$ ; consequently  $Q_t T_{t,L} \subset Q_{t+1}$ . On every actual prefix,

$$\pi_{t+1}(E_h T_{t,L}) = L \pi_t(E_h).$$

Both sides are affine in  $E_h$ , so this equality extends to all of  $H_t$ , including its points with some negative coordinates. Restricting back to  $Q_t$  yields  $LP_t \subset P_{t+1}$ . Taking the idle command shows  $P_t \subset P_{t+1}$ . The initial section contains all seeds, hence so does every  $P_t$ .

It remains to bound vertices without assuming a minimal hidden representation. In its affine hull,  $Q_t$  is a bounded polytope defined by the  $K_t$  coordinate inequalities  $e_s \geq 0$ . Two distinct vertices cannot have the same zero-coordinate set. Indeed, if they did, their difference would give a nonzero direction preserving all active equalities, and sufficiently small motion in both directions from either point would preserve the remaining strict inequalities. That point would

not be a vertex. There are at most  $2^{K_t}$  zero sets. A linear image of a polytope is the convex hull of the images of its vertices, proving  $|\text{ext } P_t| \leq |\text{ext } Q_t| \leq 2^{K_t}$ .  $\square$

The section  $Q_t$ , rather than the entire hidden simplex, is essential. For an arbitrary unit hidden state, the identity relating the two probe maps need not hold. It holds on the affine span of reachable *distributions*. This is the finite-horizon version of the accessible-space/observable-quotient precaution in classical realization [8, Section 4]; the vertex bound accounts for the resulting lift. In particular, replacing  $2^{K_t}$  by  $K_t$  without further hypotheses would not be justified.

For a full-dimensional compact seed hull  $S \subset D$ , define

$$(6) \quad \delta_M(S, D, \mathcal{L}) = \min_{\substack{S \subset P \subset D \\ P \text{ a polytope, } |\text{ext } P| \leq M}} \left\{ \text{vol}_d \left( \text{conv} \bigcup_{L \in \mathcal{L}} LP \right) - \text{vol}_d(P) \right\}.$$

If the feasible set is empty, put  $\delta_M = +\infty$ . The maps in the union need not send all of  $D$  into  $D$ . Only the implementing sequence from Lemma 3.1 must obey that constraint. The quantity is a geometric optimization on observable polytopes, not an optimization over candidate transition tables.

**Theorem 3.2** (Volume budget for a state profile). *Suppose  $|\det L| = 1$  for every  $L \in \mathcal{L}$  and  $I_d \in \mathcal{L}$ . If there is no full-dimensional polytope  $P$  with  $S \subset P \subset D$  and  $LP = P$  for all  $L \in \mathcal{L}$ , then every nonempty minimum in (6) is strictly positive. Every realization of  $C_N$  satisfies*

$$(7) \quad \sum_{t=0}^{N-1} \delta_{2^{K_t}}(S, D, \mathcal{L}) \leq \text{vol}_d(D) - \text{vol}_d(S).$$

*In particular, a uniform state bound  $K$  implies  $N\delta_{2^K} \leq \text{vol}_d(D) - \text{vol}_d(S)$ .*

*Proof.* The set of feasible polytopes with at most  $M$  vertices is compact in the Hausdorff metric: represent them by  $M$  points in the compact set  $D$ , permitting repetitions, and impose the closed condition that their convex hull contain  $S$ . Convex hull, finite union followed by convex hull, and volume of compact convex sets are continuous. Thus the minimum is attained whenever the set is nonempty.

Because the identity is allowed, the displayed volume difference is nonnegative. If it vanishes at  $P$ , the full-dimensional convex bodies  $P$  and  $\text{conv} \bigcup_L LP$  have equal volume and one contains the other, so they are equal. Thus  $LP \subset P$ . The determinant hypothesis makes their volumes equal, hence  $LP = P$  for every  $L$ , contrary to the assumption. Therefore  $\delta_M > 0$ .

For the polytopes in Lemma 3.1,

$$\text{vol}_d(P_{t+1}) - \text{vol}_d(P_t) \geq \text{vol}_d \left( \text{conv} \bigcup_L LP_t \right) - \text{vol}_d(P_t) \geq \delta_{2^{K_t}}.$$

Summing telescopes. The endpoint inclusions give (7). The minima are nonincreasing in  $M$ , which gives the assertion for a uniform bound.  $\square$

The volume hypothesis is a property of the mean dynamics and the observation domain, not a small-ball or metric-dimension assumption. Under an invertible affine change of predictive coordinates, using the conjugate affine maps, both sides of (7) are multiplied by the same absolute determinant. Thus the normalized budget is independent of this coordinate choice. The proof also works for volume-preserving affine maps with an idle map.

**Corollary 3.3** (Effective finite obstructions). *In dimension two, for explicitly given rational or real-algebraic polygons  $S, D$  and volume-preserving linear maps, every nonempty  $\delta_M$  is a computable real-algebraic number. If the hypothesis of Theorem 3.2 holds, one can compute a*

rational  $0 < c_M \leq \delta_M$  and hence a finite horizon excluding any specified uniform width  $K$  with  $M = 2^K$ .

*Proof.* Use  $M$  pairs of vertex coordinates in  $D$  as variables. Containment of each vertex of  $S$  in their hull is expressed with nonnegative barycentric variables. A finite partition by determinant signs and cyclic orders identifies each possible convex hull, including repetitions and collinear points. On every such piece the areas of  $P$  and  $\text{conv} \bigcup_L LP$  are polynomial expressions, by the polygon area formula. Thus the graph of the objective, its feasible domain and the statement that a number is its minimum are first-order formulas over the real closed field of algebraic numbers. Quantifier elimination, followed by real-root isolation, computes the minimum and a positive rational lower bound when it is positive [2]. Algebraic inputs are represented by defining polynomials and isolating intervals. The procedure is finite; no polynomial complexity in  $K$ , the horizon, or a succinct circuit description is asserted.  $\square$

#### 4. A FIXED-ALPHABET FAMILY WITH UNBOUNDED COMPATIBILITY COST

We apply the volume bound with

$$a = 1/10, \quad S = a[-1, 1]^2, \quad D = [-1, 1]^2, \quad \mathcal{L} = \{I_2, R\},$$

where  $R$  is any planar rotation of infinite order. The terminal array is (1). The fixed alphabets have respectively four seed symbols, two command symbols, two queries and two outputs. Rotation preserves the norm of every actual predictive vector, so the uniform full-support bound stated in the introduction holds at every horizon.

**Proposition 4.1** (All separate positive minima are three). *At every internal cut of  $C_{N,R}$ , ordinary normalized row rank and separate normalized positive minimum both equal three, for every rotation  $R$  and every  $N \geq 0$ .*

*Proof.* For a prefix at cut  $t$ , put  $z = R^{c_1 + \dots + c_t} ax$ . Its entire future response is affine in  $z$ . The all-idle prefixes contain the four seeds, which affinely span  $\mathbb{R}^2$ , and the all-idle suffix with the two coordinate queries distinguishes both coordinates. Normalization supplies an independent constant coordinate. Hence the residual row rank is exactly three.

Consider the triangle

$$(8) \quad T = \text{conv}\{v_0, v_1, v_2\}, \quad v_0 = (1/2, 0), \quad v_1 = (-1/2, 1/2), \quad v_2 = (-1/2, -1/2).$$

It contains the centered disk of radius  $1/(2\sqrt{5})$ , while every vertex has norm at most  $1/\sqrt{2}$ . All reachable  $z$  have norm  $\sqrt{2}/10 < 1/(2\sqrt{5})$ , and thus lie in  $T$ . Starting from any  $v_s$ , any future rotation word has both mean coordinates in  $[-1, 1]$ . It therefore defines a legal normalized future channel. Barycentric decomposition of  $z$  in  $T$  gives an exact three-state factorization of the whole suffix array. This proves  $\kappa_t = 3$ ; Definition 2.2 embeds it in a complete machine with finite, unrestricted registers at other cuts.  $\square$

**Theorem 4.2** (Unbounded width with effective rational data). *For every infinite-order rotation  $R$ ,  $W_N(R) \rightarrow \infty$ . More precisely, put  $\delta_M = \delta_M(S, D, \{I, R\})$ . These numbers are positive for  $M \geq 3$ , and every feasible profile satisfies*

$$(9) \quad \sum_{t=0}^{N-1} \delta_{2^{K_t}} \leq \frac{99}{25}.$$

*For  $R_0$  in (3), the target arrays are rational and the thresholds excluding a bounded width are effective in the sense of Corollary 3.3.*

*Proof.* An invariant polygon containing  $S$  would have nonzero vertices whose orbits under  $R$  remain in its finite vertex set, since an invertible linear map taking a polygon onto itself permutes its vertices. An infinite-order planar rotation has no finite orbit away from zero. No such polygon exists. The triangle in (8) is feasible for the definition of  $\delta_M$  when  $M \geq 3$ , so these minima are positive by Theorem 3.2. Its volume budget gives (9), since  $4 - 4a^2 = 99/25$ . For any  $K$ , horizons greater than  $99/(25\delta_{2K})$  exclude all width- $K$  machines. This proves the asserted divergence.

The eigenvalue  $\zeta = (3 + 4i)/5$  of  $R_0$  is not a root of unity. Otherwise  $\zeta + \zeta^{-1} = 6/5$  would be a rational algebraic integer, hence an integer. The contradiction proves that  $R_0$  has infinite order. Rationality of its powers and of the seeds proves rationality of every specified channel entry. Corollary 3.3 applies.  $\square$

The divergence does not follow merely by invoking the classical absence of a stationary positive realization of an irrational rotation. The matrices of a proposed machine may change at every time, and depend on  $N$ . Inequality (9) excludes these machines as well. In particular there is no function of the maximum separate positive minimum alone that bounds simultaneous width on this class.

#### 4.1. Constructive finite realization.

**Theorem 4.3** (Exact polygon realization). *For any planar rotation  $R$  and any  $N \geq 1$ , the channel  $C_{N,R}$  has an exact realization of peak at most  $4\lceil\sqrt{N+1}\rceil$ . It also has an exact realization of peak  $3(N+1)$ , with rational rows when  $R$  has rational entries. Both constructions store finite labels, not real predictive vectors.*

*Proof.* Put  $M = 4\lceil\sqrt{N+1}\rceil$ ,  $u_s = (\cos(2\pi s/M), \sin(2\pi s/M))$  for  $0 \leq s < M$ , and

$$\rho_t = \frac{\sqrt{2}}{10} \sec^{t+1}(\pi/M), \quad P_t = \text{conv}\{\rho_t u_s : 0 \leq s < M\} \quad (0 \leq t \leq N).$$

The inradius of  $P_0$  is  $\sqrt{2}/10$ , so  $S \subset P_0$ . The inradius of  $P_{t+1}$  is  $\rho_t$ , and hence

$$(10) \quad P_t \cup RP_t \subset P_{t+1}.$$

All these polygons lie in  $D$ . Indeed, with  $L = N + 1$ ,

$$\cos(\pi/M) \geq 1 - \frac{5}{16L}, \quad \cos^L(\pi/M) \geq 1 - \frac{5}{16} = \frac{11}{16}, \quad \rho_N \leq \frac{16\sqrt{2}}{110} < 1.$$

The first bound uses  $M \geq 4\sqrt{L}$  and  $\pi^2 < 10$ ; the second is Bernoulli's inequality.

Initialize by a convex decomposition of the observed seed  $ax$  in  $P_0$ . At cut  $t$ , the machine stores  $s \in [M]$ . After command  $c$ , replace it by a random label whose mean vertex in  $P_{t+1}$  is  $R^c \rho_t u_s$ , using (10). Induction gives

$$\mathbb{E}[\rho_t u_{s_t} \mid x, c_1, \dots, c_t] = R^{c_1 + \dots + c_t} ax.$$

The terminal binary row has mean  $e_j^T \rho_N u_s$ . This proves the specified full conditional law. The final binary register fits within  $M$  states.

The update coefficients can be written explicitly. If the direction of  $R^c u_s$  falls between  $u_l$  and  $u_{l+1}$ , let its offset be  $0 \leq \theta \leq \omega = 2\pi/M$ . Set

$$A = \frac{\rho_t \sin(\omega - \theta)}{\rho_{t+1} \sin \omega}, \quad B = \frac{\rho_t \sin \theta}{\rho_{t+1} \sin \omega}, \quad T_{t,c}(s, k) = A \mathbf{1}_{k=l} + B \mathbf{1}_{k=l+1} + \frac{1 - A - B}{M}.$$

Both coefficients are nonnegative and  $A + B \leq (\rho_t/\rho_{t+1}) \sec(\pi/M) = 1$ . Since  $\sum_k u_k = 0$ , these rows have the required mean. Boundary choices agree. Initialization uses the same triangular fan, replacing  $\rho_t$  by the norm of the seed. Only a vertex *index* is stored. In fact, the ratio  $\rho_t/\rho_{t+1}$

is constant, so each command matrix is the same at every training epoch for this construction. The final decoder still depends on the chosen horizon.

For the rational alternative, decompose  $ax$  into the three vertices  $v_i$  of (8); its weights are

$$1/2 + ax_1, \quad 1/4 - ax_1/2 + ax_2, \quad 1/4 - ax_1/2 - ax_2.$$

Store the pair  $(i, q)$ , initially  $q = 0$ , and add  $c$  to  $q$  at each command. At cut  $t$  at most  $3(t + 1)$  states are available. The decoder has mean  $e_j^T R^q v_i$ , which belongs to  $[-1, 1]$  because  $\|v_i\|_2 < 1$ . This is an exact realization, with rational initialization, transitions and output rows when  $R$  is rational.  $\square$

The polygon construction provides known exact stochastic rows. For a rational rotation, its trigonometric constants are algebraic; for the golden angle they are fixed computable real constants. Neither is being silently identified with a bounded fair-bit computation. The rational  $3(N + 1)$  construction can use the separately charged rational-row sampler of the retained development [13]. Its extra workspace is not asserted to preserve the atomic peak. Similarly, an autonomous machine required to check the input length has an additional clock task; that task is not part of Definition 2.1.

## 5. AN EXPLICIT MULTI-CUT INEQUALITY

We now give a quantitative expansion estimate for the rotation in Theorem 1.1. Throughout this section,  $\alpha = (\sqrt{5} - 1)/2$ ,  $R$  is rotation by  $2\pi\alpha$ , and  $a = 1/10$ . The Euclidean unit disk is denoted by  $\mathbb{B}^2$ .

**Lemma 5.1** (Finite orbit covering). *For every integer  $M \geq 3$ , there is an integer  $q$  with  $32M \leq q < 64M$  such that  $\{R^k u : 0 \leq k < q\}$  is a  $3\pi/q$ -net of the unit circle in angular distance, for every unit  $u$ .*

*Proof.* Let  $F_0 = 0, F_1 = 1, F_{m+1} = F_m + F_{m-1}$  and take the first Fibonacci number  $q = F_m$  at least  $32M$ . Consecutive positive Fibonacci numbers have ratio less than two, so  $q < 64M$ . Put  $p = F_{m-1}$ . The elementary identities

$$\gcd(p, q) = 1, \quad F_m \alpha - F_{m-1} = (-1)^{m-1} \alpha^m, \quad F_m \alpha^m < 1$$

follow by induction (or by the formula for  $F_m$  obtained from the two roots of  $z^2 = z + 1$ ). Thus  $|\alpha - p/q| < 1/q^2$ . The first  $q$  multiples of  $p/q$  form the uniform  $q$ -grid modulo one. Each differs from the corresponding multiple of  $\alpha$  by less than  $1/q$  in circular distance. Every point of the circle is within  $1/(2q)$  of a grid point and hence within  $3/(2q)$  turns of an orbit point. Multiplying by  $2\pi$  proves the assertion, also after a common rotation by  $u$ .  $\square$

**Lemma 5.2** (A polygon cannot be too nearly invariant). *If  $a\mathbb{B}^2 \subset P \subset \sqrt{2}\mathbb{B}^2$  is a polygon with at most  $M \geq 3$  vertices, then*

$$(11) \quad d_H(P, RP) \geq \frac{a}{64M^3}.$$

*Proof.* Write  $\varepsilon = d_H(P, RP)$  and  $r = \max_{z \in P} \|z\|_2$ . Choose a vertex  $v$  of norm  $r$ . Rotational invariance of Hausdorff distance and the triangle inequality give  $d_H(P, R^k P) \leq k\varepsilon$ . By Lemma 5.1, for every unit direction  $u$  some  $k < q$  puts  $R^k v$  within angular distance  $3\pi/q$  of  $u$ . For the support function  $h_P$ , it follows that

$$(12) \quad h_P(u) \geq r \cos(3\pi/q) - q\varepsilon, \quad r - h_P(u) \leq \frac{9\pi^2 \sqrt{2}}{2q^2} + q\varepsilon.$$

The directions of the at most  $M$  vertices have an empty circular arc of length at least  $2\pi/M$ . At its midpoint  $u_0$ , every vertex has scalar product at most  $r \cos(\pi/M)$ . Consequently

$$r - h_P(u_0) \geq r(1 - \cos(\pi/M)) \geq \frac{2a}{M^2}.$$

Here  $1 - \cos s \geq 2s^2/\pi^2$  for  $0 \leq s \leq \pi$ , and  $r \geq a$ . Using  $q \geq 32M$ ,  $\pi^2 < 10$  and  $\sqrt{2} < 3/2$  shows that the first term on the right of (12) is less than  $a/M^2$ . It follows that  $q\varepsilon \geq a/M^2$ . The bound  $q < 64M$  proves (11).  $\square$

**Lemma 5.3** (Area pays for Hausdorff displacement). *If  $a\mathbb{B}^2 \subset P \subset R_*\mathbb{B}^2$  and  $U = \text{conv}(P \cup RP)$ , for an arbitrary planar rotation  $R$ , then*

$$(13) \quad \text{area}(U) - \text{area}(P) \geq \frac{a}{R_*} d_H(P, RP)^2.$$

*Proof.* Let  $d_+ = \max_{u \in \mathbb{S}^1} (h_{RP}(u) - h_P(u))_+$ . When  $d_+ > 0$ , choose a maximizing direction  $u$  and  $x \in RP$  with  $u \cdot x = h_P(u) + d_+$ . The triangle with vertices  $x$  and the two points  $\pm av$ , where  $v \perp u$  is a unit vector, lies in  $U$ . Its part in  $\{z : u \cdot z > h_P(u)\}$  lies outside  $P$ . Similar triangles give its area as

$$\frac{ad_+^2}{u \cdot x} \geq \frac{ad_+^2}{R_*}.$$

The zero case needs no argument. Repeating this with  $P$  and  $RP$  interchanged gives the same bound with  $d_-$ . Rotation preserves area, so the two excess areas coincide. For compact convex sets,  $d_H(P, RP) = \max(d_+, d_-)$ , proving the claim.  $\square$

**Theorem 5.4** (Quantitative temporal obstruction). *For the golden-angle rotation and  $S, D$  of Section 4,*

$$(14) \quad \delta_M \geq \frac{1}{6000000M^6} \quad (M \geq 3).$$

*Every exact realization of  $C_{N,R}$  therefore satisfies*

$$(15) \quad \sum_{t=0}^{N-1} 2^{-6K_t} \leq 24000000.$$

*In particular  $W_N(R) \geq \frac{1}{6} \log_2(N/24000000)$ .*

*Proof.* A polygon feasible for (6) contains  $a\mathbb{B}^2$  and lies in  $\sqrt{2}\mathbb{B}^2$ . The last two lemmas give

$$\text{area}(\text{conv}(P \cup RP)) - \text{area}(P) \geq \frac{a^3}{4096\sqrt{2}M^6} > \frac{1}{6000000M^6},$$

using  $a = 1/10$  and  $\sqrt{2} < 10/7$ . Minimize over  $P$  to obtain (14). Apply Theorem 3.2 and bound  $\text{area}(D) - \text{area}(S)$  by 4. If  $K_t \leq W$  at all times, the left side of (15) is at least  $N2^{-6W}$ .  $\square$

Combining Proposition 4.1, Theorems 4.2, 4.3 and 5.4 proves Theorem 1.1. The profile inequality gives more than a bound on one minimum peak. For example, at most  $24000000 \cdot 2^{6k}$  of the command-input cuts can have width at most  $k$ , independently of the widths at the other cuts. The same statement follows directly by restricting the nonnegative sum.

**Proposition 5.5** (Robustness at a fixed excluded profile). *Fix a finite horizon and a profile excluded for  $C_{N,R}$  by either volume bound. There is a strictly positive uniform row-total-variation distance from  $C_{N,R}$  to all arrays realized with that profile. For the rational family, a positive rational lower distance can be computed from the fully listed array and profile by real quantifier elimination.*

*Proof.* Initialization, update and decoder rows range over a finite product of compact simplices. The realized array is a polynomial, and hence continuous, function of those rows. Its image is compact. An excluded array has strictly positive distance to this image in the maximum of the finitely many row-TV distances. For rational target entries the minimum distance is a semialgebraic optimization, after expressing absolute values by auxiliary variables; real quantifier elimination and root isolation give the stated rational lower bound [2]. No uniform lower distance as the horizon or profile varies follows from this argument.  $\square$

The exact golden-angle lower bound uses a specified computable real rotation; it is not presented as an algebraic-input computation. The rational family supplies algebraic excluded-horizon and fixed-profile robustness certificates instead. Neither the numerical values of its  $\delta_M$  nor optimal rates are asserted by the finite regression tests.

## 6. EXACT COMPOSITION OF FEASIBLE PROFILES

The previous bounds accumulate a compatibility cost through time. There is also an exact composition operation across distinguished experiments. Its hypothesis is operational: the distinguishing label must be recovered at the end and is not externally available after its initial preparation.

Take  $m$  complete terminal arrays  $C_i$ , on a common horizon and common future input alphabets. Their initial alphabets may be identified by padding. Define the *verifiably tagged sum*  $C^\oplus$  by receiving  $(i, x)$  initially and requiring terminal output  $(i, b)$  with law  $C_i(b \mid x, \mathbf{y}, j)$ . A wrong tag has probability zero. The tag is not repeated in later inputs, and previous outputs are not readable as memory. All branches have the same full suffix alphabet.

For two sets of integer profiles their sum below denotes coordinatewise Minkowski sum, including the already defined upward closure.

**Theorem 6.1** (Profile addition under a retained tag). *For the internal registers of the tagged sum,*

$$(16) \quad \mathcal{F}(C^\oplus) = \mathcal{F}(C_1) + \cdots + \mathcal{F}(C_m).$$

*The identity holds for arbitrary horizons and arbitrary stochastic realizations. It is an identity of complete feasible-profile sets, not just of separate minima or a scalar matrix rank.*

*Proof.* Fix a realization and a cut  $t$ . Let  $S_{t,i}$  consist of states having positive probability after some prefix from branch  $i$ . If one state belonged to  $S_{t,i}$  and  $S_{t,k}$  with  $i \neq k$ , run the same fixed future input word from that state. Exact tag recovery in branch  $i$  forces this conditional continuation to emit tag  $i$  with probability one: a positive mixture weight could not otherwise give zero wrong-tag probability. The same reasoning in branch  $k$  forces tag  $k$ . This is impossible. Thus the sets  $S_{t,i}$  are disjoint.

For every allowed next input, a positive transition from  $S_{t,i}$  leads to  $S_{t+1,i}$ , since its source is reachable after some branch- $i$  prefix and the full product suffix is allowed. Restricting the machine to these state sets and stripping its terminal tag therefore gives a complete realization of  $C_i$ . In particular its profile  $(|S_{t,i}|)_t$  is feasible. Their coordinatewise sum does not exceed the original profile. Padding any one of the restricted realizations absorbs each unused coordinate and gives membership in the right side of (16).

Conversely, use disjoint copies of the branch registers and transition rows. Initialization selects the declared branch, which is thereafter stored by membership in its disjoint register. The final decoder emits its tag and answer. This gives the sum of any feasible branch profiles and proves the reverse inclusion. No independent shared seed or free branch selector is supplied.  $\square$

If the final tag were dropped, this proof would fail: states serving two branches could be identified. Likewise, branch-dependent legal suffixes must not be substituted for the common full alphabet without a separate argument. These are hypotheses of the operation, not conclusions about unlabelled mixtures.

**Corollary 6.2** (An exact growing two-cut frontier). *Let every branch be the two-cut array (18), with a fixed  $9/10 \leq h < 1$ , and let  $m \geq 1$ . Its tagged sum has exactly the feasible internal profiles*

$$(17) \quad K_1 \geq 3m, \quad K_2 \geq 3m, \quad K_1 + K_2 \geq 7m.$$

*The Pareto-minimal pairs are  $(3m + j, 4m - j)$ ,  $j = 0, \dots, m$ . Both separate minima are  $3m$ , and the minimum full peak, including the  $2m$ -symbol terminal output, is  $\lceil 7m/2 \rceil$ .*

*Proof.* Appendix A proves the primitive feasible set as the upward closure of  $(3, 4), (4, 3)$ . Its  $m$ -fold Minkowski sum has the listed minimal pairs. To check that (17) has no additional holes, put  $u = K_1 - 3m$ ,  $v = K_2 - 3m$ . If  $u, v \geq 0$  and  $u + v \geq m$ , choose an integer  $j$  with  $\max(0, m - v) \leq j \leq \min(m, u)$ . Then  $(K_1, K_2) \geq (3m + j, 4m - j)$ . The peak is minimized by the nearest integer balance of  $j$  and  $m - j$ , giving  $\lceil 7m/2 \rceil$ . The output register has  $2m \leq \lceil 7m/2 \rceil$  labels.  $\square$

The primitive answer probabilities have full support, but the tagged sum has zeros at wrong tags. We do not use it as the full-support part of Theorem 1.1; that theorem already has a uniform full-support interval and fixed alphabets. The two results answer different questions: (17) is an exact finite Pareto law, whereas (15) excludes bounded simultaneous width while every separate positive minimum remains three.

## 7. COMPARISON, IMPLEMENTATION AND FURTHER QUESTIONS

**7.1. Stationary positive realization and finite causal width.** Benvenuti–Farina [1, Theorems 2 and 3] formulate existence of positive realizations by invariant polyhedral cones and shift-invariant positive sequences. Their Example 4 uses an irrational planar rotation to prevent a finite stationary realization. Monràs–Winter [8, Theorem 6 and Lemma 7] give the corresponding stochastic cone criterion and a rotation example. These are direct antecedents, not merely neighboring subjects.

Theorem 1.1 makes a different finite assertion. The matrices are allowed to be unrelated at different epochs, and a new machine may be selected at every horizon. Each entire finite array is positively realizable, while each of its cuts separately needs exactly three states. The lower bound is the accumulation of enlargement along  $P_t \subset P_{t+1}$  and  $RP_t \subset P_{t+1}$ . An invariant-cone existence theorem or a peripheral-spectrum argument for one common matrix does not, by itself, give this quantitative inequality for changing rows. Conversely, our theorem does not re-prove or extend the full stationary positive-realization existence classification.

The reachable-section construction is deliberately compatible with classical quotient realizations. In [8, Section 4, Theorem 9], the accessible subspace and its unobservable kernel determine the minimal linear quotient; arbitrary positive realizations can contain more directions. That is why Lemma 3.1 uses a section of a simplex before projecting. It does not identify minimum hidden dimension with a minimum number of vertices of an unlifted observable polygon. The related distinction between restricted and unrestricted positive factorizations appears explicitly in [5, Definition 1, Theorem 1]. The exponential allowance  $2^{K_t}$  is conservative, but makes the lower bound valid for all competing hidden representations.

The recent work of Lumbreras–Ma–Thompson–Gu [7] studies irreducible errors and decision failures of finite classical world models, with exact quantum realizations. Its Section IV.2 and ensuing proofs use repetition of one update, Perron–Frobenius limits and an irrational phase.

Our task has no quantum simulator or decision-loss claim: it compares exact *finite-horizon* cut-dependent classical realizations. The common rotation ancestry and different row-sharing quantifiers are both relevant. We do not infer a novelty boundary from the absence of a citation to this manuscript in that work.

**7.2. Residual restrictions, direct sums and sampling.** The finite-generation and canonical residual constructions of Esposito–Lemay–Denis–Dupont [4] and Denis–Esposito [3, Proposition 16] concern state languages constrained by the residual representation. The lower bound here places no such constraint on a state’s full continuation. Indeed all separate minima stay three in the rotation example, so a large list of actual residuals alone would not prove its causal width lower bound. Classical hidden-Markov and filtered-experiment comparison remain part of the surrounding theory [12, 9]; our wordwise finite profile statement is not claimed to be a new general comparison theorem for filtered spaces.

Nonnegative direct-sum additivity itself is familiar, including the tensor version in [11, Lemma 4.1]. Theorem 6.1 uses the same positivity principle to separate *reachable state sets at every time*; it identifies a sum of entire feasible profile sets. Taking only sums of separate ranks would lose the tradeoff in (17). Its tag and full common suffix alphabet are explicit and cannot be omitted.

The additive encoder construction in the preserved article [13] uses weighted replacement. The sampling step is weighted reservoir sampling, as described, for example, in [10, Appendix A.2]: replace the current sample with probability equal to the new weight divided by total weight. When total previous weight is zero, the dummy label is chosen from the existing alphabet. Neither that sampling algorithm nor the classical simplex inputs are novelty claims of the present paper. The earlier online consequences and rational sampler remain available without being needed for the rotation lower bound.

**7.3. What is and is not charged.** The finite-horizon bounds concern exact atomic stochastic transducers, not a bit-operation model. Both alphabet cardinality and all persistent hidden choices are charged. The row table and the prescribed external epoch are not. The rational family permits separately charged fair-bit sampling; the algebraic or computable-real polygon rows are not given a finite-denominator implementation claim. Sampling and verification costs therefore do not disappear into the phrase “exact realization.”

The new lower bound holds even with the external clock and arbitrary cut-dependent rows. The polygon upper construction has common command matrices across its training epochs, but its prescribed decoder depends on  $N$ . This does not define one finite machine that works at every horizon with an unchanged decoder. No automatic transfer from the clocked peak to autonomous length recognition is made.

**7.4. Conclusions.** The proved separation is between *separate positive minima* and *simultaneous positive width*, with fixed alphabets, uniformly positive response probabilities, and an arbitrarily long horizon. The projected reachable-section budget applies to a class of volume-preserving mean dynamics. The golden-angle family has an explicit multi-cut inequality and a constructive square-root upper bound; the rational family has effective excluded-horizon certificates. The tagged operation separately supplies exact growing Pareto frontiers.

The optimal growth of  $W_N$ , a sharp measure of lift complexity, quantitative stability uniform in the horizon, and general optimization of informative acquisition or validation actions remain distinct questions. The logarithmic lower bound is not matched by the square-root upper bound. Complete arbitrary-profile minimization is not claimed. These distinctions do not affect the unbounded separation or the exact tagged frontier.

The historical geometric, large-deviation and nonlinear-operator chains are preserved as separate mathematics. No finite-array argument here is claimed to discharge their analytic gates. The focused article contains the proofs required for its new claims; the cumulative volumes are archival records, not an additional burden of certification for its referee.

#### APPENDIX A. THE RETAINED TWO-CUT PRIMITIVE

The following proof is retained from revision 31 [13]; its role here is the input to Corollary 6.2, not a new claim.

The following experiment has only two internal memory cuts. The first input is  $x = (x_1, x_2) \in \{-1, 1\}^2$ , received as one symbol. A command  $j \in \{1, 2, 3, 4, 5\}$  is then received, followed by a query  $k \in \{1, 2\}$ . The machine emits  $B \in \{-1, 1\}$  in the update receiving  $k$ . Let  $K_1$  count states after  $x$  and  $K_2$  states after  $j$ ; a retained final answer has two labels. No further access to  $x$  or  $j$  is permitted. For  $0 < h \leq 1$  prescribe the conditional mean vectors

$$(18) \quad \begin{array}{c|ccccc} j & 1 & 2 & 3 & 4 & 5 \\ \hline z_{x,j} & (h, h) & (h, -h) & (-h, 0) & (-h/2, hx_1/4) & (-h/2, hx_2/4) \end{array}.$$

The answer law is  $\mathbb{P}(B = b \mid x, j, k) = (1 + bz_{x,j}(k))/2$ .

The program is clocked and uses arbitrary stochastic rows. Thus every allowed implementation has common rows  $E(s \mid x)$ ,  $T(t \mid s, j)$  and  $D(b \mid t, k)$ ; all past randomness is in  $s$  or  $t$ .

We first record the geometric estimate used by the converse.

**Lemma A.1** (A quantitative forced triangle). *Put  $h = 1 - \delta$ , where  $0 \leq \delta \leq 1/10$ . If a triangle  $P \subset [-1, 1]^2$  contains  $(h, h)$ ,  $(h, -h)$  and  $(-h, 0)$ , then every point  $(-h/2, y) \in P$  satisfies*

$$(19) \quad |y| \leq \beta(\delta) := \frac{1}{4} + \frac{\delta}{2(1-\delta)} + \frac{\delta}{2-3\delta} < \frac{h}{2}.$$

*Proof.* A convex representation of  $(h, h)$  includes a vertex  $A$  for which  $2 - A_1 - A_2 \leq 2\delta$ , so  $A_1, A_2 \geq 1 - 2\delta$ . A representation of  $(h, -h)$  similarly includes a vertex  $B$  with  $B_1 \geq 1 - 2\delta$  and  $B_2 \leq -1 + 2\delta$ . These vertices are distinct. Call the third vertex  $D$ . In a representation of  $(-h, 0)$ , let  $u$  be the total weight on  $A, B$ . Since their first coordinates are at least  $1 - 2\delta$  and  $D_1 \geq -1$ ,

$$-1 + \delta \geq -1 + 2(1 - \delta)u, \quad u \leq \frac{\delta}{2(1 - \delta)}.$$

The zero second coordinate implies  $|D_2| \leq u/(1 - u) \leq \delta/(2 - 3\delta)$ . For a point of  $P$  with first coordinate  $-h/2$ , the total weight  $v$  on  $A, B$  satisfies

$$-h/2 \geq -1 + 2hv, \quad v \leq \frac{1 - h/2}{2h} = \frac{1}{4} + \frac{\delta}{2h}.$$

Its second coordinate has absolute value at most  $v + (1 - v)|D_2| \leq \beta(\delta)$ . Finally the two fractions in  $\beta$  increase with  $\delta$  while  $h/2$  decreases, and

$$\beta(1/10) = \frac{1}{4} + \frac{1}{18} + \frac{1}{17} = \frac{223}{612} < \frac{9}{20}.$$

This proves the strict bound throughout the interval, including zero.  $\square$

**Lemma A.2** (Centered square in an inscribed triangle). *If a triangle in  $[-b, b]^2$  contains  $[-a, a]^2$ , with  $a > 0$ , then  $b \geq 2a$ .*

*Proof.* Write its three barycentric functions as  $\lambda_s(u) = c_s + d_s \cdot u$ . They are nonnegative on  $[-a, a]^2$ , so  $c_s \geq a\|d_s\|_1$  and  $\sum_s c_s = 1$ . If the vertices are  $v_s$ , affine reconstruction gives  $\sum_s v_s d_s^T = I_2$ . Taking traces yields  $2 \leq b \sum_s \|d_s\|_1 \leq b/a$ .  $\square$

This necessary bound is sufficient for our contradiction; no claim of its attainability in dimension two is used. The required two-dimensional trace argument has been proved here; its general-dimensional geometric background is recorded in [13].

**Theorem A.3** (Exact incompatible minima and their Pareto frontier). *For every  $9/10 \leq h \leq 1$ , both cuts of (18) separately admit an exact three-state realization and have ordinary normalized residual rank three. No realization has  $(K_1, K_2) = (3, 3)$ . The entire feasible profile region is*

$$(20) \quad \{(K_1, K_2) : K_1 \geq 3, K_2 \geq 4\} \cup \{(K_1, K_2) : K_1 \geq 4, K_2 \geq 3\}.$$

*Thus the exact Pareto-minimal profiles are  $(3, 4)$  and  $(4, 3)$ , and the minimum full peak is four. For  $h < 1$  the specified array has full support. At  $h = 9/10$  all answer probabilities belong to  $[1/20, 19/20]$ .*

*Proof.* The four rows at the first cut vary independently through the last two second coordinates of (18). They form a nondegenerate affine square, hence have normalized row rank three. At the second cut the response vectors lie in  $\mathbb{R}^2$  and include three affinely independent points  $(h, h), (h, -h), (-h, 0)$ . Its normalized row rank is also three. Factoring through a stochastic register cannot increase rank, so both state counts are at least three.

Here are matching one-sided constructions. Put  $a = h/4$ . At the first cut, three continuation vectors with free coordinate pairs

$$(21) \quad (-a, -a), \quad (3a, -a), \quad (-a, 3a)$$

and the fixed coordinates from (18) enclose the four actual rows. The triangle is legal because  $3a \leq 3/4$ . The barycentric encoder weights for  $(ax_1, ax_2)$  are

$$(\lambda_0, \lambda_1, \lambda_2) = \left( \frac{2 - x_1 - x_2}{4}, \frac{1 + x_1}{4}, \frac{1 + x_2}{4} \right).$$

After  $j$ , represent the resulting two-dimensional mean in the convex hull of the four corners of  $[-1, 1]^2$ . For a mean  $(u, v)$  the weights on  $(\varepsilon_1, \varepsilon_2)$  are  $(1 + \varepsilon_1 u)(1 + \varepsilon_2 v)/4$ . The decoder returns the queried corner coordinate. This is a single machine of profile  $(3, 4)$ .

For profile  $(4, 3)$ , first retain  $x$ . Every actual second-cut mean lies in the triangle with vertices  $h(1, 1), h(1, -1), h(-1, 0)$ . At a mean  $(u, v)$  its weights on those vertices are

$$(22) \quad \frac{h + u + 2v}{4h}, \quad \frac{h + u - 2v}{4h}, \quad \frac{h - u}{2h}.$$

For the last two columns they are respectively  $(1/4, 0, 3/4)$  or  $(0, 1/4, 3/4)$ ; for the first three columns they are the three unit vectors. These rows followed by the binary decoder prove the second construction. All tables are rational when  $h$  is rational.

Suppose now that a  $(3, 3)$  machine exists. Let  $G_1, G_2, G_3$  be its full first-cut continuation arrays. Since their convex hull contains an affine square of dimension two, their affine span equals the affine span of the four actual rows. Therefore each  $G_s$  has the first three columns of (18) unchanged and has last columns  $(-h/2, u_s)$  and  $(-h/2, v_s)$  for some  $u_s, v_s$ . The first encoder then forces

$$(23) \quad [-a, a]^2 \subseteq \text{conv}\{(u_s, v_s) : 1 \leq s \leq 3\}.$$

This affine-slice deduction allows arbitrary state continuations; it neither assumes that they are residuals nor restricts them beforehand to the residual hull.

The three states at the second cut have decoder mean vectors  $D_1, D_2, D_3 \in [-1, 1]^2$ . Their triangle  $P$  contains all actual second-cut rows, and hence the three points in Lemma A.1. Every shifted continuation of each  $G_s$  must also lie in  $P$ , because the update after  $j$  is a common stochastic row into these same three decoder states. In particular,  $(-h/2, u_s), (-h/2, v_s) \in P$ . Lemma A.1 gives  $|u_s|, |v_s| \leq \beta(1 - h) < h/2 = 2a$ . This contradicts Lemma A.2 applied to (23).

No  $(3, 3)$  realization exists. Padding the two constructions proves (20). The full-support and probability bounds follow immediately from the displayed means.  $\square$

# GENERAL THETA FOUNDATIONS I: COMPATIBILITY OF POSITIVE MEMORY AND ONLINE SIMPLEX SYNTHESIS

QIAN QI

**ABSTRACT.** We distinguish the separate positive realization of continuation arrays from their simultaneous realization by a finite causal machine. In the clocked atomic stochastic-row model, canonical affine sections yield a simultaneously rank-minimal machine whenever those sections are simplices; in particular, full-support arrays of cut rank at most two have no compatibility obstruction. We construct a full-support family of cut rank three whose two individual minimum state counts are both three, but whose exact Pareto-minimal profiles are  $(3, 4)$  and  $(4, 3)$ . Thus the compatibility obstruction occurs already at rank three and persists away from support boundaries. In the opposite direction, every additive stochastic encoder admits an online realization with no increase in its label alphabet. Consequently every simplex enclosing a contracted cube gives an online query encoder with the same number of states. This transfers all classical critical cube–simplex inclusions, including the non-Hadamard dimensions five and nine, to optimal online realizations. We also identify exact conditional query synthesis with classical worst-case random-access geometry at a checkpoint, and separate that equivalence from the cost of computing an encoder. Explicit rational tables, a finite fair-bit sampling ledger, and internal stochastic-language conventions complete the realization statements.

## 1. INTRODUCTION

A finite statistical response law may have a small positive factorization at every cut and nevertheless require a larger state space when those factorizations must be executed in succession. The difficulty is not linear dimension alone: the generators selected at one cut determine continuations which must be available at the next. Conversely, some families have enough additive structure that a static factorization already specifies a lossless online implementation. This paper proves both statements in one precise model.

Our first main result is the family in Theorem 3.3. An input with four possible values is followed by a five-valued command and a binary query. Only the final binary answer is released. Each of the two internal cuts separately has minimum state count three. No machine has three states at both cuts, even though all prescribed answer probabilities can be bounded between  $1/20$  and  $19/20$ . The profiles  $(3, 4)$  and  $(4, 3)$  are both realized explicitly. The proof excludes arbitrary stochastic encoders and decoders, not merely residual-state machines or a chosen architecture. It uses a forced affine slice at the first cut and a quantitative triangle constraint at the second.

The contrast is sharp in cut rank. Proposition 2.1 shows that the intersection of the normalized causal polytope with the affine span of the actual residuals is closed under normalized shifts. If these canonical sections are simplices, their vertices provide a simultaneously optimal machine (Theorem 2.2). All nonempty one-dimensional sections are intervals, so full-support cut ranks at

*Key words and phrases.* Causal realization, stochastic automata, nonnegative rank, cube absorption, random access codes, compatible memory.

most two cannot exhibit the preceding failure. This criterion uses an intrinsic polytope, not unknown transition coefficients. The invariant-cone and residual-realization mechanisms have classical antecedents [5, 10, 2]; the explicit rank-three obstruction is stated separately from them.

Our second main result is Theorem 4.1. A stochastic encoder on a product input alphabet which is additive in its input coordinates can be computed by a finite-state replacement process using exactly the same label alphabet. There is no retained coordinate selector or common random seed. An enclosing simplex has affine barycentric coordinates, so every static simplex encoder for the binary-query channel

$$(1) \quad \mathbb{P}(B = b \mid x, j) = \frac{1 + b\eta x_j}{2}, \quad x \in \{-1, 1\}^n, \quad j \in [n], \quad b \in \{-1, 1\},$$

has an online realization of the same peak. In particular, in every dimension and at every nonzero signal,

$$(2) \quad K_n(\eta) = n + 1 \iff W_n^{\text{fo}}(\eta) = n + 1 \iff W_n^{\text{ad}}(\eta) = n + 1.$$

The quantities on the right count all acquisition cuts;  $K_n$  constrains only the cut preceding the query. The proof of the first implication works for every enclosing simplex, not only orthogonal or Hadamard ones.

The static critical inequality  $\eta \leq 1/n$  is classical cube–simplex geometry. We state its relationship to the absorption index explicitly. Nevskii and Ukhalov’s critical simplices in dimensions five and nine [7] give, by the online theorem, six- and ten-state implementations at  $\eta = 1/5$  and  $\eta = 1/9$ . We display the rational vertices and the replacement distributions, so this consequence does not rely on a hypothetical static-to-dynamic transfer. Critical simplex matrices are also closed under a normalized tensor construction, giving further explicit online families without invoking unproved Hadamard existence. The static inclusions are not claimed as new.

A further distinction can be settled exactly. The minimum checkpoint alphabet for (1) equals that for classical private-randomness random access with worst-case success at least  $(1 + \eta)/2$ . This follows already from the geometric characterization and cube-containment argument of Kondo et al. [6, Theorem 14, Lemma 15]. We give the short normalization and exactification proof in Section 6. No extra persistent symmetrization seed is required. Therefore exact conditional rows do not themselves establish a different checkpoint exponent from classical random-access coding [1]. The online implementation, not that exponent, is the object of the present synthesis theorem.

| Notation                           | Meaning                                                 |
|------------------------------------|---------------------------------------------------------|
| $\mathcal{R}_t, \mathcal{P}_t$     | actual normalized residuals, all legal future arrays    |
| $L_t, r_t$                         | canonical affine section, affine dimension plus one     |
| $(K_1, K_2)$                       | simultaneous register bounds at two designated cuts     |
| $K_n(\eta)$                        | query-cut minimum, with unrestricted upstream memory    |
| $W_n^{\text{fo}}, W_n^{\text{ad}}$ | full acquisition peak: fixed or adaptive order          |
| $\xi(S)$                           | cube absorption by homothety about the simplex centroid |

A state count means the number of persistent labels. The primary model has exact atomic stochastic rows and an externally declared clock. Program descriptions and row-construction time are not part of that count. Section 7 gives a separate finite fair-bit implementation with its additional phase and sampling registers. A query is a current input, not a stored word; a model requiring a query buffer must charge it. These conventions are used consistently in both upper and lower bounds.

## 2. CANONICAL AFFINE SECTIONS OF A CAUSAL ARRAY

We use finite alphabets and a finite horizon. At a controller stage an action is chosen before its next report is received. A terminal answer is an action with a dummy following report. A complete normalized causal array  $C(\mathbf{a} \mid \mathbf{y})$  prescribes the conditional law of all actions for every externally supplied report word. Nonanticipation means that the marginal of an action prefix depends only on reports preceding that prefix. Intermediate buffers that must survive an update are included as charged cuts. The rows may depend on the declared time, but not on an unrecorded history, schedule variable or persistent random seed.

At a cut  $t$ , let  $\mathcal{P}_t$  be the polytope of normalized causal arrays on the remaining interface. For a controller prefix  $h$  whose probability, with past reports fixed, is positive, let  $R_h \in \mathcal{P}_t$  be its normalized future array. Remove duplicate rows to form the finite residual set  $\mathcal{R}_t$ . This is a property of  $C$ , not of a chosen realization. We require the full array, including unsupported environmental inputs; an almost-sure partial specification is a different completion problem. Set

$$(3) \quad A_t = \text{aff } \mathcal{R}_t, \quad L_t = A_t \cap \mathcal{P}_t, \quad r_t = \dim A_t + 1.$$

The slice  $L_t$  is a compact polytope of dimension  $r_t - 1$ , since it contains  $\mathcal{R}_t$ . Normalization places  $A_t$  in a hyperplane not containing zero, so  $r_t$  is also the ordinary row rank of the normalized residuals.

If  $R$  is a future array, write  $p_R(a)$  for its next-action probability. It is independent of the next report  $y$ . For  $p_R(a) > 0$ , denote by  $R^{a,y}$  the normalized continuation after that action and report. For an actual residual this is another actual residual at the child cut.

**Proposition 2.1** (Affine slices are closed under positive shifts). *If  $G \in L_t$  and  $p_G(a) > 0$ , then  $G^{a,y} \in L_{t+1}$  for every next report  $y$ .*

*Proof.* Write  $G = \sum_h c_h R_h$  with real coefficients satisfying  $\sum_h c_h = 1$ . Taking an action marginal gives  $p_G(a) = \sum_h c_h p_{R_h}(a)$ . Restriction to  $(a, y)$  is linear in the unnormalized arrays, hence

$$G^{a,y} = \sum_{h: p_{R_h}(a) > 0} \frac{c_h p_{R_h}(a)}{p_G(a)} R_h^{a,y}.$$

The coefficients sum to one. They need not be positive: the display asserts membership in the affine span at the child, not a convex realization. Since  $G \in \mathcal{P}_t$  and  $p_G(a) > 0$ , its normalized shift is a valid nonnegative causal array. Thus it lies in both factors of (3) at the child cut.  $\square$

**Theorem 2.2** (A canonical sufficient criterion and the rank-two case). *If every  $L_t$  is a simplex, a single stochastic clocked machine realizes  $C$  with exactly  $r_t$  labels at cut  $t$ , simultaneously. No realization can use fewer than  $r_t$  at that cut. In particular, every complete finite causal array with  $r_t \leq 2$  at every cut has a simultaneously rank-minimal realization. This includes full-support arrays with arbitrary finite action and report alphabets.*

*Proof.* In any realization, conditioning on a prefix expresses  $R_h$  as a convex combination of the state continuations at cut  $t$ . Its affine dimension therefore forces at least  $r_t$  labels.

Choose the vertices of  $L_t$  as the states at cut  $t$ . Every actual residual is their convex combination. From vertex  $G$ , choose the next action with probability  $p_G(a)$ . After the next report, express  $G^{a,y} \in L_{t+1}$  as a convex combination of the child vertices and use those weights as the update row. An action of probability zero may have an arbitrary unused update. Proposition 2.1 ensures that this construction is possible, and the action probability is independent of the unread report. Initialization uses the barycentric representation of  $C$ . Backward induction verifies the entire specified future law from every vertex state. A simplex of dimension  $r_t - 1$  has exactly  $r_t$  vertices, proving the claim. A zero-dimensional slice is a point and a compact one-dimensional slice is a segment, which proves the last assertion.  $\square$

This criterion differs from requiring the residual hull itself to be a simplex: internal vertices can lie outside that hull. It also differs from searching for unknown enclosing simplices and unknown shifts simultaneously. The polytope  $L_t$  is fixed by linear equations and inequalities from the input array; its normalized-shift closure is proved, not an additional feasibility hypothesis. For fully listed rational arrays, vertices and barycentric rows can be found by rational linear algebra and finite polyhedral enumeration. The explicit array may already be exponentially large in the horizon. No succinct-input polynomial bound, autonomous row-reuse theorem, or universal equality between rank and state complexity follows.

The next section shows that the rank-two conclusion is sharp as a uniform statement about the maximum cut rank. At rank three, separate rank-optimal enclosures need not be causally compatible even for a full-support family.

### 3. A FULL-SUPPORT OBSTRUCTION AT RANK THREE

The following experiment has only two internal memory cuts. The first input is  $x = (x_1, x_2) \in \{-1, 1\}^2$ , received as one symbol. A command  $j \in \{1, 2, 3, 4, 5\}$  is then received, followed by a query  $k \in \{1, 2\}$ . The machine emits  $B \in \{-1, 1\}$  in the update receiving  $k$ . Let  $K_1$  count states after  $x$  and  $K_2$  states after  $j$ ; a retained final answer has two labels. No further access to  $x$  or  $j$  is permitted. For  $0 < h \leq 1$  prescribe the conditional mean vectors

$$(4) \quad \begin{array}{c|ccccc} j & 1 & 2 & 3 & 4 & 5 \\ \hline z_{x,j} & (h, h) & (h, -h) & (-h, 0) & (-h/2, hx_1/4) & (-h/2, hx_2/4) \end{array}.$$

The answer law is  $\mathbb{P}(B = b \mid x, j, k) = (1 + bz_{x,j}(k))/2$ .

The program is clocked and uses arbitrary stochastic rows. Thus every allowed implementation has common rows  $E(s \mid x)$ ,  $T(t \mid s, j)$  and  $D(b \mid t, k)$ ; all past randomness is in  $s$  or  $t$ .

We first record the geometric estimate used by the converse.

**Lemma 3.1** (A quantitative forced triangle). *Put  $h = 1 - \delta$ , where  $0 \leq \delta \leq 1/10$ . If a triangle  $P \subset [-1, 1]^2$  contains  $(h, h)$ ,  $(h, -h)$  and  $(-h, 0)$ , then every point  $(-h/2, y) \in P$  satisfies*

$$(5) \quad |y| \leq \beta(\delta) := \frac{1}{4} + \frac{\delta}{2(1-\delta)} + \frac{\delta}{2-3\delta} < \frac{h}{2}.$$

*Proof.* A convex representation of  $(h, h)$  includes a vertex  $A$  for which  $2 - A_1 - A_2 \leq 2\delta$ , so  $A_1, A_2 \geq 1 - 2\delta$ . A representation of  $(h, -h)$  similarly includes a vertex  $B$  with  $B_1 \geq 1 - 2\delta$  and  $B_2 \leq -1 + 2\delta$ . These vertices are distinct. Call the third vertex  $D$ . In a representation of  $(-h, 0)$ , let  $u$  be the total weight on  $A, B$ . Since their first coordinates are at least  $1 - 2\delta$  and  $D_1 \geq -1$ ,

$$-1 + \delta \geq -1 + 2(1 - \delta)u, \quad u \leq \frac{\delta}{2(1 - \delta)}.$$

The zero second coordinate implies  $|D_2| \leq u/(1 - u) \leq \delta/(2 - 3\delta)$ . For a point of  $P$  with first coordinate  $-h/2$ , the total weight  $v$  on  $A, B$  satisfies

$$-h/2 \geq -1 + 2hv, \quad v \leq \frac{1 - h/2}{2h} = \frac{1}{4} + \frac{\delta}{2h}.$$

Its second coordinate has absolute value at most  $v + (1 - v)|D_2| \leq \beta(\delta)$ . Finally the two fractions in  $\beta$  increase with  $\delta$  while  $h/2$  decreases, and

$$\beta(1/10) = \frac{1}{4} + \frac{1}{18} + \frac{1}{17} = \frac{223}{612} < \frac{9}{20}.$$

This proves the strict bound throughout the interval, including zero.  $\square$

**Lemma 3.2** (Centered square in an inscribed triangle). *If a triangle in  $[-b, b]^2$  contains  $[-a, a]^2$ , with  $a > 0$ , then  $b \geq 2a$ .*

*Proof.* Write its three barycentric functions as  $\lambda_s(u) = c_s + d_s \cdot u$ . They are nonnegative on  $[-a, a]^2$ , so  $c_s \geq a\|d_s\|_1$  and  $\sum_s c_s = 1$ . If the vertices are  $v_s$ , affine reconstruction gives  $\sum_s v_s d_s^T = I_2$ . Taking traces yields  $2 \leq b \sum_s \|d_s\|_1 \leq b/a$ .  $\square$

This necessary bound is sufficient for our contradiction; no claim of its attainability in dimension two is used. Its general-dimensional version belongs to classical cube-absorption geometry; see Section 5.

**Theorem 3.3** (Exact incompatible minima and their Pareto frontier). *For every  $9/10 \leq h \leq 1$ , both cuts of (4) separately admit an exact three-state realization and have ordinary normalized residual rank three. No realization has  $(K_1, K_2) = (3, 3)$ . The entire feasible profile region is*

$$(6) \quad \{(K_1, K_2) : K_1 \geq 3, K_2 \geq 4\} \cup \{(K_1, K_2) : K_1 \geq 4, K_2 \geq 3\}.$$

*Thus the exact Pareto-minimal profiles are  $(3, 4)$  and  $(4, 3)$ , and the minimum full peak is four. For  $h < 1$  the specified array has full support. At  $h = 9/10$  all answer probabilities belong to  $[1/20, 19/20]$ .*

*Proof.* The four rows at the first cut vary independently through the last two second coordinates of (4). They form a nondegenerate affine square, hence have normalized row rank three. At the second cut the response vectors lie in  $\mathbb{R}^2$  and include three affinely independent points  $(h, h), (h, -h), (-h, 0)$ . Its normalized row rank is also three. Factoring through a stochastic register cannot increase rank, so both state counts are at least three.

Here are matching one-sided constructions. Put  $a = h/4$ . At the first cut, three continuation vectors with free coordinate pairs

$$(7) \quad (-a, -a), \quad (3a, -a), \quad (-a, 3a)$$

and the fixed coordinates from (4) enclose the four actual rows. The triangle is legal because  $3a \leq 3/4$ . The barycentric encoder weights for  $(ax_1, ax_2)$  are

$$(\lambda_0, \lambda_1, \lambda_2) = \left( \frac{2 - x_1 - x_2}{4}, \frac{1 + x_1}{4}, \frac{1 + x_2}{4} \right).$$

After  $j$ , represent the resulting two-dimensional mean in the convex hull of the four corners of  $[-1, 1]^2$ . For a mean  $(u, v)$  the weights on  $(\varepsilon_1, \varepsilon_2)$  are  $(1 + \varepsilon_1 u)(1 + \varepsilon_2 v)/4$ . The decoder returns the queried corner coordinate. This is a single machine of profile  $(3, 4)$ .

For profile  $(4, 3)$ , first retain  $x$ . Every actual second-cut mean lies in the triangle with vertices  $h(1, 1), h(1, -1), h(-1, 0)$ . At a mean  $(u, v)$  its weights on those vertices are

$$(8) \quad \frac{h + u + 2v}{4h}, \quad \frac{h + u - 2v}{4h}, \quad \frac{h - u}{2h}.$$

For the last two columns they are respectively  $(1/4, 0, 3/4)$  or  $(0, 1/4, 3/4)$ ; for the first three columns they are the three unit vectors. These rows followed by the binary decoder prove the second construction. All tables are rational when  $h$  is rational.

Suppose now that a  $(3, 3)$  machine exists. Let  $G_1, G_2, G_3$  be its full first-cut continuation arrays. Since their convex hull contains an affine square of dimension two, their affine span equals the affine span of the four actual rows. Therefore each  $G_s$  has the first three columns of (4) unchanged and has last columns  $(-h/2, u_s)$  and  $(-h/2, v_s)$  for some  $u_s, v_s$ . The first encoder then forces

$$(9) \quad [-a, a]^2 \subseteq \text{conv}\{(u_s, v_s) : 1 \leq s \leq 3\}.$$

This affine-slice deduction allows arbitrary state continuations; it neither assumes that they are residuals nor restricts them beforehand to the residual hull.

The three states at the second cut have decoder mean vectors  $D_1, D_2, D_3 \in [-1, 1]^2$ . Their triangle  $P$  contains all actual second-cut rows, and hence the three points in Lemma 3.1. Every shifted continuation of each  $G_s$  must also lie in  $P$ , because the update after  $j$  is a common stochastic row into these same three decoder states. In particular,  $(-h/2, u_s), (-h/2, v_s) \in P$ . Lemma 3.1 gives  $|u_s|, |v_s| \leq \beta(1-h) < h/2 = 2a$ . This contradicts Lemma 3.2 applied to (9). No (3,3) realization exists. Padding the two constructions proves (6). The full-support and probability bounds follow immediately from the displayed means.  $\square$

For  $h < 1$  all residual minimal faces at each cut coincide with the full terminal-channel face. Thus the support-component rank is just three at each cut; support separation is not the source of the failure. The obstruction is simultaneous positivity of the shifted generators. Theorem 2.2 and Theorem 3.3 together locate the first possible maximum cut rank for this phenomenon at three. They also distinguish an actual obstruction from a bilinear feasibility reformulation: the complete feasible profile set is determined here.

#### 4. ADDITIVE ENCODERS ADMIT LOSSLESS ONLINE SYNTHESIS

The preceding obstruction involves two successive nonlinear choices of positive generators. Additivity provides a different situation in which the encoding stage can always be made causal without enlarging its alphabet.

Let  $X_1, \dots, X_n$  be finite input sets and  $S = [m]$  a label set. An encoder is a map  $\lambda : \prod_i X_i \rightarrow \Delta_m$ . Call it additive if there are vectors  $a \in \mathbb{R}^m$  and  $f_i(x_i) \in \mathbb{R}^m$  such that

$$(10) \quad \lambda(x) = a + \sum_{i=1}^n f_i(x_i).$$

The summands need not be probability vectors or have positive entries. All that is assumed is  $\lambda(x) \in \Delta_m$  for every product input.

**Theorem 4.1** (Additive encoding without a persistent selector). *Every encoder (10) has an exact fixed-order streaming realization with at most  $m$  states after each input. This holds for every externally prescribed permutation of the inputs. The construction uses only scalar replacement probabilities and fresh input-dependent draws on  $[m]$ ; it never retains the index of the chosen summand. Rational encoder data give rational transition rows.*

*Proof.* For each label  $s$ , put

$$\ell_{i,s} = \min_{x_i \in X_i} f_{i,s}(x_i), \quad c_s = a_s + \sum_i \ell_{i,s}, \quad g_{i,s}(x_i) = f_{i,s}(x_i) - \ell_{i,s}.$$

Because the input is a full Cartesian product, each scalar minimum can be attained independently. Consequently  $c_s = \min_x \lambda_s(x) \geq 0$ , and  $g_i(x_i)$  is nonnegative. Normalization of (10), with all other coordinates fixed, shows that  $\sum_s f_{i,s}(x_i)$  is independent of  $x_i$ . Therefore

$$w_i = \sum_s g_{i,s}(x_i) \geq 0$$

is constant in  $x_i$ . With  $w_0 = \sum_s c_s$ , one has  $w_0 + \sum_i w_i = 1$ . Delete zero-weight summands. For the others define  $q_0 = c/w_0$  and  $q_i(x_i) = g_i(x_i)/w_i$ , so

$$(11) \quad \lambda(x) = w_0 q_0 + \sum_i w_i q_i(x_i).$$

Let  $W_t = w_0 + \sum_{i \leq t} w_i$ . If  $w_0 > 0$ , initialize from  $q_0$ . At the first positive-weight input when  $W_{t-1} = 0$ , simply draw from  $q_t(x_t)$ ; before it a dummy label suffices. When  $W_t > 0$ , retain the

old label with probability  $W_{t-1}/W_t$  and otherwise replace it by a fresh draw from  $q_t(x_t)$ . A zero-weight input leaves the label unchanged. Induction gives the state law

$$\mathbb{P}(S_t = s \mid x_{1:t}) = \frac{w_0 q_0(s) + \sum_{i \leq t} w_i q_i(s \mid x_i)}{W_t}.$$

At  $t = n$  the denominator is one and the law is exactly  $\lambda(x)$ . Equivalently, each update is the single atomic row

$$(12) \quad T_{t,x_t}(s, s') = \frac{W_{t-1}}{W_t} \mathbf{1}_{\{s=s'\}} + \frac{w_t}{W_t} q_t(s' \mid x_t).$$

Only  $s'$  persists. The weights and their prefix sums are known program data associated with the external clock. The same construction works in every prescribed permutation. Minima and arithmetic preserve rationality.  $\square$

**Corollary 4.2** (Rank-saturating additive channels). *Let  $C_x$  be a finite family of normalized terminal channels, additive in the product coordinates of  $x$ , with affine dimension  $r - 1$ . If  $C_x$  can be represented through  $r$  legal normalized generators at a checkpoint, then it can be acquired sequentially with at most  $r$  labels at every input cut, for any fixed order. Thus its checkpoint and acquisition-peak minima agree at  $r$ . If a final output must be retained, the complete peak is at most  $\max(r, |B|)$  for output alphabet  $B$ .*

*Proof.* A convex representation through  $r$  generators enclosing a set of affine dimension  $r - 1$  makes those generators affinely independent. Their barycentric coordinates are affine functions of  $C_x$ , hence additive in  $x$ . They are stochastic on all product inputs. Apply Theorem 4.1, then the unchanged terminal decoder. The affine-dimension lower bound holds for every acquisition method because the complete input must pass through the checkpoint label.  $\square$

For (1), a decoder state has a mean vector  $v_s \in [-1, 1]^n$ . Conditioning on the state gives

$$(13) \quad \eta x = \sum_s E(s \mid x) v_s.$$

Consequently  $K_n(\eta)$  is the smallest number of outer-cube points whose convex hull contains  $\eta[-1, 1]^n$ . This checkpoint formulation is classical random-access geometry in the normalization of Section 6. An adaptive acquisition schedule still produces one distribution  $E(\cdot \mid x)$ , with no past-dependent input supplied to the decoder, so it obeys the same lower bound.

**Theorem 4.3** (Every simplex encoder has the same optimal online peak). *Let  $n \geq 1$  and  $\eta > 0$ . If a simplex with vertices  $v_0, \dots, v_n \in [-1, 1]^n$  contains  $\eta[-1, 1]^n$ , those very decoder vertices admit an exact online encoder with at most  $n + 1$  states. Hence (2) holds for every  $n$  and  $\eta$ . No hypothesis concerning a Hadamard matrix is required.*

*Proof.* Write the simplex's affine barycentric coordinates as  $\lambda_s(z) = a_s + b_s \cdot z$ . Then  $\lambda_s(\eta x) = a_s + \eta \sum_i b_{s,i} x_i$  is an additive stochastic encoder on the product cube. Theorem 4.1 computes it without expanding the label set. The unchanged binary decoder with mean  $v_{s,j}$  gives (1). Conversely,  $K_n(\eta) \leq W_n^{\text{ad}}(\eta) \leq W_n^{\text{fo}}(\eta)$  and  $K_n(\eta) \geq n + 1$  by affine dimension. A final binary output requires no more than  $n + 1$  labels.  $\square$

The theorem concerns the peak, not simultaneous optimality of the individual  $t + 1$  prefix bounds. Its sampler can occupy all  $n + 1$  labels at an early cut. Nor does it assert online equality for arbitrary nonsimplicial checkpoint codebooks: their barycentric encoders need not be affine. The rank-three example in Section 3 shows why general static factorizations cannot be promoted to joint realizations without additional structure.

## 5. CRITICAL CUBE ABSORPTION AND NON-HADAMARD ONLINE ENCODERS

We separate the classical static geometry from the online consequence. Let  $Q_n = [0, 1]^n$ . For a nondegenerate simplex  $S \subset Q_n$ , let

$$\xi(S) = \inf\{\rho > 0 : Q_n \subset c(S) + \rho(S - c(S))\}, \quad \xi_n = \inf_{S \subset Q_n} \xi(S),$$

where  $c(S)$  is its centroid. The universal lower bound  $\xi_n \geq n$ , the Hadamard equality construction, the axial-diameter formulas and the non-Hadamard equalities  $\xi_5 = 5$ ,  $\xi_9 = 9$  belong to the classical cube-absorption literature; Nevskii and Ukhlov give the needed results and antecedents in [7]. Their Theorem 2 proves that equality in  $S \subset Q \subset nS$ , with homothety about the simplex centroid, forces the centroids to coincide. Thus a critical simplex in their normalization gives, under  $v = 2u - \mathbf{1}$ , precisely

$$(14) \quad n^{-1}[-1, 1]^n \subset \text{conv}\{v_0, \dots, v_n\} \subset [-1, 1]^n.$$

Away from the critical value, centering at the origin and centering at the simplex centroid must not be silently identified.

For reference, the centered obstruction has a short proof. If the barycentric coordinates are  $a_s + b_s \cdot z$ , containment of  $\eta[-1, 1]^n$  gives  $a_s \geq \eta \|b_s\|_1$  and  $\sum_s a_s = 1$ . Reconstruction gives  $\sum_s v_s b_s^T = I_n$ , whence

$$(15) \quad n = \sum_{s,i} v_{s,i} b_{s,i} \leq \sum_s \|b_s\|_1 \leq \eta^{-1}.$$

This is a proof of a classical inequality in the present notation, not a new static threshold. The extra conclusion is that every feasible simplex, critical or not, has the same online peak by Theorem 4.3.

**Proposition 5.1** (Explicit online rows for a critical simplex). *For any simplex satisfying (14), write its barycentric functions as  $a_s + \sum_i b_{s,i} z_i$ . Then*

$$(16) \quad a_s = \frac{1}{n+1} = \frac{1}{n} \sum_i |b_{s,i}|, \quad \sum_s |b_{s,i}| = 1, \quad \sum_s b_{s,i} = 0.$$

*The distributions*

$$(17) \quad q_i(s \mid x_i) = |b_{s,i}| + b_{s,i} x_i$$

*and updates*

$$(18) \quad T_{t,x_t}(s, s') = \frac{t-1}{t} \mathbf{1}_{\{s=s'\}} + \frac{1}{t} q_t(s' \mid x_t)$$

realize the critical query channel with  $n+1$  states. Multiplying the final decoder means by  $n\eta$  gives every  $0 < \eta \leq 1/n$  at the same peak. The origin of a replacement draw is not retained.

*Proof.* Every inequality in (15) is an equality at  $\eta = 1/n$ . Thus  $a_s = n^{-1} \|b_s\|_1$  for each  $s$ , and  $v_{s,i} b_{s,i} = |b_{s,i}|$  for each pair  $(s, i)$ . Evaluating the  $s$ th barycentric function at its own vertex gives  $1 = a_s + \|b_s\|_1 = (n+1)a_s$ , so the centroid is zero. The  $i$ th diagonal entry of  $\sum_s v_s b_s^T = I_n$  yields the second identity; barycentric normalization yields the third. Hence (17) is a probability vector. Induction in (18) gives

$$\mathbb{P}(S_n = s \mid x) = \frac{1}{n} \sum_i q_i(s \mid x_i) = a_s + \frac{1}{n} \sum_i b_{s,i} x_i.$$

This is exactly the barycentric distribution of  $x/n$ . Its decoder mean is  $x_j/n$ , and the claimed attenuation completes the proof. Unlike a Hadamard construction, an individual  $q_i$  need not have mean vector  $x_i e_i$ ; the required cancellation holds after averaging all coordinates.  $\square$

**5.1. Two rational non-Hadamard implementations.** The following vertices are taken from [7, Theorem 4 and Section 9], in its  $[0, 1]^n$  normalization. They are reproduced to specify the actual online rows, not as new static constructions. In dimension five the six rows of  $U_5$  are

$$(19) \quad U_5 = \begin{pmatrix} 1/2 & 1 & 1/3 & 1 & 1 \\ 1/2 & 0 & 1/3 & 1 & 1 \\ 1/2 & 1/2 & 1/3 & 0 & 1 \\ 1/2 & 1/2 & 0 & 1/3 & 0 \\ 0 & 1/2 & 1 & 1/3 & 0 \\ 1 & 1/2 & 1 & 1/3 & 0 \end{pmatrix}.$$

In dimension nine, choose the parameter  $t = 1/2$  in their family:

$$(20) \quad U_9 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 1/2 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 & 1/2 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 1 & 1/2 & 0 & 0 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1/2 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1/2 & 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 1/2 & 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1/2 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1/2 & 1 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

Put  $V_d = 2U_d - \mathbf{1}$  entrywise and  $M_d = [\mathbf{1} \ V_d]$ . The inverse gives  $\lambda_s(z) = (1, z^T)(M_d^{-1})_{\cdot s}$ ; its first row is  $a_s$  and its other rows are  $b_{s,i}$ . Direct rational multiplication gives

$$(21) \quad \begin{array}{c|ccc} d & |\det M_d| & a_s & \sum_i |b_{s,i}| \\ \hline 5 & 32 & 1/6 & 5/6 \\ 9 & 12800 & 1/10 & 9/10 \end{array}$$

and  $V_d^T(b_{s,i})_{s,i} = I_d$ ,  $V_d^T a = 0$ . Thus the displayed matrices also verify (14) directly: all barycentric coordinates are nonnegative on  $d^{-1}[-1, 1]^d$ , sum to one and reconstruct  $z$ . Equations (17)–(18) are full transition formulas requiring only these finite rational inputs.

**Corollary 5.2** (Online optimality beyond Hadamard orders). *For  $d = 5$  and  $d = 9$  and every  $\eta > 0$ ,*

$$K_d(\eta) = W_d^{\text{ad}}(\eta) = W_d^{\text{fo}}(\eta) = d + 1 \iff \eta \leq 1/d.$$

*The matrices (19)–(20) and (18) give rational acquisition rows. No Hadamard matrix of order six or ten is used or needed.*

*Proof.* Apply Proposition 5.1 to the two matrices, and use the dimension lower bound and (15) for the converse.  $\square$

In the terminology of [7], the five-dimensional seed is perfect; their nine-dimensional seed is critical but is not perfect. Equality of the absorption factor, not the stronger condition that every cube vertex touches a dilated face, is what the online argument uses.

**5.2. Closure of normalized critical matrices.** This elementary closure gives an explicit growing family of such encoders. Let  $M = [\mathbf{1} \ V]$  be the augmented matrix of a centered critical simplex of dimension  $d$ , and let  $m = d + 1$ . Its centroid condition and (16) say that the first row of  $M^{-1}$  is  $\mathbf{1}^T/m$  and every column of  $M^{-1}$  has absolute sum one. Conversely, these two conditions together with  $V \in [-1, 1]^{m \times d}$  and invertibility imply the critical inclusion by barycentric positivity.

**Proposition 5.3** (Normalized tensor closure). *If  $M$  and  $N$  satisfy the preceding conditions, so does  $M \otimes N$  with its all-ones column placed first. It gives a critical simplex of dimension  $(d+1)(e+1) - 1$ . Thus tensor products of the rational seeds of sizes 2, 6 and 10 give explicitly specified optimal online simplex encoders whenever*

$$n+1 = 2^a 6^b 10^c > 1, \quad a, b, c \text{ nonnegative integers.}$$

*Proof.* Entries of  $M \otimes N$  are products of entries in  $[-1, 1]$ , so the new vertices are in the cube. The first inverse row is uniform on the product index set. Since  $(M \otimes N)^{-1} = M^{-1} \otimes N^{-1}$ , the absolute column sums multiply and remain one. Invertibility and the converse observation prove the critical inclusion; the online assertion follows from Proposition 5.1. The seed of size two is  $\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$ .  $\square$

No general multiplicativity of nonnegative rank is asserted. This is an explicit operation on the normalized critical matrices just defined; the static tensor algebra is not used as a priority claim.

## 6. EXACT QUERY SYNTHESIS AND CLASSICAL WORST-CASE CODING

Fix a finite decoder dictionary  $D = \{v_1, \dots, v_m\} \subset [-1, 1]^n$ , with private encoder and decoder randomness and no shared seed. A worst-case success guarantee  $(1 + \eta)/2$  means that for every input  $x$  there is a probability vector  $E_x$  such that

$$x_i \sum_s E_x(s) v_{s,i} \geq \eta \quad \text{for all } i.$$

The same  $E_x$  must serve all future queries. Merely requiring average success over queries is a different condition.

**Proposition 6.1** (Checkpoint exactification with no added states). *For  $0 \leq \eta \leq 1$  the following are equivalent for the fixed dictionary:*

- (1) *it achieves worst-case random-access success at least  $(1 + \eta)/2$ ;*
- (2)  $\eta[-1, 1]^n \subseteq \text{conv } D$ ;
- (3) *it exactly realizes (1) after changing only the encoder.*

*Thus the minimum checkpoint alphabet in the exact problem equals the minimum alphabet in the private-randomness worst-case coding problem. No runtime symmetrization or retained random partition is necessary.*

*Proof.* Assume the first condition and fix  $u \in \mathbb{R}^n$ . Choose an input corner with  $x_i = \text{sign}(u_i)$  when  $u_i \neq 0$ , and let  $z_x = \sum_s E_x(s) v_s$ . Then

$$\max_{v \in \text{conv } D} u \cdot v \geq u \cdot z_x \geq \eta \sum_i |u_i|.$$

The right side is the support function of  $\eta[-1, 1]^n$ . The separating hyperplane theorem gives the second condition. It gives an exact convex representation of every  $\eta x$  using the same dictionary, which is the required new encoder in the third condition. The third condition implies the first immediately.  $\square$

This is a translation of the geometry already present in [6, Theorem 14, Lemma 15 and equations (143)–(149)], not a new coding exponent. In their  $[0, 1]^n$  normalization the dictionary is  $S = (D + \mathbf{1})/2$ , its directed  $\ell^\infty$  Hausdorff error from the Boolean corners is  $e(D)$ , and the largest centered cube factor is

$$\eta(D) = 1 - 2e(D), \quad p_{\text{worst}}(D) = 1 - e(D) = \frac{1 + \eta(D)}{2}$$

whenever the factor is nonnegative. The factor two is essential when passing from errors to means. Their model has  $m = 2^k$  messages; the proposition uses any integer  $m$ . Their Lemma 15 explicitly passes to cube containment. It is therefore not appropriate to call the exact checkpoint channel a strictly harder cardinality problem solely because it specifies equality rather than a lower bound on success.

Exactification can change a non-affine encoder into a different non-affine encoder. The proposition does not bound the storage needed to compute it online. Theorem 4.1 supplies that missing step for additive encoders, and Theorem 4.3 supplies it for every simplex dictionary. This is the precise division between the static coding theorem and the online theorem here.

The first-order entropy rate  $1 - h_2((1 + \eta)/2)$  and logarithmic communication overhead are classical [1]. The preceding revision proved a fully charged blockwise exact realization with logarithmic state excess  $O_\eta(\sqrt{n \log n})$ , and uniform row-error results; those proofs and statements remain in the unchanged supporting article. Neither exactification nor the present online simplex theorem proves a matching second-order law for that block construction. The retained entropy theorem is not used as a new contribution of this revision.

Likewise, the optimal  $(2^k - 1, k)$  classical construction and its static bound in [6, Theorems 16–17] overlap the Hadamard/Sylvester checkpoint case. The online synthesis applies to its simplex without increasing the number of messages, but does not change that existing optimality statement. Their conjecture-dependent results for other message sizes remain conjecture-dependent; none is used to infer an unconditional finite phase diagram here.

## 7. FINITE COINS AND STOCHASTIC-LANGUAGE CONVENTIONS

**7.1. A separate fair-bit register ledger.** The exact label counts above refer to atomic stochastic rows. They do not include the internal computation of a real-probability sampler. For the rational constructions a fully finite implementation is available, with an additional cost which can be stated without hiding a counter or the current input.

**Proposition 7.1** (Finite fair-bit implementation of rational rows). *Consider  $T$  input stages, an at-most- $m$ -label transducer with  $m \geq 2$ , and current input alphabet size at most  $d$ . Suppose every row has a common denominator for its entries of size at most  $D \geq 2$ . Put  $b = \lceil \log_2 D \rceil$ . In a self-paced protocol which supplies the next input only after the preceding update completes, the transducer has an exact fair-bit implementation using at most*

$$(22) \quad 2(T + 1)md2^b$$

*states, including phase, current input, old label, sampler prefix and terminal output. Each stage uses fewer than  $2b$  fair bits on average. Thus its persistent bit cost is at most*

$$\lceil \log_2(T + 1) \rceil + \lceil \log_2 m \rceil + \lceil \log_2 d \rceil + b + 2.$$

*This changes the implementation model and does not assert preservation of the atomic optimum in total states.*

*Proof.* For a row of denominator  $D_\rho \leq D$ , let  $b_\rho = \lceil \log_2 D_\rho \rceil$ . Draw  $b_\rho$  fair bits to form an integer  $J$  between zero and  $2^{b_\rho} - 1$ . If  $J \geq D_\rho$ , repeat; otherwise map  $J$  through the row's integer cumulative sums to the new label. A denominator-one row is deterministic. The acceptance probability is  $D_\rho/2^{b_\rho} > 1/2$ , unless it is one, and the accepted integer is uniform. This proves exactness and the expectation bound.

Retain the phase, old label and current input throughout an attempted draw. The proper binary prefixes of length less than  $b_\rho$  form a tree with  $2^{b_\rho} - 1 \leq 2^b - 1$  nodes. On the last bit, acceptance can move directly to the ready state containing the new label; rejection returns to the root. Hence a separate leaf or unbounded trial counter is unnecessary. There are at most

$(T + 1)m$  ready states,  $Tmd(2^b - 1)$  sampler states and two final states. Their sum is at most (22). The input provider waits at an explicit ready boundary; the phase is stored, not supplied as a free data-dependent clock.  $\square$

For (19) the distributions  $q_i$  have denominators dividing six, and for (20) they divide ten. Thus a row at acquisition stage  $t$  has denominator dividing  $6t$  or  $10t$ , respectively. The critical decoders are also rational. More generally the normalized matrix tensors in Proposition 5.3 have rational denominators bounded by products of fixed seed denominators; their logarithms are  $O(\log(n+1))$ . The finite-coin implementation of those families therefore uses  $O(\log(n+1))$  persistent bits, with explicit rational row data. This assertion concerns the critical polynomial-size matrix families, not efficient construction of a fixed-interior-signal exponential codebook.

## 7.2. Internal normalization of probabilistic automata.

**Definition 7.2** (Proper stochastic-language automaton). On a finite alphabet  $\Sigma$ , a proper probabilistic automaton consists of a finite state set, an initial probability row  $\alpha$ , nonnegative transition matrices  $T_a$  for  $a \in \Sigma$ , and stopping probabilities  $\tau_s$ , with

$$\tau_s + \sum_{a,t} T_a(s, t) = 1.$$

Stopping emits no further symbol; a transition emits its label  $a$ . Termination is almost sure from every reachable state. The generated stochastic language and state languages are

$$L(w) = \alpha T_w \tau, \quad L_s(w) = e_s^T T_w \tau.$$

They are probability distributions on finite words. Unreachable states are removed. The automaton is residual if every reachable state language is  $L_u(w) = L(uw)/L(u\Sigma^*)$  for some positive-mass prefix  $u$ .

These are the conventions used when comparing with probabilistic residual automata [3, 2]. If a nonnegative representation initially has state continuation masses  $h_s \in (0, \infty)$ , normalization replaces  $T_a(s, t)$  by  $T_a(s, t)h_t/h_s$ ,  $\tau_s$  by  $\tau_s/h_s$ , and  $\alpha_s$  by  $\alpha_s h_s$ . The identity  $h_s = \tau_s + \sum_{a,t} T_a(s, t)h_t$  gives stochastic rows. States with  $h_s = 0$  have no contribution to any generated word and are deleted. Thus finite nonzero continuation masses can be normalized without adding states. Infinite continuation mass is not a stochastic language and is not included in this convention.

For completeness, we retain the operational separation with a proof in these internal terms. It is a result of the preceding revision, not a new succinctness-priority assertion.

**Proposition 7.3** (A normalized residual/positive separation). *For  $n \geq 2$  and rational  $0 < \eta \leq (2n - 1)^{-1}$ , define the finite language*

$$(23) \quad L(u_{x_1} \cdots u_{x_n} q_j o_b) = \frac{2^{-n}}{n} \frac{1 + b\eta x_j}{2},$$

*using disjoint input, query and output symbols, and give zero mass to all other words. Every residual automaton has at least  $2^n$  states. A proper rational positive automaton has at most  $(n + 1)(n + 2)/2 + n(n + 1) + 1$  states, including phase and query storage.*

*Proof.* The query-phase residuals are the  $2^n$  vertices of an affine cube, with probabilities  $(1 + b\eta x_j)/(2n)$  on the two-symbol words  $q_j o_b$ . Conditioning any proper automaton on a supported prefix expresses that residual as a convex combination of normalized state languages. Nonnegativity forces each used language to be supported on those two-symbol words. A residual of (23) after length  $t$  is concentrated on length  $n + 2 - t$ . Hence a residual state used here must itself be one of the query-phase cube vertices. Extremality forces a separate state for each of the  $2^n$  vertices.

For the upper bound, generate the input bits independently and fairly. At phase  $t$  use labels  $0, 1, \dots, t$ . On the next input, retain the old label with probability  $t/(t+1)$ ; otherwise replace it by  $t+1$  for a positive bit and zero for a negative bit. After  $t$  inputs the probability of label  $i > 0$  is  $\mathbf{1}_{\{x_i=1\}}/t$  and the probability of zero is the fraction of negative bits. At phase  $n$ , associate means  $v_0 = -\eta \mathbf{1}$  and  $v_i = -\eta \mathbf{1} + 2n\eta e_i$ . They are in the cube when  $\eta \leq (2n-1)^{-1}$ , and their mixture has mean  $\eta x$ . Emit  $q_j$  uniformly, store  $(s, j)$ , emit  $o_b$  with mean  $v_{s,j}$ , and terminate. Phase tags require  $\sum_{t=0}^n (t+1)$  states, query buffers require  $n(n+1)$ , and one state terminates. Every state language is normalized and every row is rational. Multiplication of the three stages yields (23).  $\square$

## 8. CONSEQUENCES AND RETAINED RESULTS

The main distinction is now witnessed, rather than merely formulated. At full-support cut rank three, independent minimum positive factorizations need not fit one machine; the exact profile set (6) exhibits the cost of that incompatibility. At cut rank at most two, canonical affine sections always yield compatible minimum realizations. Additive encoders give a different structural class with no online alphabet penalty, regardless of the size or shape of the original residual hull.

For the binary-query problem, the minimal  $n+1$  checkpoint alphabet has an online realization whenever it exists. The critical geometric threshold is therefore shared by checkpoint and full acquisition peak, not only in Hadamard dimensions. The static absorption results are classical; the transition formulas transfer each of them to an actual online machine. At larger message alphabets a generic encoder need not be additive, and the present theorem does not identify every finite state count or the second-order streaming excess. No new complete varying-signal phase diagram is inferred.

The full-support two-cut experiment has a fixed order of three atomic inputs. It establishes a compatibility obstruction, not a theorem optimizing all informative experimental actions or all report-dependent collision-validation schedules. The earlier controlled minimax, marked-saddle, positive-noise collision, fixed-clock scheduling, revelation, entropy-rate and acquired-transport results remain in the unchanged supporting article and cumulative mathematical volumes. Their statistical experiments and resource conventions are not replaced by the binary-query interface. Known-target exact stochastic rows and acquired-target approximate guarantees remain distinct.

The repository's historical A2/A3/A4 and B2/B1/B3/B4/C1/C2/D1 derivations have independent Fourier, large-deviation, operator-domain, semigroup and optional-projection hypotheses. Preserving those derivations does not make them consequences of a finite positive-realization theorem. The new proof dependencies are internal and explicit: affine slices locate the rank boundary; the forced-triangle obstruction proves a nonattainable profile; additive synthesis transfers critical simplices to online memory; exactification identifies the correct classical checkpoint comparison. No historical analytic gate is marked complete on the strength of that transfer.

The primary literature comparison also has precise limits. We use the cube-absorption statements and explicit simplices of [7], and the full v3 worst-case coding characterization of [6]. Positive realization and residual-state representations are older frameworks [5, 10, 3, 2]; their general existence language is not claimed as an invention. The support/affine arguments here must be distinguished from arbitrary nonnegative-rank minimization [4], and complete arrays from incomplete machine specifications [9]. General filtered-experiment comparison [8] is not a priority claim of the paper. The exact quantifiers and explicit constructions, rather than the size of the preserved development, are the mathematical assertions submitted for independent examination.

# GENERAL THETA FOUNDATIONS I: POSITIVE REALIZATION AND EXACT STREAMING MEMORY

QIAN QI

**ABSTRACT.** We study the number of retained states needed to realize a specified finite causal experiment. A criterion for simultaneous attainment of the support-component rank is given by enclosing simplices and common positive shift equations. Unlike a residual-vertex criterion, it allows all internal continuations, including those outside the residual hull. For a binary-query channel on  $n$  acquired bits, we determine the exponential memory rate at every fixed signal strength  $0 < \eta < 1$ . The checkpoint, fixed-order streaming, and adaptive-acquisition minima all have rate  $1 - h_2((1 + \eta)/2)$ . The upper construction realizes every conditional probability exactly and has a fully charged sequential buffer; its excess logarithmic space is  $O_\eta(\sqrt{n \log n})$ . At row total-variation tolerance  $\varepsilon$ , the corresponding rate is obtained by replacing  $\eta$  by  $(\eta - 2\varepsilon)_+$ . We also construct an exact  $(t + 1)$ -state online encoder for  $\eta \leq (2n - 1)^{-1}$  and determine the sharp  $n + 1$ -state threshold  $\eta = 1/n$  whenever a Hadamard matrix of order  $n + 1$  exists. The entropy exponent is classical in random-access coding; the conclusions here concern exact conditional channel synthesis and the complete retained-state cost. The relation to residual probabilistic automata is made explicit by a finite language with exponentially many residual states and a polynomial-size positive realization.

## 1. INTRODUCTION

A finite statistical memory is a collection of possible continuations, not a collection of numerical coordinates. A low-dimensional space of predictions can require many positive generators. Conversely, insisting that every internal state be an observed residual can exclude much smaller stochastic realizations. There is a third constraint: positive factorizations at successive cuts must arise from the same causal machine. The distinctions between dimension, positivity, and compatibility are the subject of this paper.

We work with complete finite response arrays, known primitive probabilities, and an explicit list of charged cuts. Arbitrary stochastic rows are atomic operations. Every retained selector, observation buffer, and data-dependent protocol state is included in the register. The program and the declared clock are fixed before observations. These conventions distinguish an exact state-count theorem from a finite-random-bit implementation or an acquired calibration theorem.

**1.1. The realization question.** At a cut  $t$ , normalized residual continuations form a finite set  $\mathcal{R}_t$  in a causal polytope  $\mathcal{P}_t$ . Intersections of their minimal faces partition them into support components. If component  $j$  has affine dimension  $r_{t,j} - 1$ , every stochastic implementation needs at least  $s_t = \sum_j r_{t,j}$  states. Residual vertices attain this bound when each component hull is a simplex. That sufficient condition does not describe all rank-saturating realizations.

Theorem 2.3 gives a necessary and sufficient condition for attaining the whole profile  $s_t$ . Each component must admit an enclosing simplex with  $r_{t,j}$  normalized causal vertices in its affine slice. The vertices need not be residuals. Their one-step restrictions must satisfy common nonnegative

*Key words and phrases.* Causal realization, stochastic automata, nonnegative rank, random access codes, streaming memory, exact channel synthesis.

shift equations with the next cut's vertices. Thus the condition separates static enclosure from simultaneous causal realization. For explicit algebraic arrays it becomes a finite existential system over the real numbers. This is an exact equality criterion, not a polynomial-time algorithm for a succinct controller or a solution of autonomous shared-row minimization.

**1.2. The growing experiment.** An input  $x \in \{-1, 1\}^n$  is acquired one coordinate at a time. After all coordinates have been acquired, a query  $j \in [n]$  is supplied. The required binary response is

$$(1) \quad \mathbb{P}(B = b \mid x, j) = \frac{1 + b\eta x_j}{2}, \quad b \in \{-1, 1\}.$$

The signal  $\eta$  is specified, and the law is required for every input and query. Write  $K_n$  for the smallest state count at the query barrier,  $W_n^{\text{ad}}$  for the smallest whole-schedule peak with adaptive acquisition, and  $W_n^{\text{fo}}$  for the fixed-order peak. In the latter two quantities all persistent choices during acquisition are charged. They satisfy  $K_n \leq W_n^{\text{ad}} \leq W_n^{\text{fo}}$ .

Let  $h_2$  be binary entropy in bits and put

$$(2) \quad I(u) = 1 - h_2((1 + u)/2), \quad 0 \leq u \leq 1.$$

The main quantitative conclusion, Theorem 4.4, is

$$(3) \quad \lim_{n \rightarrow \infty} \frac{\log_2 K_n(\eta)}{n} = \lim_{n \rightarrow \infty} \frac{\log_2 W_n^{\text{ad}}(\eta)}{n} = \lim_{n \rightarrow \infty} \frac{\log_2 W_n^{\text{fo}}(\eta)}{n} = I(\eta) \quad (0 < \eta < 1).$$

The checkpoint upper error is  $O_\eta(\log n)$  bits. The streaming error is  $O_\eta(\sqrt{n \log n})$  bits. A fixed codebook is chosen in the existence proof, so there is no persistent public random seed hidden from the state count. For every rowwise total-variation tolerance  $\varepsilon$ , Theorem 5.1 gives the rate  $I((\eta - 2\varepsilon)_+)$ .

The exponent in (3) is not new as a random-access coding exponent. Ambainis, Nayak, Ta-Shma and Vazirani [1, 2] prove the matching first-order communication rate for success probability at least  $(1 + \eta)/2$ . We prove a version fixing *each* conditional response in (1), and then account for the largest retained register during a one-pass implementation. A success inequality by itself is not an exact conditional channel. Likewise, a short message by itself is not a space bound for computing that message from a stream. The proofs below keep both distinctions.

Finite-dimensional information is also obtained. An elementary online simplex construction gives the exact acquisition profile  $t + 1$  for  $0 < \eta \leq (2n - 1)^{-1}$ , improving the smaller signal regime of the preceding development. Any  $n + 1$ -state checkpoint factorization requires  $\eta \leq 1/n$ . If a Hadamard matrix of order  $n + 1$  exists, a different online encoder attains that entire interval with peak  $n + 1$  (Theorem 3.4). In particular, the threshold is sharp on the infinite sequence  $n = 2^k - 1$ . The latter construction has peak  $n + 1$ ; it is not claimed to have only  $t + 1$  states at every earlier cut.

### 1.3. One notation and resource convention.

| Symbol                                  | Meaning                                                                  |
|-----------------------------------------|--------------------------------------------------------------------------|
| $C, R_h, \mathcal{P}_t$                 | Complete causal law, normalized residual, and ambient causal polytope.   |
| $r_{t,j}, s_t$                          | Rank of support component $j$ , and their sum.                           |
| $B_{t,j,k}$                             | An internal normalized continuation, not necessarily a residual.         |

| $\eta, \varepsilon, I$                  | Specified signal, uniform row-TV tolerance, and entropy rate in bits.    |

State counts are cardinalities; their binary memory cost is the ceiling of their base-two logarithm. The query is an atomic current input and is answered without retaining an uncharged copy. Input-dependent scheduling information has to be retained. A terminal output can use two labels; this constant does not affect any rate. An externally scheduled overwrite may draw fresh independent randomness, but past randomness survives only through the retained label.

**1.4. Relationship with the preceding foundations development.** The causal-experiment, predictive-quotient, minimax-contact, and physical comparison results of the preceding development [10] are preserved in a separate complete mathematical companion. The present article proves its new claims without asking the reader to reconstruct a proof from that volume. Section 7 identifies the relations with positive realization, residual automata, and random-access coding. The old known-target physical memory theorems remain unchanged; neither a new fully adaptive collision theorem nor closure of the historical analytic pipeline is inferred from (3).

## 2. COHERENT POSITIVE REALIZATIONS AT THE RANK BOUND

**2.1. Finite causal arrays.** Fix a finite horizon and finite action and report alphabets. A complete causal array  $C(\mathbf{a} \mid \mathbf{y})$  is nonnegative and normalized, and its action-prefix marginal depends only on preceding reports. A terminal output is an action with a dummy subsequent report. All storage cuts required by the interface are included. In particular, an action which must be remembered while awaiting a report has a charged buffer cut; it is not available later as an uncharged input. Legal operation and buffer-copy requirements can be specified as zeros and mandatory readouts in the complete array. Elementary phases may be split to expose them. The results below concern the resulting fixed, clocked interface.

For a controller prefix  $h$  of positive conditional mass, let  $R_h$  be its normalized array of future actions, with future reports supplied externally. Let  $\mathcal{R}_t$  be all distinct such arrays at cut  $t$  and  $\mathcal{P}_t$  the polytope of normalized causal arrays on its remaining interface. Neither object is a runtime oracle. At zero-mass prefixes no residual is defined; the complete array still specifies which continuations have zero mass. Partial almost-sure specifications require a choice, or an optimization, of complete extensions and are a different input to the theorem.

For  $B \in \mathcal{P}_t$ , let  $p_B(a)$  be its next-action marginal, independent of the unread report. Let  $S_{a,y}B$  be the unnormalized restriction obtained by fixing that action and the next report. If  $p_B(a) > 0$ ,  $S_{a,y}B/p_B(a) \in \mathcal{P}_{t+1}$ ; at zero probability the restriction is zero. For an actual residual, each positive normalized restriction is again an actual residual. These maps are linear before normalization.

Write  $F_t(R)$  for the minimal face of  $\mathcal{P}_t$  containing  $R$ . Join two members of  $\mathcal{R}_t$  when their minimal faces intersect, and let  $\mathcal{R}_{t,j}$ ,  $1 \leq j \leq c_t$ , be the connected components. Define

$$(4) \quad r_{t,j} = 1 + \dim \text{aff } \mathcal{R}_{t,j}, \quad s_t = \sum_{j=1}^{c_t} r_{t,j}.$$

Normalization places each component in an affine hyperplane not through zero, so  $r_{t,j}$  is also its ordinary linear row rank.

**Lemma 2.1** (Separated-generator bound). *Every stochastic realization has at least  $s_t$  states at cut  $t$ . If it has exactly  $s_t$ , the states used by component  $j$  are precisely  $r_{t,j}$  affinely independent points of  $\mathcal{P}_t \cap \text{aff } \mathcal{R}_{t,j}$ .*

*Proof.* Starting the machine from a state  $s$  defines a normalized continuation  $B_s \in \mathcal{P}_t$ . Conditioning on a prefix gives

$$R_h = \sum_s E_h(s) B_s, \quad E_h(s) \geq 0, \quad \sum_s E_h(s) = 1.$$

Every positively used  $B_s$  belongs to  $F_t(R_h)$ , by the face property. Consequently the sets of states used by different support components are disjoint. The convex hull of the states used by component  $j$  contains  $\mathcal{R}_{t,j}$ , and hence has at least  $r_{t,j}$  generators. This proves the lower bound. Equality in the sum leaves exactly that many generators in each component and no additional used states. Containment of an affine space of dimension  $r_{t,j} - 1$  in their affine span forces independence and equality of the two affine spans. No residual-state restriction has been imposed.  $\square$

**Definition 2.2** (Coherent enclosing simplices). A coherent rank enclosure consists, at every cut and component, of  $r_{t,j}$  points  $B_{t,j,k} \in \mathcal{P}_t \cap \text{aff } \mathcal{R}_{t,j}$  whose convex hull contains  $\mathcal{R}_{t,j}$ , together with nonnegative numbers  $w_{t,j,k,a,y,u}$ , where  $u$  ranges over all vertices selected at the next cut, satisfying

$$(5) \quad S_{a,y} B_{t,j,k} = \sum_u w_{t,j,k,a,y,u} B_{t+1,u},$$

$$(6) \quad \sum_u w_{t,j,k,a,y,u} = p_{B_{t,j,k}}(a).$$

The initial array belongs to the initial selected hull. At the terminal cut there is the single empty continuation. Action-buffer phases obey the same equations on their explicitly split interface.

The enclosure points are automatically affinely independent: they contain a set of the full required affine dimension. In particular, “simplex” describes an enclosing object, not the residual hull.

**Theorem 2.3** (Rank saturation and causal compatibility). *For a complete finite clocked causal array, the following are equivalent:*

- (1) *A stochastic realization has profile  $K_t = s_t$  at every charged cut.*
- (2) *A coherent rank enclosure exists.*

*If every component residual hull is a simplex, its own vertices give such an enclosure. The equivalence itself places no simpliciality condition on the residual hulls.*

*Proof.* Suppose first that a rank-saturating machine exists. Delete unused states. Lemma 2.1 assigns its continuations to the indicated component affine slices and proves their independence and enclosure property. From a given state the actual next-action law is  $p_B$ . Conditional on action  $a$  and report  $y$ , the actual update probabilities  $q(u \mid B, a, y)$  are common to all histories

giving that state. Take  $w_u = p_B(a)q(u \mid B, a, y)$ . The law of the future program gives (5) and (6). Thus the equations hold for one simultaneous collection, including buffer cuts.

Conversely, use the selected vertices as state labels. Initialize by an enclosing convex decomposition of  $C$ . From state  $B$ , draw the next action according to  $p_B$ . When  $p_B(a) > 0$ , update after report  $y$  using  $w_u/p_B(a)$ . At zero  $p_B(a)$  the row is unused and can be assigned arbitrarily. Equation (6) makes each update stochastic, while  $p_B$  is independent of the unread report. Backward induction in (5) shows that the future array from state  $B$  is exactly  $B$ . The initialized law is therefore  $C$ . The number of labels is  $s_t$  at every cut.

For the final assertion, choose the vertices of each residual hull. They are actual residuals because the residual set is finite. Their positive normalized restrictions are residuals at the next cut and have convex decompositions in that cut's chosen vertices. Multiplying these decompositions by the action marginal supplies the required weights. This is the residual construction, now a special case of the equivalence.  $\square$

**Corollary 2.4** (Algebraic recognition). *For a fully listed rational or real-algebraic array, simultaneous attainment of  $s_t$  is decidable by a finite existential system of polynomial equalities and inequalities. A positive answer admits real-algebraic stochastic rows. Here algebraic input numbers are given by integer defining polynomials and isolating intervals.*

*Proof.* The finite residuals, component graphs, affine slices, and ranks are computed by exact linear algebra and linear feasibility. Write the unknown enclosure vertices in these affine slices and impose the linear causal-polytope constraints. Introduce convex coefficients for every residual enclosure, and weights for (5)–(6). All unknown products have degree at most two. Independence is forced by enclosure of the known full-dimensional component, so no extra determinant condition is needed. Real quantifier elimination, for example cylindrical algebraic decomposition [3, 4], decides this finite system. A nonempty semialgebraic set defined over the real algebraic numbers has a real algebraic point, which the same sample-point procedure supplies. The construction in the theorem then gives algebraic rows.  $\square$

This is not a complexity bound polynomial in the horizon or in a succinct program. Nor does it replace equalities identifying a stochastic row at different autonomous times. Those equalities are extra constraints. The theorem characterizes rank saturation, not arbitrary minimum positive rank. Its essential additional condition over a list of static enclosures is the common shift equation.

**2.2. What static rank does and does not measure.** Let  $A$  be a nonnegative row-stochastic matrix with one output alphabet. Let  $K(A)$  be the least number of normalized output rows whose convex hull contains its rows. Let  $K_{\text{aff}}(A)$  impose the additional condition that generators lie in the affine hull of the rows, and let  $K_{\text{res}}(A)$  require generators to be actual rows.

**Proposition 2.5** (The normalization boundary). *For this single-output model,*

$$(7) \quad \text{rank } A \leq \text{rank}_+ A = K(A) \leq K_{\text{aff}}(A) \leq K_{\text{res}}(A) = |\text{ext conv}\{A_i\}|.$$

*Writing  $r = \text{rank } A$ , equality  $K(A) = r$  holds if and only if an  $(r - 1)$ -simplex in the probability simplex contains every row and lies in their affine hull. For a family of queried output laws, the same convex characterization uses the product of the output simplices; ordinary nonnegative rank of the concatenated matrix is only a lower bound unless its factors satisfy all block-normalization equations.*

*Proof.* A stochastic encoder-decoder factorization is a nonnegative factorization. Conversely, if  $A = UV$  is nonnegative, discard zero rows of  $V$  and put  $d_s = \sum_y V_{sy} > 0$ . Then  $B_{sy} = V_{sy}/d_s$  is stochastic and  $E_{is} = U_{is}d_s$  has row sum one because  $A$  does. This proves  $\text{rank}_+ A = K(A)$ . The

remaining inequalities follow by restricting the generators. The extreme points of a finite hull are precisely the necessary actual-row generators, proving the last equality. If  $r$  generators enclose affine dimension  $r - 1$ , their affine hull must be the row affine hull and they are independent. This proves the simplex criterion and its converse.

With a query  $j$ , a physical state has a separate normalized decoder row for every  $j$ . Normalizing the total of a concatenated generator only fixes the sum over all blocks; it does not make every block sum one. The admissible ambient set is therefore the product of simplices, which proves the stated distinction.  $\square$

The single-output affine-slice restriction is the transpose-normalized form of restricted non-negative rank [7]. At one cut, positive generator complexity also decomposes additively over the support components: a generator cannot serve two components by the proof of Lemma 2.1, and independent component decompositions can be united. For one output alphabet these components are the disjoint support blocks of the matrix. This static additivity is not asserted to solve the compatibility problem between different cuts.

**Proposition 2.6** (A nonsimplicial equality and a strict inequality). *For the four binary-query mean rows  $(\pm a, \pm a)$ , ordinary normalized row rank is three. If  $0 < a \leq 1/3$ , their positive generator number is three although their residual hull is a square. If  $1/2 < a < 1$ , their positive generator number is four although all conditional probabilities are strictly positive.*

*Proof.* The rank assertion follows from affine dimension two. The triangle with vertices  $(-a, -a), (3a, -a), (-a, 3a)$  lies in the outer square when  $a \leq 1/3$  and contains the inner square; its defining inequalities are  $z_i \geq -a$  and  $z_1 + z_2 \leq 2a$ . This proves the first assertion. For the second, put  $d_x(z) = \frac{1}{2} \sum_{i=1}^2 (1 - x_i z_i)$  for  $x \in \{-1, 1\}^2$ . A convex representation of  $ax$  uses a generator with  $d_x(z) < 1/2$ , because its average is  $1 - a < 1/2$ . Such strict caps are disjoint for distinct  $x$ : a differing coordinate contributes one to  $d_x + d_{x'}$ . Four distinct generators are required, and the four rows themselves suffice. This proves a full-support rank gap without assuming residual-state realizations.  $\square$

### 3. EXACT FINITE STREAMING AT THE RANK THRESHOLD

**3.1. Checkpoint and streaming models.** For  $n \geq 1$  and  $0 \leq \eta \leq 1$ , the channel to be synthesized is (1). Every input coordinate is acquired exactly once before the query. In a fixed-order encoder the order is  $1, \dots, n$ . In an adaptive encoder the next unread coordinate can depend on the retained state and fresh randomness; any information required to make that choice legal must be retained. There is no readable transcript or unrecorded schedule. After acquisition, all input-dependent information passes through a single finite state before the external query arrives. One query is answered; a joint law for simultaneous answers to all queries is not required.

The checkpoint minimum  $K_n(\eta)$  imposes no bound on upstream memory. The quantities  $W_n^{\text{fo}}(\eta)$  and  $W_n^{\text{ad}}(\eta)$  impose a bound on every cut, including intermediate compression and retained random selectors. The clock in the fixed-order convention is prescribed externally. A terminal binary label counts as at most two states. The query is a current atomic input; a model requiring its storage has to charge that storage separately.

**Lemma 3.1** (Cube enclosure). *For  $\eta > 0$ ,  $K_n(\eta)$  is the smallest number of points  $z_s \in [-1, 1]^n$  whose convex hull contains  $[-\eta, \eta]^n$ . In particular  $K_n(\eta) \geq n + 1$ . This lower bound and every lower bound obtained from such an enclosure also apply to adaptive acquisition.*

*Proof.* From state  $s$ , let  $z_{s,j}$  be the mean binary output under query  $j$ . Conditioning on the complete input gives an encoder distribution  $E_x$  and hence

$$(8) \quad \eta x = \sum_s E_x(s) z_s.$$

Conversely, such a representation followed by a binary decoder with mean  $z_{s,j}$  realizes the prescribed channel. Upstream memory is unrestricted for this converse construction. Convexity reduces enclosure of the inner cube to its corners. Its affine dimension gives  $n + 1$ . For adaptive acquisition, conditioning on the complete input still gives one distribution of the retained state; the subsequent decoder is common to all inputs. This uses the acquisition barrier, not an assertion about arbitrary interactive scheduling.  $\square$

### 3.2. An online simplex with a linear signal window.

**Theorem 3.2** (An exact minimal acquisition profile). *For every  $n \geq 1$  and  $0 < \eta \leq (2n - 1)^{-1}$ ,*

$$(9) \quad K_n(\eta) = W_n^{\text{ad}}(\eta) = W_n^{\text{fo}}(\eta) = n + 1.$$

*One fixed-order encoder has exactly  $t + 1$  states after  $t$  acquired bits,  $0 \leq t \leq n$ , and this profile is minimal at each acquisition cut for that order. Its stochastic acquisition rows are rational and independent of  $\eta$ .*

*Proof.* For  $t \geq 1$  use labels  $0, 1, \dots, t$  with associated vectors

$$(10) \quad v_{t,0} = -\eta \mathbf{1}, \quad v_{t,i} = -\eta \mathbf{1} + 2t\eta e_i \quad (1 \leq i \leq t).$$

Their convex hull is

$$P_t = \{z \in \mathbb{R}^t : z_i \geq -\eta, \sum_i z_i \leq t\eta\}.$$

Every vertex lies in the outer cube because  $(2t - 1)\eta \leq 1$ . Moreover  $P_t \times \{-\eta, \eta\} \subset P_{t+1}$ . The barycentric coordinates of  $w \in P_t$  are

$$\lambda_i(w) = \frac{w_i + \eta}{2t\eta}, \quad \lambda_0(w) = \frac{t\eta - \sum_i w_i}{2t\eta}.$$

They are nonnegative and sum to one.

Here is an explicit update avoiding any stored real vector. After  $t$  inputs, the state distribution is

$$(11) \quad \mathbb{P}(S_t = i \mid x_{1:t}) = \frac{\mathbf{1}_{\{x_i=1\}}}{t}, \quad \mathbb{P}(S_t = 0 \mid x_{1:t}) = \frac{|\{i \leq t : x_i = -1\}|}{t}.$$

To acquire bit  $x_{t+1}$ , keep the old label with probability  $t/(t + 1)$ . With probability  $1/(t + 1)$  replace it by  $t + 1$  when  $x_{t+1} = 1$  and by zero when  $x_{t+1} = -1$ . For  $t = 0$  only the replacement is used. Induction proves (11). The mean of  $v_{t,S_t}$  is exactly  $\eta x_{1:t}$ . At the query barrier use the binary decoder with mean  $v_{n,S_n,j}$ . This proves exact synthesis. Only the label survives an update. The last raw bit and the replacement coin do not persist in an auxiliary register.

The final lower bound follows from Lemma 3.1. At an earlier fixed-order cut, fix the unread bits identically for all prefixes. The future response vectors for queries among the first  $t$  coordinates contain the  $t$ -dimensional cube of means  $\eta x_{1:t}$ . Factoring these continuations through the current state requires at least  $t + 1$  labels. Thus the entire acquisition profile is minimal. The final binary output uses no more labels than the peak  $n + 1$ .  $\square$

For  $t \geq 2$  the actual prefix residuals have a cube, not a simplex, as their hull. Equations (10) and (11) are therefore a growing nonsimplicial family of coherent rank enclosures. Theorem 2.3 applies without requiring that an internal vertex be a residual.

### 3.3. The sharp $n + 1$ -state boundary in Hadamard dimensions.

**Lemma 3.3** (A simplex obstruction). *If  $K_n(\eta) = n + 1$  with  $\eta > 0$ , then  $\eta \leq 1/n$ .*

*Proof.* The enclosing vertices  $v_0, \dots, v_n \in [-1, 1]^n$  are affinely independent. Write their barycentric affine functions as  $\lambda_s(z) = a_s + b_s \cdot z$ . Nonnegativity on the inner cube gives  $a_s \geq \eta \|b_s\|_1$ , and  $\sum_s a_s = 1$ . The identity  $z = \sum_s \lambda_s(z) v_s$  gives  $\sum_s v_s b_s^T = I_n$ . Taking its trace yields

$$n = \sum_s b_s \cdot v_s \leq \sum_s \|b_s\|_1 \leq \eta^{-1}.$$

This proves the assertion for arbitrary enclosing vertices, not just a chosen simplex construction.  $\square$

**Theorem 3.4** (A sharp threshold with an online realization). *Suppose that a Hadamard matrix of order  $m = n + 1$  exists. For  $\eta > 0$ ,*

$$(12) \quad K_n(\eta) = W_n^{\text{ad}}(\eta) = W_n^{\text{fo}}(\eta) = n + 1 \iff \eta \leq 1/n.$$

*This applies in particular to every  $n = 2^k - 1$ ,  $k \geq 1$ . More generally, a Hadamard matrix of order  $m \geq n + 1$  gives an  $m$ -state streaming realization whenever  $0 < \eta \leq 1/n$ .*

*Proof.* Normalize the first column of the Hadamard matrix to one, and select  $n$  other columns. Let  $v_s \in \{-1, 1\}^n$ ,  $1 \leq s \leq m$ , be their rows. Orthogonality gives

$$(13) \quad \frac{1}{m} \sum_s v_{s,j} = 0, \quad \frac{1}{m} \sum_s v_{s,i} v_{s,j} = \mathbf{1}_{\{i=j\}}.$$

For each index  $i$  and observed bit  $x_i$ , define the probability law

$$q_{i,x_i}(s) = \frac{1 + x_i v_{s,i}}{m}.$$

Its mean vector is  $x_i e_i$  by (13). At step  $i$ , retain the preceding state with probability  $(i - 1)/i$ ; otherwise redraw a label from  $q_{i,x_i}$ . The first step always draws. After  $t$  bits its state law is  $t^{-1} \sum_{i \leq t} q_{i,x_i}$ . Consequently  $\mathbb{E}[v_{S_n} | x] = x/n$ . The final decoder with mean  $n\eta v_{S_n,j}$  is legal for  $\eta \leq 1/n$  and gives mean  $\eta x_j$ . This is an online machine with  $m$  labels; the chosen index of a redraw is not separately retained. All acquisition probabilities are rational.

For  $m = n + 1$ , Lemma 3.1 proves optimality and Lemma 3.3 excludes larger signals. The Sylvester construction  $H_1 = (1)$  and  $H_{2m} = \begin{pmatrix} H_m & H_m \\ H_m & -H_m \end{pmatrix}$  gives the claimed infinite sequence directly.  $\square$

The equality in (12) concerns the peak, not every intermediate width. The encoder in this proof may have  $n + 1$  possible labels already after its first bit. In contrast, Theorem 3.2 attains the individual  $t + 1$  bounds in its smaller signal interval. Choosing the next power of two for  $m$  also gives a less than  $2(n + 1)$ -state upper bound at  $\eta \leq 1/n$  for arbitrary  $n$ ; it does not decide the exact simplex threshold in every dimension.

## 4. EXACT SYNTHESIS THROUGHOUT THE FIXED-SIGNAL RANGE

All logarithms in rates are base two. Natural logarithms are denoted by  $\ln$ . Define  $I$  by (2); thus  $I(0) = 0$ ,  $I(1) = 1$ , and  $I$  is increasing on  $[0, 1]$ .

#### 4.1. A uniform corner-cap lower bound.

**Lemma 4.1** (Entropy cap). *For  $z \in [-1, 1]^n$  and  $0 \leq u \leq 1$ , the fraction of sign vectors  $x$  with  $x \cdot z \geq nu$  is at most  $2^{-nI(u)}$ . Therefore*

$$(14) \quad K_n(\eta) \geq 2^{nI(\eta)}.$$

*Proof.* For a uniform sign vector  $X$  and  $t \geq 0$ ,

$$\mathbb{E} e^{tX \cdot z} = \prod_{i=1}^n \cosh(tz_i) \leq \cosh(t)^n.$$

Exponential Markov inequality gives the bound  $\exp\{-n \sup_{t \geq 0} (tu - \ln \cosh t)\}$ . For  $0 < u < 1$  the maximum occurs at  $t = \operatorname{arctanh} u$ . Substitution gives  $\sup (tu - \ln \cosh t) = (\ln 2)I(u)$ . The two endpoints follow by limits. If a set of generators encloses  $\eta x$ , then some generator  $z_s$  has  $x \cdot z_s \geq n\eta$ . These caps therefore cover all  $2^n$  sign vectors. The fraction bound and the union bound imply (14).  $\square$

The exponent in this lemma is the classical random-access lower exponent [1, Theorem 2.1]. Its cap proof is useful here because it applies directly to exact and perturbed conditional means.

**4.2. An enclosing codebook with exact, not one-sided, responses.** For  $0 < \eta < 1$  and  $0 < \delta \leq (1 - \eta)/2$ , put

$$(15) \quad k = \left\lceil \frac{n(1 + \eta + 2\delta)}{2} \right\rceil, \quad r = \frac{2k}{n} - 1,$$

$$(16) \quad M(n, \eta, \delta) = \left\lceil \frac{n+1}{\delta} \{n \ln(1 + 2/\delta) + 1\} 2^{nI(r)} \right\rceil.$$

Here  $k \leq n$  and  $\eta + 2\delta \leq r \leq \eta + 2\delta + 2/n$ .

**Lemma 4.2** (A Hamming-layer enclosure). *There is a set of at most  $M(n, \eta, \delta)$  sign vertices whose convex hull contains  $[-\eta, \eta]^n$ . In particular,*

$$(17) \quad K_n(\eta) \leq \min\{2^n, M(n, \eta, \delta)\}.$$

*For every fixed  $0 < \eta < 1$  there is a constant  $C_\eta$  such that*

$$(18) \quad nI(\eta) \leq \log_2 K_n(\eta) \leq nI(\eta) + C_\eta \log_2(n+1) \quad (n \geq 1).$$

*Proof.* Fix  $a \in \mathbb{R}^n$  with  $\|a\|_1 = 1$ . Orient each coordinate by the sign of  $a_i$ , choosing either orientation at zeros. Condition a uniform sign vertex  $V$  on having exactly  $k$  coordinates aligned with these orientations. Under this conditional law  $Z = a \cdot V \leq 1$  and  $\mathbb{E}Z = r$ . If  $p = \mathbb{P}(Z \geq \eta + \delta \mid k)$ , then

$$r \leq p + (1 - p)(\eta + \delta), \quad p \geq \frac{r - \eta - \delta}{1 - \eta - \delta} \geq \delta.$$

It follows that, for an unconditional uniform sign vertex,

$$(19) \quad \mathbb{P}(a \cdot V \geq \eta + \delta) \geq \delta \binom{n}{k} 2^{-n} \geq \frac{\delta}{n+1} 2^{-nI(r)} =: q.$$

For the second inequality,  $k$  is a mode of a binomial distribution with success probability  $k/n$ , so its probability is at least  $1/(n+1)$ . Rewriting that probability gives  $\binom{n}{k} \geq 2^{nh_2(k/n)}/(n+1)$ . The endpoints  $k = 0, n$  have the same interpretation by continuity.

Choose a  $\delta$ -net of the  $\ell^1$  unit sphere of size at most  $(1 + 2/\delta)^n$ . Such a net follows by taking a maximal separated set and comparing the volumes of disjoint  $\ell^1$  balls of radius  $\delta/2$  with the ball of radius  $1 + \delta/2$ . Draw  $M = M(n, \eta, \delta)$  independent uniform sign vertices. For any net

direction the probability that none has scalar product at least  $\eta + \delta$  is at most  $e^{-Mq}$ . The probability that some net direction fails is at most  $(1 + 2/\delta)^n e^{-Mq} \leq e^{-1} < 1$ . Hence a fixed choice of vertices succeeds on every net direction. Their support function is one-Lipschitz in the  $\ell^1$  norm, so it is at least  $\eta$  on the entire unit sphere. Homogeneity and convex separation imply that their hull contains the inner cube. Repeated vertices can be discarded. Full retention gives the other upper bound.

For fixed  $\eta$ , take  $\delta = 1/n$  once  $n \geq 2/(1 - \eta)$ . Then  $r \leq \eta + 4/n$ , and the derivative  $I'(u) = \frac{1}{2} \log_2((1+u)/(1-u))$  is bounded on a fixed neighborhood of  $\eta$  lying below one. Thus  $nI(r) \leq nI(\eta) + O_\eta(1)$  for sufficiently large  $n$ . The remaining factor in (16) is polynomial up to a logarithm and contributes  $O(\log(n+1))$  bits. Enlarging  $C_\eta$  handles the finitely many smaller  $n$ . Combine this with Lemma 4.1.  $\square$

The hull containment gives a convex representation of *each*  $\eta x$ , and hence exactly the means in (1). It does not merely ensure that a coordinate is correct with probability at least  $(1 + \eta)/2$ . Once a successful vertex set has been chosen, all its probabilities are fixed in the program. No random choice of a codebook survives at runtime. For rational  $\eta$ , the enclosure linear systems admit rational encoder coefficients; for algebraic  $\eta$  they admit coefficients in the corresponding ordered field. The proof is an existence and finite-synthesis result, not a claim of fast codebook construction.

#### 4.3. From a terminal codebook to a one-pass machine.

**Lemma 4.3** (Charged block realization). *Suppose the  $\ell$ -coordinate channel at signal  $\eta$  has a checkpoint codebook with  $M$  generators. Then, for  $1 \leq \ell \leq n$ ,*

$$(20) \quad W_n^{\text{fo}}(\eta) \leq \max\{2, 2^\ell M^{\lfloor n/\ell \rfloor}\}.$$

*All conditional output probabilities are realized exactly.*

*Proof.* Split the fixed input order into  $b = \lfloor n/\ell \rfloor$  full blocks and a final remainder of length less than  $\ell$ . While acquiring a block, retain the previously chosen block labels and its current raw prefix. Upon completing a block, draw one label using that block's exact encoder, overwrite its raw buffer, and retain only the new label with the previous labels. The encoder table is a fixed row of the declared program. A remainder is retained raw.

At a cut the state is a tuple of at most  $b$  codebook labels and at most  $\ell$  raw bits. During the overwrite the old buffer is replaced atomically, not retained alongside a new private selector. Thus the number of possible labels is bounded as in (20). The compression epochs are prescribed clock phases; they do not depend on observations.

For a query in a complete block, use the corresponding label's decoder coordinate. Its conditional mean is  $\eta x_j$  independently of the other labels. For a query in the remainder, draw a binary response of mean  $\eta x_j$  from the retained bit. At most two terminal labels are required. The label sampling uses fresh randomness, and all its persistent effect is in the tuple. No unread bit, chosen codebook, or previous random seed is a free register.  $\square$

**Theorem 4.4** (Exact fixed-signal streaming rate). *For every fixed  $0 < \eta < 1$ , there exists  $C'_\eta < \infty$  such that*

$$(21) \quad nI(\eta) \leq \log_2 K_n(\eta) \leq \log_2 W_n^{\text{ad}}(\eta) \leq \log_2 W_n^{\text{fo}}(\eta),$$

$$(22) \quad \log_2 W_n^{\text{fo}}(\eta) \leq nI(\eta) + C'_\eta \sqrt{n \log_2(n+1)}.$$

*Consequently all three normalized logarithmic complexities converge to  $I(\eta)$ , as in (3). The checkpoint has the stronger error bound (18).*

*Proof.* The lower bounds have already been proved and survive adaptive acquisition. For sufficiently large  $n$ , choose  $\ell = \lceil \sqrt{n \log_2(n+1)} \rceil \leq n$ . Lemma 4.2 supplies a block codebook with  $\log_2 M \leq \ell I(\eta) + C_\eta \log_2(\ell + 1)$ . Lemma 4.3 gives, after increasing an absolute constant,

$$\log_2 W_n^{\text{fo}} \leq \ell + \frac{n}{\ell} \{ \ell I(\eta) + C_\eta \log_2(\ell + 1) \} \leq n I(\eta) + O_\eta(\sqrt{n \log(n+1)}).$$

Again the finitely many smaller  $n$  are absorbed into  $C'_\eta$ . Division by  $n$  proves the limits.  $\square$

This theorem covers every fixed interior signal, rather than just two endpoint windows. It does not determine every finite integer value of  $K_n$  or  $W_n$ , their lower-order difference, or a uniform sharp law when  $\eta$  varies with  $n$ . Equations (16) and (20) remain explicit nonasymptotic bounds in those varying-signal problems. In the strong finite regime  $\eta > 1 - 1/n$ , the disjoint-cap argument gives  $K_n = W_n^{\text{ad}} = W_n^{\text{fo}} = 2^n$ : the encoder average of  $\frac{1}{2} \sum_i (1 - x_i z_i)$  is below  $1/2$ , and its strict caps for distinct input corners are disjoint. Full retention matches this bound. That sharper endpoint statement is consistent with, but not needed for, Theorem 4.4.

## 5. UNIFORMLY APPROXIMATE EXPERIMENTS AND THEIR EXACT RATE

For two binary-output channels on the same input/query set, define

$$d_{\text{row}}(P, \tilde{P}) = \max_{x,j} \text{TV}(P(\cdot | x, j), \tilde{P}(\cdot | x, j)).$$

For  $\varepsilon \geq 0$ , this is a uniform comparison of experiments, not an error averaged over a selected input prior. Let  $K_n^\varepsilon(\eta)$ ,  $W_n^{\text{ad},\varepsilon}(\eta)$  and  $W_n^{\text{fo},\varepsilon}(\eta)$  denote the corresponding minima allowing  $d_{\text{row}} \leq \varepsilon$ . Put  $\kappa = (\eta - 2\varepsilon)_+$ .

**Theorem 5.1** (A sharp row-error memory rate). *If  $0 < \kappa < 1$ , then*

$$(23) \quad 2^{nI(\kappa)} \leq K_n^\varepsilon(\eta) \leq K_n(\kappa), \quad W_n^{\text{fo},\varepsilon}(\eta) \leq W_n^{\text{fo}}(\kappa).$$

*In particular, for fixed  $\eta \in (0, 1]$  and fixed  $0 \leq \varepsilon < \eta/2$  with  $\kappa < 1$ , all three normalized logarithmic approximate complexities converge to  $I(\kappa)$ . For  $\varepsilon \geq \eta/2$ , one query state and at most two terminal states suffice, so the rate is zero. At  $(\eta, \varepsilon) = (1, 0)$  the exact state counts equal  $2^n$ .*

*Proof.* Let  $m_j(x)$  be the mean output of an admissible approximate channel. Binary total variation is half the absolute difference of means; hence  $|m_j(x) - \eta x_j| \leq 2\varepsilon$ . Factoring the approximate channel through states gives  $m(x) = \sum_s E_x(s) z_s$ , with  $z_s \in [-1, 1]^n$ . Therefore

$$x \cdot m(x) \geq n(\eta - 2\varepsilon) = n\kappa$$

when  $\kappa > 0$ . Some used generator has  $x \cdot z_s \geq n\kappa$ . The caps in Lemma 4.1 cover the input corners, giving the lower bound, also for adaptive acquisition.

Conversely, exactly synthesize the channel with mean  $\kappa x_j$ . Its distance from the required one is  $(\eta - \kappa)/2 = \varepsilon$ . This proves the upper bounds and allows Theorem 4.4 to be applied at the fixed signal  $\kappa$ . If  $\kappa = 0$ , the fair-output channel is independent of input and query and has row defect  $\eta/2$ . It needs one state before output. Finally, an exact noiseless response to every query determines every input bit through the stored generator; the cap argument at  $u = 1$ , or disjoint supports, gives  $2^n$  states, matched by retention.  $\square$

**5.1. A statistical consumer: reusable binary sensors.** Consider a parameter  $x \in \{-1, 1\}^n$  and a preparation interface that reveals its coordinates during acquisition. A later single coordinate measurement has conditional mean  $\eta x_j$ . A simulator must be installed before the measurement index is chosen. Theorem 4.4 is an exact state-cost theorem for this simulator, not a theorem about a prior chosen to fit a codebook. Theorem 5.1 gives its uniform error-memory exponent, with the same lower bound against adaptive acquisition.

**Corollary 5.2** (Comparison under downstream experiments). *A simulator with row defect  $\varepsilon$  changes the expectation of any common  $[0, 1]$ -valued decision loss, after one queried report and arbitrary parameter-independent postprocessing, by at most  $\varepsilon$ , uniformly in  $x$  and in a randomized query distribution independent of the simulator's hidden state. If a sequence of fresh installations has conditional row defect at most  $\varepsilon$  at each round and is coupled to the same downstream history-dependent controller, the  $T$ -round path-law defect is at most  $\min(1, T\varepsilon)$ .*

*Proof.* At one round, mixture over the common query and contraction under postprocessing do not increase total variation; bounded losses then have expectation difference at most  $\varepsilon$ . For repeated installations, couple the two executions only while their public histories agree. The downstream action laws then agree and the chance of a first discrepant report in each active round is at most  $\varepsilon$ . A union bound proves the path statement. The conditional hypothesis is essential; it is ensured, for example, by fresh independent reinstallation and fresh sampling randomness at every round.  $\square$

A single compressed label need not support a sequence of independent queries with the product output law. Observing an answer may change the conditional distribution of that label. Thus repeated use of the same unrefreshed code is not justified by the one-query theorem. If all  $n$  noisy answers are required jointly and independently, the specified product channel has full matrix rank  $2^n$  for every  $\eta > 0$ , and needs at least  $2^n$  query-barrier states. Indeed its transition matrix is the  $n$ -fold Kronecker power of the invertible binary symmetric channel. The distinction between a later chosen measurement and a joint vector of measurements is operational, not a change of notation.

The transport argument in the corollary is classical total-variation contraction and coupling. Its quantitative memory input is the new exact-synthesis law. It is a local statistical consumer, not a claim that a Fourier, large-deviation, or nonlinear-semigroup theorem in a different part of the foundations program has been proved by finite channel synthesis.

## 6. RESIDUAL AUTOMATA AND ARBITRARY POSITIVE STATES

For a stochastic language  $L$  on finite words and a prefix  $u$  with  $L(u\Sigma^*) > 0$ , its normalized residual is  $L_u(v) = L(uv)/L(u\Sigma^*)$ . A residual probabilistic automaton requires every state's generated language to be one of these residuals. An arbitrary probabilistic automaton need not satisfy that restriction. The distinction is explicit in the probabilistic residual line initiated by Esposito, Lemay, Denis and Dupont [6], and in [5, Section 2 and Propositions 16, 19]. Canonical minimality within a residual representation class is consequently not a minimum over all positive generators.

The following construction makes the distinction within the precise streaming family, without appealing to a conjectured difference between models. It concerns the total number of states of a generative automaton; its clock is explicitly incorporated in the states.

**Theorem 6.1** (A finite-language separation). *Fix  $n \geq 2$  and rational  $0 < \eta \leq (2n - 1)^{-1}$ . There is a finite stochastic language  $L_{n,\eta}$  such that every residual probabilistic automaton generating it has at least  $2^n$  states, whereas an unrestricted rational probabilistic automaton has at most*

$$(24) \quad \frac{(n+1)(n+2)}{2} + n(n+1) + 1$$

*states. The lower bound holds already for the states used immediately before the query symbol.*

*Proof.* Use distinct symbols  $u_-, u_+$  for acquired bits,  $q_j$  for queries, and  $o_-, o_+$  for answers. Give mass

$$(25) \quad L_{n,\eta}(u_{x_1} \cdots u_{x_n} q_j o_b) = \frac{2^{-n}}{n} \frac{1 + b\eta x_j}{2}$$

to those words and zero to every other word. The masses sum to one. After a length- $n$  supported prefix, the residual has probabilities  $(1 + b\eta x_j)/(2n)$  on  $q_j o_b$ . These  $2^n$  residuals are an injective affine image of the corners of an  $n$ -cube. In particular, every one is an extreme point of their convex hull.

In a probabilistic realization, condition on such a prefix. The residual is a convex combination of the state languages then occupied. Since it is supported on words of length two of the displayed query-answer form, nonnegativity forces every positively used state language to have that same support restriction. In a residual automaton that state language must itself be a residual of  $L_{n,\eta}$ . A residual after a supported prefix of length  $t$  is concentrated on length  $n + 2 - t$ ; hence a residual concentrated on length two must come from  $t = n$ . There are no other supported prefix types at that length. Therefore the used state languages belong to the  $2^n$  cube-corner residuals above. Extremality forces each corner to occur as a state language. They are distinct, proving the lower bound.

For the upper bound, generate the  $u$ -symbols as independent fair bits. Simultaneously run the encoder of Theorem 3.2; a transition labelled  $u_x$  and updating to  $s'$  has probability  $\frac{1}{2}T_{t,x}(s, s')$ . Include the phase  $t$  in the state. The acquisition phases  $t = 0, \dots, n$  have a total of  $\sum_{t=0}^n (t+1) = (n+1)(n+2)/2$  states. At phase  $n$ , emit  $q_j$  uniformly and enter a state retaining  $(s, j)$ ; there are at most  $n(n+1)$  such states. Emit  $o_b$  with the exact decoder probability and enter one common terminating state. Every transition and terminal probability is nonnegative rational, and the generated language is (25). This proves (24) with its clock and query buffer included.  $\square$

The theorem does not assert that exponential succinctness differences between probabilistic models are new. Its role is to identify a concrete instance in which a residual-only minimum cannot be substituted for the all-machine minimum in this paper. In the present example the latter has a genuinely online positive realization. The state languages of that realization generally lie outside the residual hull.

One can equivalently treat the query as an external input, recovering the checkpoint and streaming models of Section 3. Turning it instead into a generated symbol in (25) is what permits a direct comparison with stochastic-language automata. The factor  $1/n$  is essential: it normalizes the query choice rather than appending an unnormalized family of conditional laws.

## 7. THEOREM BOUNDARIES AND FURTHER QUESTIONS

**7.1. What is inherited from realization theory.** The probabilistic residual finite-state automata paper of Esposito-Lemay-Denis-Dupont [6] is an essential predecessor, not a peripheral citation. Its announced characterization uses finite generation by residual stochastic languages and canonical minimal forms. The later full treatment [5, Propositions 16, 19] provides a unique inclusion-minimal residual generating set and the finite-generation characterization by residual probabilistic automata. The relevant restriction is on the state languages. Our explicit comparison in Theorem 6.1 uses that restriction rather than inferring an all-machine minimum from the word “canonical.” The publisher record and abstract of [6], and the full cited sections of [5], are the bases of this comparison; we do not claim a completed line-by-line audit of the 2002 chapter.

Positive stochastic realization, including stable polyhedral sets of continuations, is classical [8, 12]. The stationary HMM existence question in [12] is not the same input as a fully listed finite controlled array. Nevertheless the principle that positive generators must be closed under appropriate shifts is shared. Theorem 2.3 should therefore not be read as an invention of positive realization. It makes rank saturation, affine-slice enclosure, and the simultaneous finite shift constraints explicit. Its use here is the non-residual streaming construction, the sharp

Hadamard-dimensional peak threshold, and the charged exact-synthesis bounds, not an assertion that a finite normal form alone settles the general realization problem.

Gillis–Glineur [7, Definition 1 and Theorem 1] distinguish restricted nonnegative rank from unrestricted nonnegative rank and relate the former to nested polytopes. Proposition 2.5 is the normalized single-output specialization, with the transpose convention made explicit. A queried law has block-normalization constraints, and coherent realization has constraints between cuts; these must not be removed when applying a static matrix theorem.

Compatible coverings for incompletely specified sequential machines [11] concern a different form of missing information. Our array theorem uses complete laws and allows support zeros in those laws; it does not choose a canonical completion of a partial law. Filtered-experiment comparison [9] is an adjacent comparison framework, not a result replaced by the constructions here. No general non-overlap assertion about that framework is made. The precise remaining source-access limits are recorded with the revision response.

**7.2. What is inherited from random-access coding.** The classical lower and upper communication rates in [1, Theorems 2.1 and 2.2] are  $(1 - h_2(p))n$  and  $(1 - h_2(p))n + O(\log n)$  for recovery success at least  $p$ . Their upper construction uses a finite family of masks and permutations to make the guarantee hold for every input and coordinate. Thus the entropy function and the polynomial-overhead communication scale are classical; neither is claimed as a new discovery here.

Our exact-channel proof uses a support-function enclosure of the entire inner cube. It supplies exact prescribed conditional probabilities, not only a success inequality. The block construction then prices all retained raw data and selected codewords. The limiting exponent remains the classical one, but the operational conclusion is about exact channel synthesis at every row and the peak of the whole streaming schedule. The proof of Theorem 5.1 shows precisely how a uniform row-error tolerance changes that exponent. It does not claim a result for arbitrary sequentially repeated queries on one installation.

**7.3. Precision and implementation.** Atomic stochastic rows can contain a specified real parameter. A rational row can be sampled exactly by a variable-length fair-bit procedure, but that statement alone does not give a bounded-time or bounded-workspace sampler. The present state counts concern atomic rows. The finite codebooks and rows may be enormous as program objects; program description length and computational time are not included in  $K_n$  or  $W_n$ . This is the same distinction as in the preceding known-target physical statements. Acquiring an unknown target and approximating its stochastic row requires calibration data, retained counters, and precision-dependent workspace. Those results are retained with their original costs in the mathematical companion [10].

**7.4. Conclusions.** The proved exact class is now described by the coherent-enclosure criterion, which is necessary and sufficient for the support-component rank profile to be attained. Residual-hull simpliciality is one sufficient subcase. The growing query family has nonsimplicial residual hulls, an explicit minimal acquisition profile in a linear signal window, and a sharp  $n + 1$ -state threshold in Hadamard dimensions.

Unrestricted positive-state minimization, autonomous row sharing, and joint optimization over all controlled policies remain different problems. We have not supplied an example in which every static cut attains its rank bound but no simultaneous rank profile exists; the criterion states the exact compatibility test rather than claiming such a separation without proof. The historical geometric and unbounded-operator obligations of the larger program are likewise not consequences of a finite-state coding theorem.

The former fixed-interior-signal gap in the query family is resolved at the level of its exponential rate, both exactly and at a fixed uniform row-error tolerance. Finite-size checkpoint versus streaming gaps, optimal lower-order terms, the sharp simplex threshold in all dimensions, and critical regimes with signal varying with  $n$  are not identified by these limits. The explicit enclosure and block bounds provide quantitative statements in those regimes without replacing them by an unsupported exact phase diagram.

# GENERAL THETA FOUNDATIONS I: INTRINSIC CONTINUATION GEOMETRY AND CAUSAL MEMORY

QIAN QI

**ABSTRACT.** We study the number of persistent states needed to realize a causal statistical response. For a complete finite response array we define an intrinsic support-component rank from all normalized continuations. Every stochastic realization obeys this cutwise lower bound. If the convex hull in each component is a simplex, residual vertices attain all these bounds simultaneously through normalized causal updates. The criterion is finite and effective on rational data, and the complete class is closed under independent products of terminal channels, with multiplicative state counts. A growing binary random-access experiment then separates predictive dimension from positive memory: its exact minimum whole-schedule peak is  $n + 1$  for  $0 < \eta \leq n^{-2}$  and  $2^n$  for  $1 - n^{-1} < \eta \leq 1$ , even when acquisition order is chosen adaptively. The weak-signal bound is attained by an explicit sequence of compatible enclosing simplices, not merely by a final encoder. Minimax contact connects the classification to the marked physical audit and its exact five-state decision law. The previously established positive-noise saddle, fixed-clock validation-order classification, support-boundary jump, causal foundations and transport proofs are retained as supporting mathematics. Exact physical counts assume a specified target and atomic stochastic rows; acquired calibration has separately priced approximation guarantees.

## 1. INTRODUCTION

A finite stochastic experiment can have a low-dimensional predictive image and nevertheless require many persistent states. The reason is positivity: an internal state describes a normalized future experiment, not an arbitrary vector in a linear span. Causality imposes a second constraint. Positive representations at successive cuts must be joined by common stochastic updates, and a schedule chosen from observations cannot reappear as an uncharged clock.

We seek conditions under which those constraints admit an intrinsic and exact state count. A lower bound obtained from selected faces and an independently supplied upper program can certify a particular example. It does not yet tell us when the continuation geometry itself determines a complete answer. Theorem 2.2 supplies such a condition for a finite class of causal experiments. Its data are all normalized continuation rows of the response array, their minimal faces in the causal polytope, and the connected components of the face-intersection graph. The resulting sum of affine ranks is a lower bound against every stochastic realization. If the residual convex hull in each component is a simplex, a canonical residual-vertex construction attains those ranks at every cut in one machine.

The condition does not assume a dimension-growth law, a metric entropy exponent, or a proposed controller. It can be checked by exact linear feasibility and rank. It is also not universal: an explicitly given full-support square has rank three and needs four states. The failure example makes clear what the completeness hypothesis excludes. For independent terminal channels the complete class is closed under products, and its intrinsic capacities multiply (Theorem 3.1). At every declared schedule vertex this gives an exact field rather than a field of analyst-selected certificates. The schedule optimum follows by a bottleneck recurrence.

A second theorem gives a more substantial separation in a growing experiment. Read  $n$  bits, then answer a later coordinate query with specified bias  $\eta$ . Every input and every query must have exactly the required conditional output law. The checkpoint geometry is the containment of  $[-\eta, \eta]^n$  in a convex hull inside  $[-1, 1]^n$ . For  $0 < \eta \leq n^{-2}$ , a sequence of enclosing simplices has  $(t+1)$  vertices after  $t$  reports and is closed under appending the next bit. Its barycentric updates implement the channel with peak  $n+1$ , which the affine dimension forces. For  $\eta > 1 - n^{-1}$ , disjoint corner caps force  $2^n$  states, attained by full retention. Both lower bounds hold after any adaptive acquisition schedule, because the whole acquired transcript must pass through the state before the query. Both regimes include full-support laws. Thus the same predictive rank  $n+1$  can be attained by causal memory or be exponentially smaller than it.

The statistical application enters in the opposite direction: a minimax saddle first forces continuations, and the intrinsic geometry then prices them. Bayes indifference alone does not specify an optimal continuation. For the marked two-preparation family, contact and stationarity fix two coordinates left free by a least-favorable prior. The five forced rows have canonical support components of dimensions 1, 0, 1, recovering the exact count  $2 + 1 + 2 = 5$ . These rows remain forced in the full-support physical rectangle. Their independent query-channel products have capacity  $5^m$ ; this is a statement about specified product continuations, not a new formula for the multi-block minimax value.

The proof structure is therefore

$$\begin{aligned}
 & \text{uniform saddle contact} \longrightarrow \text{forced normalized continuations} \\
 & \longrightarrow \text{intrinsic positive geometry} \longrightarrow \text{compatible simplex updates} \\
 & \longrightarrow \text{one causal realization with matching memory.}
 \end{aligned}$$

The general positive-realization and residual-automaton mechanisms have classical antecedents. Section 6 compares the precise claims with stochastic realization, residual automata, nested-polytope factorization, incomplete-machine minimization and random-access coding. We do not claim a new general minimax interchange or a solution of unrestricted positive-rank minimization.

**1.1. Resource and parameter conventions.** All persistent randomness belongs to the register. A fixed finite program and known row constants are read-only; an unknown target is not a free constant. The finite-state theorems use atomic stochastic rows, not free finite-length exact sampling of arbitrary real coins. The random-access query is one atomic input, explicitly distinct from a bit-serial query buffer. Input-dependent acquisition choices are allowed, but their retained protocol information is charged. The physical twelve-state optimum is over externally declared validation clocks; no adaptive collision optimum is inferred from it.

For a specified positive-noise Brownian target the exact physical saddle and five/twelve-state conclusions are retained. Acquired target calibration instead gives an approximate-score controller with finite counter and precision costs. The main theorems keep these quantifiers separate.

**1.2. Organization and the retained development.** Sections 2–6 contain the current theorem spine and its proofs. The supporting sections then retain the previous causal foundations, exact saddles, physical identification and validation-order proofs, revelation laws, finite-architecture certification, all-preparation localization, and transport consumers. Their stable theorem labels remain resolvable in this single manuscript. No predecessor proof is discarded to shorten the main narrative. The historical A2 geometric root and B4/C2 operator gates retain their own hypotheses; neither the present class theorem nor the growing query example replaces those independent derivations.

## 2. AN INTRINSIC CONTINUATION INVARIANT

We first give a finite realization theorem whose input is the complete response law, rather than a selected collection of lower certificates. The distinction between a law and an implementation is essential: states in a competing implementation need not themselves be residuals of the law. The lower bound below allows all such states.

**2.1. Normalized causal residuals.** Fix a finite horizon, finite alphabets, and a list of charged cuts. At an elementary stage the machine chooses an action  $a$ , then receives a report  $y$ . A terminal output is an action followed by a dummy report. Let  $C(\mathbf{a} \mid \mathbf{y})$  be a nonnegative normalized array whose action-prefix marginal depends only on the reports preceding that prefix. Thus an action cannot read its own future report. Every necessary buffer cut is an elementary cut. Time-dependent rows are allowed; a persistent seed, data-dependent clock, or protocol register is not a free input.

These conventions describe exact realization of a *specified* causal array on the full declared alphabet. For a model imposing only almost-sure requirements, one must first specify a legal completion on unsupported words, or optimize over those completions. Changing the completion can change the answer. Additional autonomous row-identification constraints are not part of the clocked theorem below.

For a positive-mass controller prefix  $h = (\mathbf{a}_{\leq t}, \mathbf{y}_{\leq t})$ , let  $R_h$  be the normalized array of future actions conditional on that prefix and on externally supplied future reports. Positivity of the prefix refers to its marginal in  $C$ , with past reports fixed, and not to a prior on environmental parameters. Write  $\mathcal{R}_t$  for the finite set of distinct such arrays. Duplicate arrays are removed. Let  $\mathcal{P}_t$  be the polytope of all normalized causal arrays on the remaining interface. Its defining equations express normalization and nonanticipation; its inequalities express nonnegativity.

Legality restrictions are included in the response array's zero pattern. A mandatory retained output or buffer is included through its prescribed later readout, so that deleting it changes the continuation task.

If  $R \in \mathcal{R}_t$  and its next action has probability  $p_R(a) > 0$ , then, for every next report  $y$ ,

$$(1) \quad R(a\mathbf{a} \mid y\mathbf{y}) = p_R(a)R^{a,y}(\mathbf{a} \mid \mathbf{y}), \quad R^{a,y} \in \mathcal{R}_{t+1}.$$

The scalar  $p_R(a)$  is independent of  $y$ . If  $p_R(a) = 0$ , the entire left side is zero. These are normalized residuals of a controller, not posteriors in its runtime register.

**Definition 2.1** (Support components and their rank). For  $R \in \mathcal{R}_t$ , denote its minimal face in  $\mathcal{P}_t$  by  $F_t(R)$ . Join two residuals when their minimal faces intersect. Let  $\mathcal{R}_{t,1}, \dots, \mathcal{R}_{t,c_t}$  be the connected components of this graph, and put

$$(2) \quad d_{t,j} = \dim \text{aff } \mathcal{R}_{t,j}, \quad s_t(C) = \sum_{j=1}^{c_t} (d_{t,j} + 1), \quad e_t(C) = \sum_{j=1}^{c_t} |\text{ext conv } \mathcal{R}_{t,j}|.$$

Call the residual geometry *componentwise simplicial* at  $t$  if each  $\text{conv } \mathcal{R}_{t,j}$  is a simplex, including a point as a zero-dimensional simplex.

Everything in this definition is determined by  $C$  and the charged interface. For finite rational data, face intersection is a linear feasibility problem with the two zero patterns imposed, affine dimension is a matrix rank, and extreme-point membership is another linear feasibility problem. No witness subfamily or trial controller enters the definition. Since normalized residuals lie in an affine hyperplane not containing zero,  $d_{t,j} + 1$  equals their ordinary row rank. For terminal-output channels the ambient polytope is a product of probability simplices; two minimal faces intersect precisely when their allowed-output sets intersect at every future input.

**Theorem 2.2** (Intrinsic simultaneous realization). *Every stochastic clocked realization of  $C$ , with all persistent variables included in its register, has*

$$(3) \quad K_t \geq s_t(C)$$

*at every charged cut. A single stochastic realization has profile  $K_t = e_t(C)$  simultaneously at all cuts. If the residual geometry is componentwise simplicial at every cut, then*

$$(4) \quad K_t^{\min} = s_t(C) = e_t(C) \quad \text{simultaneously,} \quad W^{\min}(C) = \max_t s_t(C).$$

*A realizing machine is obtained directly from residual vertices and barycentric one-step updates. Thus the statement determines an exact profile, not just unrelated lower bounds at individual cuts.*

*Proof.* Conditioning a realizing machine on a controller prefix gives

$$(5) \quad R_h = \sum_s E_h(s)B_{t,s}, \quad E_h(s) \geq 0, \quad \sum_s E_h(s) = 1, \quad B_{t,s} \in \mathcal{P}_t.$$

Here  $B_{t,s}$  is the future program starting in the actual state  $s$ . It may lie outside the convex hull of the residuals. If  $E_h(s) > 0$ , the defining property of a face implies  $B_{t,s} \in F_t(R_h)$ . A state used for residuals in two different components would therefore belong to two intersecting minimal faces, which would join those components. This is impossible. The states used by distinct components are disjoint. Within component  $j$ , the affine span of its residuals is contained in the affine span of its used state continuations, and hence at least  $d_{t,j} + 1$  states are required. Summing proves (3). This argument does not replace stochastic encoders by deterministic ones.

For the upper construction, at cut  $t$  choose as states all extreme points of the component convex hulls. Every such point is an actual residual, since the residual set is finite. Each residual is a convex combination of these chosen states. Given a state  $R$ , choose its next action with

probability  $p_R(a)$ . For positive  $p_R(a)$ , represent  $R^{a,y}$  from (1) as a convex combination of the chosen states at cut  $t + 1$ , and use those coefficients as the update row after report  $y$ . At zero  $p_R(a)$  choose an arbitrary update on the unused row. The action row remains independent of the unread report. Initialization is the decomposition of  $C$  at the first cut; the terminal continuation is realized by its prescribed output row.

Backward induction proves the entire future array from every chosen state. In particular, the updates at different cuts implement the same law; no separate factorization is being spliced without checking its shifts. This gives the profile  $e_t(C)$ . In the simplicial case each component has exactly  $d_{t,j} + 1$  vertices, so the upper and lower profiles coincide. Within each component the barycentric coefficients are unique, although arbitrary minimum-size realizations need not be unique or have states equal to residuals.  $\square$

**Corollary 2.3** (A complete, finite test for the stated class). *For a complete finite rational response array, componentwise simpliciality and the numbers in (4) can be decided from linear systems, rational linear feasibility, and a finite graph. When the test succeeds, rational transition tables realizing the exact profile can be constructed. The same holds for real algebraic input using exact sign and linear-feasibility decisions over the specified ordered field.*

*Proof.* Enumerate the positive-prefix normalized residuals and their zero patterns. Solve the pairwise face-intersection problems in the stated causal polytope, find the connected components, and find the extreme residuals of each component hull. A component hull is a simplex exactly when its number of vertices equals its affine dimension plus one. Solve the barycentric systems in the proof of Theorem 2.2. All operations are finite and preserve the indicated field.  $\square$

The input table can be exponentially large in the horizon. The corollary is a completeness and synthesis result for an explicit class, not a polynomial algorithm in a succinct program length. It does not say that ordinary rank solves unrestricted positive realization. Nor does it claim that residual-state minimization, by itself, minimizes over all probabilistic machines; that last conclusion uses the separated-component lower bound. The distinction is also present in residual automata [21] and nested-polytope formulations [19].

**2.2. Exact schedule fields without selected certificates.** Consider a terminal-output channel on finitely many tapes, internally ordered on each tape, with a full product input alphabet. At a vector  $v$  of consumed-prefix lengths let  $\mathcal{R}_v$  consist of the channel rows for *all* prefixes at  $v$  as functions of the remaining suffixes. The rows and their minimal faces are independent of the path used to reach  $v$ . Define  $s(v), e(v)$  by (2).

**Corollary 2.4** (Intrinsic declared-order minimization). *If every component hull at every schedule vertex is a simplex, the least width on each declared schedule  $\pi$  is  $\max_{v \in \pi} s(v)$ . In particular,*

$$(6) \quad W_{\text{clk}}^{\min} = \min_{\pi} \max_{v \in \pi} s(v).$$

*The minimum is computed by the bottleneck recurrence on the finite schedule graph. The same residual-vertex construction supplies the updates for every allowed next-tape restriction.*

*Proof.* Restriction of an actual prefix row by any next tape symbol is an actual row at the corresponding child vertex. Apply the proof of Theorem 2.2 on the entire schedule graph, then on each path. The last-edge decomposition of paths gives the bottleneck recurrence. No lower certificate or upper residual family is an extra input to this corollary.  $\square$

An observation-dependent choice of tape has to be included as a controller action in  $C$ . Theorem 2.2 also classifies such a specified causal array when its normalized residual geometry passes the same test. Equation (6) alone optimizes declared paths, not all adaptive arrays. A

scalable experiment for which the peak optimum is unchanged even by adaptive acquisition is solved in Section 4.

**2.3. Why the completeness hypothesis has content.** The condition is neither universal nor a restatement of the answer. Consider four binary-query channels with response vectors  $(\epsilon, \epsilon), (\epsilon, 1 - \epsilon), (1 - \epsilon, \epsilon), (1 - \epsilon, 1 - \epsilon)$ , where  $0 < \epsilon < 1/4$ . All output probabilities are positive, so there is one support component. Its affine dimension is two and  $s = 3$ , but four states are necessary. Indeed, for each corner of the square a convex representation of its displayed row needs a generator with total coordinate error at most  $2\epsilon < 1/2$ . Two distinct corner-error sums add to at least one, so no generator can serve two corners. Four deterministic corner generators suffice. The nonsimplicial square therefore has state count four rather than three. This is a strict failure of the lower bound outside its completeness class, not an unsupported claim that the class contains every experiment.

### 3. PRODUCTS AND INTRINSIC MEMORY GROWTH

A classification becomes more useful when it survives independent composition. For the following statement a continuation is a normalized channel from a finite future-query alphabet  $Y$  to a finite output alphabet  $O$ . Multiple components are allowed. The joint experiment requires the whole product output law, not merely the correct marginal means.

**Theorem 3.1** (Multiplicativity on the complete class). *Let  $\mathcal{R} \subset \prod_{y \in Y} \Delta(O)$  and  $\mathcal{S} \subset \prod_{z \in Z} \Delta(A)$  be finite sets whose support-component hulls are simplices. Form the independent product rows*

$$(R \otimes S)(o, a \mid y, z) = R(o \mid y)S(a \mid z).$$

*Their component hulls are again simplices, and their intrinsic capacities satisfy*

$$(7) \quad s(\mathcal{R} \otimes \mathcal{S}) = s(\mathcal{R})s(\mathcal{S}).$$

*Consequently every joint stochastic encoder and decoder for the product requires this many states; correlated internal implementations cannot reduce the number. For independent terminal channels whose residual sets pass the test at every individual cut, the product profile on any interleaving is exactly the product of the individual capacities at the corresponding vector of cuts.*

*Proof.* Minimal faces of a query channel are given by the allowed outcomes at each query. Two product faces intersect exactly when the faces in each factor intersect: supports multiply, and a nonempty intersection must have nonempty projected supports in both factors for every query. The component graph of the product is the graph product with a loop at each vertex. Its connected components are precisely products of components, because one can move along a path in one factor while holding the other fixed.

In a component with  $k$  simplex vertices, the flattened normalized channel vectors of those vertices are linearly independent. Indeed, normalization turns any linear dependence into an affine dependence. For components with  $k$  and  $l$  vertices, their  $kl$  product vectors are linearly independent by the tensor-product rank identity. Every product of rows is a convex combination of these vectors, and every one of these product vertices is itself a product row. Hence the component hull is their  $(kl - 1)$ -simplex. Summing  $kl$  over pairs of components gives (7). The cut lower bound allows arbitrary normalized joint generators, not just product generators. The upper construction uses products of the individual generators. Restriction of a product residual changes only the factor whose input is read, so compatibility holds simultaneously throughout the interleaving graph.  $\square$

The independence in the specification of the output channel is indispensable. Independent inputs or additive payoffs alone do not force a product of optimal response channels. In particular, (7) is not a multiplicativity claim for arbitrary nonnegative rank or for the marked minimax values  $U_N$ .

**Corollary 3.2** (A full-support family at a preparation barrier). *For  $q \geq 2$  and  $0 < \lambda < 1$ , let*

$$T_\lambda(b | a) = \lambda \mathbf{1}_{a=b} + (1 - \lambda)/q, \quad a, b \in [q].$$

*Acquire  $n$  input symbols before releasing any output; subsequently produce the specified independent product channel  $T_\lambda^{\otimes n}$ . The exact minimum peak is  $q^n$ , even if acquisition and output schedules depend on retained observations and internal randomization, provided all schedule memory is charged and no past transcript can be read back. For a declared schedule, at quiescent cuts between completed release operations, the exact width with  $m$  acquired but unreleased symbols is  $q^m$ . An intermediate held-output cut is charged separately using the active count immediately before that release. At  $\lambda = 0$ , one state suffices until an output-buffer cut.*

*Proof.*  $T_\lambda$  has eigenvalues 1 and  $\lambda$  with multiplicity  $q - 1$ , so its  $q$  rows are independent and form a simplex. All entries are positive. Theorem 3.1 gives  $q^m$  at any fixed active cut. For an adaptive schedule at the barrier, condition on the complete input word  $x$ . Its state law is an encoder  $E(s | x)$ ; the law of the entire subsequently produced labelled output vector is a decoder  $D(\mathbf{b} | s)$ . Any output-order choices are included in this law before taking the labelled-output projection. Thus  $T_\lambda^{\otimes n} = ED$ , whose rank  $q^n$  bounds the state count. This argument charges, rather than reveals, the acquisition transcript. Retaining the full input word gives the matching fixed-order upper bound. Releasing a symbol samples its output and discards that input; even if the output itself is held for one cut, there are at most  $q q^{m-1} = q^m$  states. At  $\lambda = 0$  the outputs are independent of all inputs, and can be sampled without retaining them.  $\square$

This is a rank-boundary phenomenon entirely inside full support, unlike the physical support boundary in Theorem A.17.2. For every fixed  $n$ , the product law tends uniformly in total variation to the input-independent output law, with defect at most  $n\lambda(1 - 1/q)$ . Thus a one-state generator approximates it with that defect, while every nonzero  $\lambda$  has the stated exact memory. The estimate follows by coupling each output with an independent uniform symbol and summing the per-coordinate disagreements. Exact memory and approximate statistical performance are different quantities.

#### 4. A SCALABLE FULL-SUPPORT EXPERIMENT WITH TWO EXACT MEMORY LAWS

We next keep the final answer alphabet binary while the preparation length grows. This distinguishes intrinsic positive memory from ordinary predictive dimension, and gives an exact causal construction rather than a checkpoint factorization alone.

An input  $x = (x_1, \dots, x_n) \in \{-1, 1\}^n$  is fixed. Each coordinate can be read once during acquisition. After acquisition an external query  $j \in [n]$  arrives as one atomic symbol, and a bit  $B \in \{-1, 1\}$  is emitted. For a specified  $0 \leq \eta \leq 1$ , the required experiment is

$$(8) \quad \Pr(B = b | x, j) = \frac{1 + \eta x_j}{2}.$$

Acquisition may choose the next unread coordinate using the retained state. At the query cut the entire acquisition transcript has been discarded except for that state. Neither a public persistent seed nor a transcript of the chosen order is given to the decoder. The external round number is a declared clock; any data-dependent schedule variables must be stored. The output is sampled in the update receiving  $j$ , so  $j$  need not be buffered after that update. Exact arbitrary stochastic rows are atomic, as in the preceding realization theorems.

Let  $W_n(\eta)$  be the least whole-schedule peak over these controllers. Let  $K_n(\eta)$  be the least number of states just before the query, without an upstream cap. For  $0 < \eta < 1$  every required answer probability has full support. Equality with (8) is required for every input and every query; an average success criterion is different.

**Theorem 4.1** (Linear and exponential exact memory regimes). *For every integer  $n \geq 1$ ,*

$$(9) \quad K_n(\eta) = W_n(\eta) = n + 1, \quad 0 < \eta \leq n^{-2},$$

$$(10) \quad K_n(\eta) = W_n(\eta) = 2^n, \quad 1 - n^{-1} < \eta \leq 1.$$

*In the weak-signal regime a fixed-order streaming controller has exactly  $t + 1$  states after  $t$  input bits, simultaneously for  $0 \leq t \leq n$ . For that fixed order these counts are minimal. Both peak lower bounds hold for arbitrary adaptive acquisition schedules. The two displayed regimes are not asserted to exhaust the intermediate parameter range.*

**4.1. The intrinsic checkpoint geometry.** For a query-state  $s$ , write  $z_s(j) = \mathbb{E}[B \mid s, j] \in [-1, 1]$ . An encoder gives (8) exactly if and only if

$$(11) \quad \eta x = \sum_s E(s \mid x) z_s \quad \text{for every } x \in \{-1, 1\}^n.$$

Thus  $K_n(\eta)$  equals the smallest number of points in  $[-1, 1]^n$  whose convex hull contains  $[-\eta, \eta]^n$ . Necessity is conditioning on the state. Conversely any such containment supplies a stochastic encoder and binary decoder. This is a normalized nested-polytope formulation, not an identification with unrestricted matrix rank [19]. It says nothing by itself about the memory needed to compute the encoder online.

For  $\eta > 0$ , the inner cube has affine dimension  $n$ , whence

$$(12) \quad K_n(\eta) \geq n + 1.$$

Equivalently, the matrix in (8), with input words as rows and pairs  $(j, b)$  as columns, has ordinary rank  $n + 1$ . Adaptive acquisition cannot evade (11): after the barrier there is still only one retained state law for each complete input, and the same decoder on every input.

**4.2. A compatible sequence of enclosing simplices.** We construct the encoder using only a label, never a stored real vector. For  $t \geq 1$  put  $b_t = t\eta$  and define

$$(13) \quad P_t = \{z \in \mathbb{R}^t : z_i \geq -b_t, \sum_{i=1}^t z_i \leq b_t\}.$$

Its vertices are  $v_{t,0} = (-b_t, \dots, -b_t)$  and  $v_{t,i} = v_{t,0} + (t+1)b_t e_i$ ,  $1 \leq i \leq t$ . The distinguished coordinate of  $v_{t,i}$  is  $t^2\eta$  and its other coordinates are  $-t\eta$ . Therefore  $P_t \subset [-1, 1]^t$  when  $\eta \leq n^{-2}$  and  $t \leq n$ . Set  $P_0 = \{()\}$ . The key causal inclusion is

$$(14) \quad P_t \times \{-\eta, \eta\} \subset P_{t+1}.$$

Indeed old coordinates are at least  $-t\eta$ , the new coordinate is at least  $-\eta$ , and the new sum is at most  $t\eta + \eta = b_{t+1}$ . For  $w \in P_t$  its barycentric coordinates are

$$(15) \quad \lambda_0(w) = \frac{b_t - \sum_i w_i}{(t+1)b_t}, \quad \lambda_i(w) = \frac{w_i + b_t}{(t+1)b_t} \quad (1 \leq i \leq t).$$

They are nonnegative, sum to one, and reconstruct  $w$ .

*Proof of (9).* At time  $t$  the register is an index  $s \in \{0, \dots, t\}$ . After bit  $x_{t+1}$ , replace it by index  $s'$  sampled from the barycentric coordinates of  $(v_{t,s}, \eta x_{t+1})$  in  $P_{t+1}$ . These are legal rows by (14). Induction gives

$$\sum_s \Pr(s \mid x_1, \dots, x_t) v_{t,s} = \eta(x_1, \dots, x_t).$$

Given the final state  $s$  and query  $j$ , draw the answer with mean  $v_{n,s}(j)$ . This is a valid binary row because  $P_n \subset [-1, 1]^n$ . The preceding identity proves (8) exactly. It also proves the entire online implementation, not just existence of a final stochastic matrix. The real vectors in the proof are read-only row descriptions; the machine stores only their indices. No past coin, real accumulator, or chosen-input transcript survives outside the register. Formula (15) shows that all acquisition rows are rational and independent of  $\eta > 0$ , because that common factor cancels. Only the final decoder depends on the specified signal strength.

The peak is  $n + 1$ ; sampling and retaining the final binary answer uses two states. Bound (12) gives the converse even with adaptive acquisition. For a fixed acquisition order, after  $t$  bits fix all future input bits and consider queries among the first  $t$  coordinates. The resulting continuation rows have affine dimension  $t$ , forcing  $t + 1$  states at that cut. This proves simultaneous minimality of the claimed streaming profile.  $\square$

### 4.3. A geometry stronger than rank.

*Proof of (10).* For a corner  $x$  and a possible generator  $z \in [-1, 1]^n$ , set

$$d_x(z) = \frac{1}{2} \sum_{i=1}^n (1 - x_i z_i).$$

Equation (11) implies that its average under the encoder for  $x$  is  $n(1 - \eta)/2 < 1/2$ . Hence some used generator has  $d_x(z) < 1/2$ . For distinct corners  $x, x'$ , at a coordinate where they differ the two corresponding summands add to one; all other summands are nonnegative. Thus  $d_x(z) + d_{x'}(z) \geq 1$ , and no generator can serve both corners. All  $2^n$  corners need distinct generators. Retaining the entire input word and then applying the single noisy query row gives the upper bound  $2^n$ . The factorization argument is independent of the acquisition order or its internal randomization.  $\square$

For  $n \geq 2$ , both exact regimes contain full-support laws. In the strong regime the ordinary rank is only  $n + 1$ , but the exact causal memory is  $2^n$ . In the weak regime the nested simplices attain that rank with a compatible streaming implementation. Thus neither support alone nor linear dimension alone determines exact memory. In persistent bits these two regimes give respectively  $\lceil \log_2(n + 1) \rceil$  and  $n$ . At  $\eta = 0$  the query-state complexity is one; the peak is two if the emitted answer must be held for a charged output cut. Every nonzero weak signal has query-state complexity  $n + 1$ , despite full support and uniform convergence to the fair-output channel as  $\eta \downarrow 0$ .

**Proposition 4.2** (Known rows, approximation, and a strict rank margin). *The input-independent fair-output channel has rowwise total-variation error  $\eta/2$  in approximating (8). For  $n \geq 2$ , any approximation factoring through at most  $n$  query states has worst rowwise error at least  $\eta/(2\sqrt{n})$ . The exact state counts in Theorem 4.1 refer to known  $\eta$  and atomic stochastic rows, not to an unknown calibration or a fixed-length finite fair-bit implementation.*

*Proof.* The first assertion is the binary total-variation formula. For the second, form the  $2^n$  by  $2n$  probability matrix  $A$ . Its nonzero singular values are  $\sqrt{n2^{n-1}}$  and  $\eta\sqrt{2^{n-1}}$  with multiplicity  $n$ . This follows by using the orthogonal row functions  $1, x_1, \dots, x_n$  and, in each query block, the orthogonal column vectors  $(1, 1)$  and  $(1, -1)$ . A matrix of rank at most  $n$  differs from  $A$

in Frobenius norm by at least its smallest nonzero singular value. If every binary-query row has total-variation error at most  $\delta$ , each pair contributes at most  $2\delta^2$ , so the squared Frobenius error is at most  $2n2^n\delta^2$ . The claimed bound follows. This is only an approximation bound, not an assertion that the two sides match.  $\square$

Random-access coding is a classical communication task [22, 23, 24]. Equation (8) fixes every conditional decoding probability, not merely a lower bound on worst-case success or an average over inputs and queries. The new causal assertion made here is the exact finite-horizon profile from (14), together with lower bounds that survive adaptive acquisition and all persistent-randomness accounting. No priority claim for the communication model or for convex coding is made.

## 5. FROM SADDLE CONTACT TO INTRINSIC MEMORY

The geometric theorems classify response laws. A statistical optimization must first determine which laws are forced. We make that logical order explicit, so that Bayes indifference is not mistaken for freedom to choose the cheapest response.

Let  $\mathcal{C}$  be the finite polytope of full-history causal response arrays and  $g_\theta(C)$  the continuous payoff against a fixed unknown parameter in a compact space. Suppose  $\mu_*$  is a least-favorable prior with value  $U$ . The optimal set is

$$\mathcal{S}_* = \left\{ C : \int g_\theta(C) d\mu_* = U \right\} \cap \bigcap_{\theta} \{ C : g_\theta(C) \geq U \}.$$

For every  $C \in \mathcal{S}_*$ , nonnegativity and zero prior integral give  $g_\theta(C) = U$  on  $\text{supp } \mu_*$ . Differentiability at an interior supporting parameter also gives  $\nabla_\theta g_\theta(C) = 0$ . These are the contact equations proved in Theorem A.7.3; they apply even when a response coordinate has zero Bayes coefficient.

**Corollary 5.1** (A contact-rigid saddle classification). *Suppose the saddle conditions determine a unique complete causal response array  $C_*$ . If its normalized residual geometry is componentwise simplicial at every charged cut, the minimum profile attaining  $U$  is exactly  $(s_t(C_*))_t$ , simultaneously. Every smaller profile misses  $U$  by a strictly positive amount in a fixed finite interface. More generally, any finite family of common normalized continuation rows forced for every  $C \in \mathcal{S}_*$  gives the support-component rank lower bound at its cut, even when those rows are obtained by parameter-independent averaging.*

*Proof.* Any value-attaining array belongs to  $\mathcal{S}_*$ , and hence equals  $C_*$  in the first assertion. Apply Theorem 2.2. The normalized finite-row realization space for a smaller fixed profile is compact. If its maximal worst-case score were  $U$ , it would contain an implementation of  $C_*$ , contrary to the lower bound. For the last assertion, each forced row factors through the same state continuations at that cut. Averaging encoder rows preserves normalization and this factorization. The separated-component lower argument therefore applies to the forced rows. This last lower bound does not, without completeness and compatibility, assert an exact whole-schedule profile.  $\square$

This corollary states a checkable implication after contact has been solved; it does not assume that every saddle is response-rigid. The following application deliberately uses only the common forced rows, because the marked saddle does not determine every coupling of fresh validation coins.

**5.1. The marked decision geometry as a complete instance.** The full-support saddle of Theorem A.15.1, proved in the supporting development, concerns

$$(\gamma, \kappa) \in [6/25, 13/50] \times [0, 1/1000].$$

Its contact equations force the following five averaged response rows on the diagonal atoms 000, 001, 110, 111, with zero response at the four other atoms:

$$(16) \quad (t, 0, 1, 1), \quad (1, 0, 1, 1), \quad (1, 1, 1, 1), \quad (1, 1, 0, 1), \quad (1, 1, 0, t), \quad 0 < t < 1.$$

The inner three rows are individually forced by strict Bayes signs. The outer rows are averages over the independent training marks; contact and stationarity fix their formerly indifferent coordinates. Every actual state encoder still factors these averages through its same decoder. These facts are proved without a count-only restriction on competitors in Theorems A.14.1 and A.15.1.

**Proposition 5.2** (Canonical five-state decision capacity). *For the forced response rows (16), the support graph has components of sizes 2, 1, 2, with affine dimensions 1, 0, 1. Their hulls are simplices. Thus their intrinsic capacity is*

$$(17) \quad 2 + 1 + 2 = 5.$$

*This recovers the exact decision count against all the original stochastic encoders, training gates, stopping rules, and independent calibration, not just against a chosen five-event compiler.*

*Proof.* Convert each response coordinate  $h(y)$  into the two probabilities  $(1 - h(y), h(y))$ . This affine embedding identifies the response cube with its normalized binary-query channel polytope. The first two rows have intersecting minimal faces: the edge of the first contains the second. The last two rows have the reflected relation. Their faces are disjoint from one another and from the singleton face of the middle row. Hence these are exactly the three support components. The first and last components each contain two distinct points; the middle contains one. Corollary 5.1 gives the five-state lower bound. The retained optimal event selection attains it and its validation implementation is proved in the supporting physical development. No new physical hypothesis is inserted.  $\square$

For  $m$  independent copies of this specified binary-query continuation, the exact joint checkpoint capacity is  $5^m$  by Theorem 3.1. This requires the product output law for the independent copies. It is not a claim that the minimax value of an  $m$ -block audit is the product of  $U_2$ , or that marginal optimality alone forces independent output randomization.

**5.2. Known-target physical exactness and acquisition.** The supporting proofs retain the earlier rational certificate and uniform two-preparation construction, with constants

$$(18) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

These are not substituted for the later exact saddle value  $U_2$ .

For every specified Brownian target  $Q_{d,\sigma}$  in  $9/10 \leq d \leq 11/10$ ,  $0 < \sigma \leq 1/24$ , the exact target-identification proof gives

$$\gamma = \frac{1}{4} - \frac{1}{2}\mathbb{E}e, \quad \kappa = \frac{1}{2}\mathbb{E}[e(1 - e)] > 0.$$

The conditional sign-error rate  $e$  is shared through the physical signal; replacing  $\mathbb{E}e^2$  by  $(\mathbb{E}e)^2$  is not justified. The retained full-support saddle and schedule theorems therefore give five decision states and minimum peak twelve over all externally declared, order-preserving validation clocks. Exactly the serial orders attain that minimum. The ideal reverse-order support limit has peak

ten. These are theorems about the specified target with its exact stochastic row available, and their proofs remain in full below.

An acquired target is different. Its finite counter and finite-bit construction in Proposition A.16.3 gives approximate score recovery with its stated calibration error and workspace. Neither that proposition nor Theorem 4.1 identifies an unknown algebraic row exactly from finitely many samples. The new intrinsic classifier does not change this distinction. Nor does its declared-path corollary convert the physical fixed-clock optimum into a lower bound for all report-dependent validation schedulers. The adaptive-acquisition quantifier of Theorem 4.1 is proved for that experiment by the barrier factorization, not imported from the collision example.

## 6. THEOREM-LEVEL RELATION TO REALIZATION AND CODING

There are three different minimization problems in the argument, and their classical precedents should not be conflated.

Positive realization versus an intrinsic complete class. Heller’s positive-realization viewpoint and the HMM realization survey of Vidyasagar [17, 18] concern the representation of stochastic laws by positive state systems. They motivate the normal form used here. Our main theorem does not replace that theory or solve its unrestricted minimization problem. Its finite input is a complete causal response array with declared cuts. From all its normalized residuals, it computes a face-intersection graph and a sum of affine ranks. Componentwise simpliciality is a finite geometric test, and under that test the lower sum equals a simultaneously realizable profile. No choice of a witness family remains in the answer. The general normal-form statement alone does not supply this all-realizations lower bound or its completeness test.

Residual minimality versus all-machine minimality. Denis and Esposito [21], Proposition 16 and their probabilistic residual-automaton results, establish canonical minimal generating subsets of residuals under their finite-generation hypotheses. The residual-vertex upper construction in our proof belongs to that line of ideas; its existence is not claimed as a new principle. But being smallest among residual-state representations need not mean being smallest among all positive representations. Our lower proof allows arbitrary state continuations outside the residual hull and rules out their sharing across distinct support components. It is this additional step, together with affine independence inside each component, that equates residual size with unrestricted stochastic size in the stated class. The square example after Corollary 2.4 exhibits failure of rank completeness outside that class.

Nested polytopes versus causally compatible covers. Gillis and Glineur [19], Definition 1 and Theorem 1, distinguish restricted nonnegative rank and give its nested-polytope formulation. Their distinction between ordinary and restricted rank is retained: we never force a competing generator into the residual affine span. For normalized binary-query channels the cube containment in (11) follows directly by conditioning. That checkpoint characterization is not a new identification of nonnegative factorization with convex geometry. The additional online question is whether covers at successive cuts admit stochastic shifts. The explicit inclusions (14) answer it for every preparation length and attain the lower rank at every acquisition cut. A final enclosing simplex without those inclusions would not establish Theorem 4.1.

Reusch and Merzenich [20] study compatible coverings for incompletely specified sequential machines. Their subject is particularly relevant when a target has support zeros. We do not infer a canonical completion from an almost-sure law. The present intrinsic theorem uses a complete array, and the retained physical support-boundary proof specifies its completion and supported tests explicitly.

Random-access codes versus exact online channel synthesis. Classical and quantum random-access coding, including the distinction between private and shared randomness, is established

in [22]. Recent work studies average and worst-case coding probabilities [23, 24]. The classical private-randomness factorization in [24], equation (4), is precisely the checkpoint conditioning mechanism underlying (11). Thus the random-access model and that factorization are not inventions of this article. The present statement fixes every conditional probability to (8) and prices the entire sequential encoder. The affine-dimension lower bound, the compatible  $(t + 1)$ -state streaming construction, and the disjoint corner-cap converse give two exact regimes with different memory scales in one growing full-support family. We do not claim the optimal success probability for every message size or a complete intermediate-signal phase diagram. Statistical contact and the scope of originality. The new geometric classification applies to laws already specified or forced. A minimax problem supplies those laws only after Bayes optimality and uniform contact have both been imposed. The marked application makes this distinction concrete: the cheaper three-event Bayes tie rule is not uniformly minimax. Contact forces the two extra coordinates before intrinsic realization is considered. This comparison isolates the hypotheses and conclusions being used; it is not a claim that no reformulation of earlier theory could imply them. No complete priority or proof-level non-overlap audit of Norberg's filtered-experiment comparison [11] is asserted. The finite geometric and online results above are proved directly, with the inherited comparison, control, and testing mechanisms attributed in the supporting text.

## SUPPORTING FOUNDATIONS AND PHYSICAL PROOFS

The following sections preserve the substantive mathematical body of revision 28. They supply the exact saddles, microscopic model, validation-order proofs, general causal foundations, and quantitative consumers used above. Earlier local scope statements describe the individual results in which they occur; the new classification and streaming theorems are stated in Sections 2–5. All predecessor theorem labels and all mathematical proofs remain available in this manuscript. The current introduction and theorem hierarchy replace repeated roadmap prose, not the supporting mathematics.

## APPENDIX A.1. CAUSAL EXPERIMENTS AND THEIR PREDICTIVE QUOTIENTS

We begin with the object and morphism structure. Its elementary probability statements fix the meaning of later resource theorems; classical kernel construction, conditional expectation and quantization are not assigned a new priority. The substantive comparisons below retain their preparation, memory and approximation coordinates simultaneously.

**A.1.1. The experimental object.** An experiment has a fixed unknown parameter  $\theta \in \Theta$ , hidden states  $X_t$ , visible actions  $A_t$ , reports  $Y_{t+1}$ , and preparation laws  $\mu_\theta$ . We impose the following six conventions.

**A0 (types and visibility).** These spaces are standard Borel. Visible histories include actions, reports and publicly recorded resource increments. A legal-action set and its remaining budget are part of the visible protocol type. Two histories with different legal continuations are not identified.

**A1 (positive kernels).** There are jointly measurable normalized nonnegative kernels  $K_t^\theta(dx', dy, dc \mid x, a)$ , with  $c$  a nonnegative resource increment. An absorbing symbol represents termination or failure. Dirac kernels are allowed. Positivity here does not require every outcome to have strictly positive probability. A hidden state can contain the necessary physical past; this notation does not assume a finite-dimensional physical closure.

**A2 (causality).** A policy is a kernel  $\alpha_t(da \mid h_t)$  depending only on visible past data and allowed independent randomization. It cannot read the unknown parameter. Stopping is with respect to the visible filtration.

**A3 (executable tests).** The specified bounded future tests include constants, required report events and their legal one-step continuations. For discrete reports the one-step instrument is

$$(\mathbb{T}_{t,a,y}f)(\theta, x) = \int f(\theta, x') K_t^\theta(dx', \{y\}, dc \mid x, a).$$

The test spaces are closed under the required instruments, finite linear combinations and the bounded monotone limits needed to recover the stated event laws. For general reports one uses event instruments and regular conditional distributions, not division by the probability of a continuous singleton.

**A4 (actual preparation).** Average risks and acquired state laws refer to the specified preparation and exploration protocol. Failed trials, calibration, resets and conditioning events retain their probabilities and implementation costs. A convenient measure on a reachable set does not replace its acquired law.

**A5 (executable resources).** Persistent labels, temporary buffers, program constants, calibration precision, preparations and clocks are distinguished. A retained selector is a state. A parameter-dependent table is not a known program constant. A simulator with  $R_t$  labels composed with a controller with  $K_t$  labels has the direct product bound  $R_t K_t$ , before any

justified quotient is taken. Atomic stochastic rows and fair-bit implementations are separately specified.

**Proposition A.1.1** (Prepared path laws). *For every fixed parameter and causal policy, the preparation and kernels uniquely determine their finite-dimensional path laws. On a finite horizon they are the iterated kernel product*

$$\mu_\theta(dx_0) \prod_{t < T} \alpha_t(da_t | h_t) K_t^\theta(dx_{t+1}, dy_{t+1}, dc_t | x_t, a_t).$$

*These laws are consistent under marginalization. For a countable horizon they determine the usual kernel extension. Deterministic dynamics give their original trajectory laws when represented by Dirac kernels.*

*Proof.* Successive integration constructs each finite law. Normalization of the last two kernels gives its preceding marginal, and induction proves consistency and uniqueness on cylinder events. The countable kernel extension gives the full law; equivalently one applies the standard extension theorem to these consistent iterated kernels. Integration against a Dirac transition is evaluation along that transition, which proves the last assertion.  $\square$

**A.1.2. Prepared predictive equivalence.** For Bayesian predictions additionally fix a prior on the parameter, and regard  $(\theta, X_t)$  as the hidden variable. A prepared posterior  $\pi$  at a given protocol type evaluates the future tests. Define  $\pi \sim_t \tilde{\pi}$  if their evaluations agree on every specified future test. This definition concerns one prepared experiment; it does not identify a prior-dependent posterior with a statistic sufficient simultaneously for all fixed parameters.

**Theorem A.1.2** (Predictive quotient and causal closure). *For finite report alphabets, predictive equivalence is preserved by every legal positive-probability report update. Its class determines the laws of all specified future experiments. Every deterministic history statistic that determines those laws factors onto this quotient. For a measurable realization it is sufficient that a countable separating test family gives a measurable evaluation map with standard Borel image, and that the chosen statistic admits a measurable factor. In finite history spaces the latter conditions are automatic.*

*Proof.* For a legal action and report, Bayes' rule gives

$$\pi'(f) = \frac{\pi(\mathbb{T}_{t,a,y}f)}{\pi(\mathbb{T}_{t,a,y}1)}.$$

Both numerator and denominator depend only on the old class by A3. Equivalent posteriors assign the same probability to the report, so updates agree on the next test space whenever that probability is positive. Null reports do not affect the prepared law and may be assigned a fixed admissible version. Induction determines every finite future report word; the monotone-class extension gives the required future events. Conversely those event laws determine the tests. If two histories have the same sufficient statistic, they have the same future evaluations; the quotient is therefore constant on its fibers. This gives the factor set-theoretically. The stated measurable factor assumption supplies its measurable version; no claim that every abstract quotient of a standard Borel space is standard Borel is used.  $\square$

**Proposition A.1.3** (Barycenters, entropy and normalized response). *In a fixed preparation, suppose a hidden target  $Z$ , observation  $Y$  and postprocessing  $W$  form a Markov chain  $Z \rightarrow Y \rightarrow W$ . For any bounded vector of tests  $f$ ,*

$$p_W = \mathbb{E}[p_Y | W], \quad p_Y = \mathbb{E}[f(Z) | Y], \quad \mathbb{E}\varphi(p_W) \leq \mathbb{E}\varphi(p_Y)$$

for every convex  $\varphi$  for which these expectations exist. For a parameter-independent kernel  $G$ ,  $P \ll Q$ , and finite  $D(P\|Q)$ , regular conditional laws give

$$D(P\|Q) = D(PG\|QG) + \int D(P(dx | w)\|Q(dx | w)) (PG)(dw).$$

Finally, if  $f, g$  are bounded and  $\pi_u(dx) = e^{ug(x)}\pi(dx)/\pi(e^{ug})$ , then

$$\left. \frac{d}{du} \pi_u(f) \right|_{u=0} = \text{Cov}_\pi(f, g).$$

*Proof.* The Markov property and the tower rule give the conditional barycenter; conditional Jensen gives convex order. The joint laws  $P(dx)G(dw | x)$  and  $Q(dx)G(dw | x)$  have relative entropy  $D(P\|Q)$ . Disintegrating by  $w$  and applying the entropy chain rule gives the identity, and hence data processing. The last equality follows by quotient differentiation; boundedness justifies differentiation under the integral.  $\square$

The barycenter statement concerns a law of predictions, not a pointwise map between reachable sets. Likewise the covariance in the last formula is a normalized response, not an independently postulated Fisher matrix or a global sufficiency theorem.

## APPENDIX A.2. ATTAINABLE RESOLUTION AND RESOURCE-AWARE SIMULATION

**A.2.1. Checkpoint and online prediction.** Fix an actual exploration protocol and its history law. Let  $p(h)$  be a bounded  $d$ -dimensional conditional prediction vector, with law  $\nu$ . For instance, a future test is sampled independently after encoding, and the coordinates include its sampling weights. Squared excess prediction loss is then  $\mathbb{E}\|p(h) - \hat{p}\|^2$ .

**Proposition A.2.1** (Checkpoint resolution). *For at most  $M$  retained labels the least checkpoint excess loss is*

$$(19) \quad \inf_{c_1, \dots, c_M} \int \min_{1 \leq j \leq M} \|p - c_j\|^2 \nu(dp).$$

*Independent randomized encoders or decoders cannot improve it. This formula concerns the stated preparation and does not provide a common codebook by separately optimizing at each unknown true parameter.*

*Proof.* Conditional squared loss decomposes into its Bayes loss and squared distance from the conditional mean. For each retained label replace a random decoder by its mean. Random assignment to the resulting centers cannot do better than a nearest center. Conversely a nearest-center assignment attains the infimum over codebooks arbitrarily closely. Conditioning on an independent shared random seed, if such a seed is allowed, gives a codebook for each seed, each with risk at least (19). Averaging cannot improve the bound. The formula does not charge the computation of a checkpoint assignment as an online algorithm; online compatibility is a separate condition.  $\square$

**Theorem A.2.2** (A matched online resolution law). *Suppose a fixed prepared experiment has a predictive state  $s_t$  in a compact metric space  $S$ , a known initial state, and updates  $s_{t+1} = F_{t,a,y}(s_t)$ . Assume every permitted update is  $\rho$ -Lipschitz for one  $0 \leq \rho < 1$ , and the prediction map  $p : S \rightarrow \mathbb{R}^d$  is  $L$ -Lipschitz. Suppose  $S$  has a  $\delta$ -net of at most  $C\delta^{-d}$  points for all sufficiently small  $\delta$ . At a checkpoint  $T$ , assume the actual law  $\nu$  of  $p(s_T)$  satisfies the small-ball bound  $\nu(B(z, a)) \leq Aa^d$  for every center  $z$  and all sufficiently small  $a > 0$ . Then for*

all sufficiently large  $M$ , the minimum online excess prediction loss with  $M$  retained predictive labels satisfies

$$(20) \quad c_0 M^{-2/d} \leq R_M^{\text{on}} \leq C_0 M^{-2/d}.$$

Here one may take

$$c_0 = \frac{1}{2}(2A)^{-2/d}, \quad C_0 = \frac{L^2 C^{2/d}}{(1-\rho)^2},$$

Any separate exploration controller, report buffer or clock is charged in addition to these  $M$  labels. The exploration protocol and the preparation are fixed before optimizing the encoder.

*Proof.* Any online  $M$ -label state is also a checkpoint encoder, so Proposition A.2.1 applies. For any  $M$  centers, the union of balls of radius  $a = (2AM)^{-1/d}$  has  $\nu$ -mass at most one half. On its complement squared distance is at least  $a^2$ . Integration gives  $c_0 M^{-2/d}$ . This argument also permits randomized online encoders.

For the upper bound take a  $\delta$ -net with  $\delta = (C/M)^{1/d}$ , and a fixed measurable nearest-net assignment (with a fixed tie rule). Quantize the known initial state and, after each legal update, quantize again. The state error obeys  $e_{t+1} \leq \rho e_t + \delta$ ,  $e_0 \leq \delta$ , and hence  $e_t \leq \delta/(1-\rho)$ . The prediction error is at most  $Le_t$ . Squaring proves the upper bound, uniformly in time. Each update uses only the current net label and the current permitted input, so the construction is online. It does not grant the encoder free access to the original discarded history. If the exploration policy needs another register, that register is combined by a product construction.  $\square$

For example, a Lebesgue density bounded above by  $B$  gives the small-ball hypothesis with  $A = Bv_d$ , where  $v_d$  is unit-ball volume. The lower hypothesis is a condition on the *acquired prediction law*. A reachable set of dimension  $d$  without a mass condition does not imply the lower bound. Similarly, the contraction assumption is additional dynamics, not a consequence of kernel positivity.

**A.2.2. Causal morphisms and simultaneous error budgets.** A causal simulator  $\Gamma : \mathfrak{E} \rightarrow \mathfrak{F}$  is a parameter-independent executable transducer that uses source preparations to supply the target interface under every allowed target policy. Its defect  $\varepsilon$  is a uniform total-variation bound on the resulting path laws, including the fields required by the task. Its resource map  $\rho_\Gamma$  bounds the source resources of the transducer composed with a target controller.

**Proposition A.2.3** (Composition and risk transfer). *Causal simulators compose. Their uniform defects add, capped at one, and their resource maps compose in the order  $\rho_{\Gamma_1} \circ \rho_{\Gamma_2}$ . For a terminal loss in  $[0, L]$  and a common target task,*

$$\mathcal{R}_{\mathfrak{E}}(\rho_\Gamma(B)) \leq \mathcal{R}_{\mathfrak{F}}(B) + L\varepsilon.$$

For reward in  $[-1, 1]$ , the corresponding maximum worst-case rewards satisfy the reverse inequality with an error  $2\varepsilon$ .

*Proof.* Interleave the two transducers; their pair of internal states is a causal implementation. Total variation contracts under a kernel and obeys the triangle inequality, proving the defect sum. If their state counts are  $R_t$  and  $M_t$ , the pair has at most  $R_t M_t$  states. Other declared resource bounds compose by execution of the two protocols. A bounded loss changes expectation by at most its range times total variation. Apply this bound to every fixed parameter and target controller and take the appropriate infimum or supremum. Uniformity in the controller is essential to this step.  $\square$

**Theorem A.2.4** (Acquisition, quantization and model-error transport). *Suppose an exact source transducer has predictive state  $s_t \in S_t$  and additional charged buffers of size  $R_t$ , supplies  $T$  target operations, and has uniform model defect at most  $\varepsilon_{\text{mod}}$ . Its initialization and update depend on a calibration quantity  $\xi$ . From  $N_{\text{cal}}$  source preparations acquire an estimate  $\hat{\xi}$  with at most  $C_{\text{cal}}$  retained labels, such that*

$$\sup_{\theta} \mathbb{P}_{\theta}(d(\hat{\xi}, \xi) > a) \leq \eta.$$

*Subsequent preparation noises are independent of calibration conditional on the fixed parameter. Let finite nets of sizes  $M_t$  have radii  $\delta_t$ . Assume, on matching input/output histories and on the good calibration event, that the quantized transducer's state error satisfies*

$$(21) \quad e_0 \leq d_0 + a_0 a + \delta_0, \quad e_{t+1} \leq \rho_t e_t + d_{t+1} + a_{t+1} a + \delta_{t+1}.$$

*Assume its next output kernel and the exact transducer's output kernel differ in total variation by at most  $\epsilon_t + L_t e_t + b_t a$ , uniformly in the fixed parameter and legal policy. All constants and nets are declared independently of that unknown parameter. Then the quantized acquired transducer has defect at most*

$$(22) \quad \Delta = \min \left\{ 1, \varepsilon_{\text{mod}} + \eta + \sum_{t < T} (\epsilon_t + L_t e_t + b_t a) \right\}.$$

*Composing it with any target controller of cut widths  $K_t$  requires at most  $C_{\text{cal}} R_t M_t K_t$  labels at aligned execution cuts and transfers its bounded reward with loss at most  $2\Delta$ . Its preparations are  $N_{\text{cal}}$  plus all source preparations specified by the transducer; no successful-trial conditioning removes the failures.*

*Proof.* On the good calibration event, iterate (21). More explicitly, with  $D_0 = d_0 + a_0 a + \delta_0$  and  $D_j = d_j + a_j a + \delta_j$ ,

$$e_t \leq \sum_{j=0}^t D_j \prod_{k=j}^{t-1} \rho_k.$$

Couple each pair of output kernels maximally while their external histories agree. On agreement the target controller sees the same inputs, so it uses the same legal action and may use the same independent randomization. Its discontinuous action choices require no Lipschitz assumption: before a disagreement their arguments are identical. The chance of a first discrepancy is bounded by the sum in (22). Add the probability of bad calibration and the exact transducer's model defect. This proves the path bound, including stopping after padding by absorbing states.

The executable approximate transducer stores its calibration label, additional buffer, and net index. Combine these with the actual target register, not its full history or an uncharged belief. The resulting product gives the state count. If an operation contains further buffer cuts, apply the same product at each such cut;  $R_t$  was assumed to include them. Preparation costs add by execution. Finally apply Proposition A.2.3.  $\square$

**Corollary A.2.5** (A finite acquisition register). *Suppose  $r_0$  calibration rows have at most  $d$  outcomes, and take  $n$  independent preparations from each row on a fixed schedule. Their empirical rows satisfy, with probability at least  $1 - \eta$  uniformly in the row probabilities,*

$$\max \text{TV}(\hat{P}, P) \leq \frac{dz}{2}, \quad \eta = \min\{1, 2r_0 d \exp(-2nz^2)\}.$$

*Their counts can be retained in at most  $(n+1)^{r_0(d-1)}$  labels. Thus Theorem A.2.4 can use  $N_{\text{cal}} = r_0 n$ ,  $a = dz/2$  and this finite calibration register when its calibration metric is the maximum row total variation.*

*Proof.* For each outcome the empirical frequency is the mean of independent Bernoulli indicators. Hoeffding's bound and a union bound over at most  $r_0 d$  coordinates give the event stated. The total-variation estimate is half the sum of coordinate errors. Retain  $d - 1$  counts per row; the last is reconstructed from the known number of draws at that stage of the clocked schedule. Each retained count takes at most  $n + 1$  values. An autonomous implementation must additionally charge its schedule.  $\square$

These results separate exact predictive equivalence, average checkpoint resolution, online realizability, and uniform simulation risk. In particular, neither an optimal checkpoint codebook nor the proof-state bundle of Section A.6 is automatically an executable finite register.

### APPENDIX A.3. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition A.3.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{s_r}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller's random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(23) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition A.3.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (23) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row.

Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section A.21 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

#### APPENDIX A.4. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(24) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z)(Q - P_\theta)h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem A.4.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(25) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_\theta^{\otimes N}(z) \{Q(\omega) - P_\theta(\omega)\} d\mu(\theta) \right]_+$$

$$(26) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_\mu(z) \text{TV}(Q, \bar{P}_\mu(\cdot | z)).$$

Here  $m_\mu(z) = \int P_\theta^{\otimes N}(z) d\mu(\theta)$  and, when  $m_\mu(z) > 0$ ,

$$\bar{P}_\mu(\omega | z) = \frac{\int P_\theta^{\otimes N}(z) P_\theta(\omega) d\mu(\theta)}{m_\mu(z)}.$$

A zero-mass term in (26) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (24) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [3] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (25). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_\mu(z)$  it equals  $m_\mu(z)(Q - \bar{P}_\mu(\cdot | z))$ , proving (26). If  $m_\mu(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem A.4.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_\theta$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^\Omega$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (24). This proves the upper bound for the union of all architectures. Conversely, retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (24).  $\square$

*Remark A.4.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_\theta^{\otimes N} d\mu(\theta)$ , not  $(\int P_\theta d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (26) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary A.4.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (25) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (25) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory's theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

## APPENDIX A.5. CONTROLLED EXPERIMENTS WITHOUT A DOMINATING ACTION

The reduction to one dominating row is not needed for a statistical dual, provided causal action choice is retained in the dual recursion. We give the finite-action theorem with a compact parameter space and an explicit protocol state. Its equality is an unrestricted-memory statement; its upper certificates apply to every smaller-memory class.

Let  $\Theta$  be compact metric and  $E$  a finite set of protocol states. At  $e \in E$  let  $\mathcal{A}_e$  be a finite set of training actions. Action  $a$  produces  $x$  in a finite alphabet  $X_a$  with law  $P_\theta^a$  and changes the protocol state to  $T(e, a, x)$ . The functions  $\theta \mapsto P_\theta^a(x)$  are continuous. An unknown  $\theta$  is fixed throughout the experiment. Conditional on it, each requested preparation uses a fresh

independent draw from the selected row. Legal validation designs form a nonempty finite set  $\mathcal{B}_e$ . Design  $b$  has a finite outcome alphabet  $Y_b$ , target law  $Q^b$  and continuous candidate law  $V_\theta^b$ . A policy may stop after at most  $N$  training actions. It then freezes  $b \in \mathcal{B}_e$  and an event on  $Y_b$ , before one candidate and one target validation. Randomization is independent of  $\theta$ . No training action is assumed to dominate another.

For a finite nonnegative measure  $\nu$  on  $\Theta$  write  $\nu_{a,x}(d\theta) = P_\theta^a(x)\nu(d\theta)$  and set

$$(27) \quad \Phi_e(\nu) = \max_{b \in \mathcal{B}_e} \sum_{y \in Y_b} \left[ Q^b(y)\nu(\Theta) - \int V_\theta^b(y)d\nu \right]_+,$$

$$F_0(e, \nu) = \Phi_e(\nu),$$

$$(28) \quad F_n(e, \nu) = \max \left\{ \Phi_e(\nu), \max_{a \in \mathcal{A}_e} \sum_{x \in X_a} F_{n-1}(T(e, a, x), \nu_{a,x}) \right\}.$$

If no training action is legal, only the stopping term is retained. All the functions vanish at the zero measure, so no posterior division is required on null histories. For positive mass, (27) is the mass times the largest posterior-predictive total variation.

**Theorem A.5.1** (Controlled posterior-predictive dual). *Let  $\mathcal{U}_N(e_0)$  be the maximum worst-case expected validation score over all randomized causal policies in the declared protocol, with at most  $N$  training preparations and no memory cap. Then*

$$(29) \quad \mathcal{U}_N(e_0) = \min_{\mu \in \mathcal{P}(\Theta)} F_N(e_0, \mu).$$

*Both extrema are attained. Each  $F_n(e, \cdot)$  is the maximum of finitely many continuous linear functionals on the cone of measures; in particular it is convex, continuous and positively homogeneous. For every prior  $\mu$ ,  $F_N(e_0, \mu)$  bounds the worst-case score of every finite-memory architecture implementing this protocol.*

*Proof.* There are finitely many histories of length at most  $N$  and finitely many event masks at each stopping history. Consequently there are finitely many deterministic policy trees, denoted by  $\Pi_N(e_0)$ . For  $\pi \in \Pi_N(e_0)$  its payoff  $g_\pi(\theta)$  is a finite sum of finite products of continuous primitive probabilities and is continuous in  $\theta$ .

A randomized causal policy induces the same outcome laws as a probability distribution on these trees: sample its finite random decision table in advance and condition on it. Conversely, with no memory cap, a sampled tree can be retained and followed. Thus the unrestricted payoff vectors are exactly the convex hull of the  $g_\pi$ . This step is not an assertion that mixing machines preserves a specified register width.

The simplex on  $\Pi_N(e_0)$  and  $\mathcal{P}(\Theta)$  are compact and convex. The expected payoff is continuous and bilinear. Minimax therefore gives

$$\max_{\lambda \in \Delta(\Pi_N)} \min_{\theta} \sum_{\pi} \lambda_{\pi} g_{\pi}(\theta) = \min_{\mu} \max_{\pi \in \Pi_N} \int g_{\pi} d\mu.$$

For a fixed measure, the terminal maximum is (27), because an event includes precisely the positive coordinates of its signed predictive measure. At a training node one selects an action and, after its observed outcome, selects a continuation tree separately on that branch. The unnormalized branch measure is exactly  $\nu_{a,x}$ . Backward induction proves (28) and identifies the right side with (29). It also proves the finite-linear-functional representation. Compactness gives an optimizing prior and an optimizing mixed tree. Finally, the minimum over fixed parameters of any policy is at most its average under  $\mu$ , which is at most  $F_N(e_0, \mu)$ . This remains true after restricting its memory or architecture.  $\square$

The minimization in (29) occurs once, outside the recursion. It cannot be replaced by fresh adversarial choices after observations. The posterior carries dependence on one fixed unknown parameter. Also, a Bayes-optimal tree for a minimizing prior need not by itself be a minimax policy; the saddle-point mixture is supplied by the finite game in the proof.

**Corollary A.5.2** (Bellman upper certificates). *Suppose functions  $\Psi_n(e, \nu)$  satisfy  $\Psi_0 \geq \Phi$  and, for  $n \geq 1$ , satisfy*

$$\Psi_n(e, \nu) \geq \Phi_e(\nu), \quad \Psi_n(e, \nu) \geq \sum_x \Psi_{n-1}(T(e, a, x), \nu_{a,x}) \quad (a \in \mathcal{A}_e).$$

*Then  $\Psi_N(e_0, \mu)$  is an upper certificate for every admissible architecture and every prior  $\mu$ . The family  $F_n$  is the least such family. An optimal prior can be chosen with at most  $d + 1$  support points, where  $d$  is the affine dimension of  $\{(g_\pi(\theta))_{\pi \in \Pi_N} : \theta \in \Theta\}$ .*

*Proof.* Induction in (28) gives  $F_n \leq \Psi_n$ . The equality case is the recursion itself. The objective depends on a prior only through its vector of integrals of the finitely many  $g_\pi$ . An optimal such vector belongs to the convex hull of their compact evaluation image. Carathéodory's theorem gives the stated support bound while preserving every pure-tree payoff.  $\square$

**Proposition A.5.3** (Causal stability). *Consider two models with the same protocol, alphabets and policy class. Suppose their training rows differ uniformly in total variation by at most  $\epsilon$ , their candidate validation rows by at most  $\eta$ , and their target validation rows by at most  $\beta$ . Their unrestricted values, or their values in any common specified memory class, differ by at most  $2N\epsilon + \eta + \beta$ .*

*Proof.* Use the same policy randomization and couple corresponding training rows while the histories agree. The probability of a first discrepancy is at most  $N\epsilon$ , even with feedback and stopping. Conditional expected validation rewards lie in  $[-1, 1]$ , so differing training histories contribute at most  $2N\epsilon$ . On agreeing histories the same frozen design and event are used, and their conditional mean rewards differ by at most  $\eta + \beta$ . The bound is uniform in the fixed parameter and in the policy. Taking minima and suprema preserves it, with the reverse inequality obtained by interchanging the models.  $\square$

**A.5.1. An informative action choice.** The following calculation distinguishes the controlled theorem from a common-row reduction. Let  $\Theta = \{(i, j) : i, j \in \{0, 1\}\}$ . Action  $R$  reports  $i$ . Action  $L$  reports  $j$  when  $i = 0$  and otherwise reports an independent fair bit. Action  $H$  reports  $j$  when  $i = 1$  and otherwise reports an independent fair bit. The candidate validation is  $\delta_{(i,j)}$  and the target is uniform on  $\Theta$ .

**Proposition A.5.4** (Strict adaptive advantage). *With two training preparations, the unrestricted adaptive value is  $3/4$  and the best nonadaptive value is  $5/8$ . Nonadaptive policies here include mixtures of schedules, with their random schedule retained. No available single training action dominates all the others.*

*Proof.* Take  $R$  first, and then  $L$  or  $H$  according to the observed  $i$ . The parameter is recovered exactly. The complement of its validation atom has score  $3/4$ . No policy can exceed  $\text{TV}(Q, \delta_\theta) = 3/4$  even with full information.

For the converse for fixed schedules, use the uniform prior. For a pair of actions  $a, b$  its Bayes value is explicitly

$$(30) \quad \sum_{x,y,\theta} \left[ \frac{1}{16} \sum_{\vartheta} P_{\vartheta}^a(x) P_{\vartheta}^b(y) - \frac{1}{4} P_{\theta}^a(x) P_{\theta}^b(y) \right]_+.$$

Substitution of the three displayed kernels gives

|     | $R$   | $L$    | $H$    |
|-----|-------|--------|--------|
| $R$ | $1/2$ | $5/8$  | $5/8$  |
| $L$ | $5/8$ | $7/16$ | $1/2$  |
| $H$ | $5/8$ | $1/2$  | $7/16$ |

This is an exact finite sum, not a parameter-grid estimate. It bounds any mixture of fixed schedules by  $5/8$ ; an early stop can be padded with an ignored observation. To attain the bound uniformly in  $\theta$ , choose with equal probabilities the schedules  $(R, L)$  and  $(R, H)$ . When the chosen branch-specific action matches  $i$ , the parameter is known and the score is  $3/4$ . Otherwise only  $i$  is known, and the complement of its two-atom fiber gives score  $1/2$ . Each fixed parameter therefore has mean score  $5/8$ .

Action  $R$  cannot distinguish parameters differing only in  $j$ . Action  $L$  cannot distinguish  $(1, 0)$  and  $(1, 1)$ , and  $H$  cannot distinguish  $(0, 0)$  and  $(0, 1)$ . An experiment which fails to distinguish such a pair cannot garble to one that distinguishes it. Hence no action is a common dominating row.  $\square$

If every binary report is additionally passed through an independent binary symmetric channel of crossover  $\epsilon$ , the primitive training rows change by at most  $\epsilon$  and have full support for  $0 < \epsilon < 1/2$ . Proposition A.5.3, applied to both policy classes, leaves an adaptive advantage at least  $1/8 - 8\epsilon$ , which is positive for  $0 < \epsilon < 1/64$ . Thus the distinction is not confined to disjoint observation supports. The finite-horizon belief recursion and its piecewise-linear structure are classical [1]. The contribution here is their explicit integration with the frozen validation score, one fixed adversarial parameter, outer certificates, and the resource conventions; no priority for Bellman recursion itself is claimed.

#### APPENDIX A.6. CONTROLLED EXPERIMENTS AT A PRESCRIBED MEMORY PROFILE

An unrestricted posterior is a useful information state for a proof, but it is not a free runtime state. We first give a resource-exact dynamic formulation and then solve a controlled family in which replacing that formulation by a policy-tree mixture changes the value strictly.

**A.6.1. A parameterwise occupation state.** Fix a finite horizon  $T$ , a compact metric parameter space  $\Theta$ , finite hidden execution spaces  $H_t$ , and register alphabets  $S_t$  of sizes at most  $K_t$ . The visible inputs to each stochastic row and all legal actions are specified. Any input that must survive a cut belongs to  $S_t$ : this includes a chosen action, an unread report buffer, a stop flag, a selected validation event and a validation accumulator. One may subdivide an operation into several cuts to expose these costs. The scheduled time is available only in the clocked convention.

For now rows at different scheduled times are independently prescribed. Let  $\mathcal{Q}_t$  be the finite product of legal row simplices at stage  $t$ . A prescription  $q \in \mathcal{Q}_t$  is a table, chosen at design time, whose runtime arguments are exactly the declared visible inputs. After summing the fixed environmental kernels its one-stage transition is a stochastic matrix  $M_{t,\theta}^q$  on the hidden-state/register pairs. We assume this matrix is jointly continuous in  $(q, \theta)$ . Both action selection and state updating occur in this matrix, in their specified causal order; it is not an arbitrary matrix chosen separately for each hidden state or each parameter.

For a continuous bundle of probability vectors  $x = (x_\theta(h, s))_{\theta \in \Theta}$  define

$$(\mathcal{T}_{t,q}x)_\theta(h', s') = \sum_{h,s} x_\theta(h, s) M_{t,\theta}^q((h, s), (h', s')).$$

The initial bundle  $x_0$  is fixed by preparation. Terminal rewards  $r_\theta(h, s) \in [-1, 1]$  are continuous in  $\theta$ . Absorbing stopped states and frozen validation phases are included in this execution, not added afterwards without charge. Put

$$(31) \quad B_T(x) = \min_{\theta \in \Theta} \sum_{h,s} x_\theta(h, s) r_\theta(h, s),$$

$$(32) \quad B_t(x) = \max_{q \in \mathcal{Q}_t} B_{t+1}(\mathcal{T}_{t,q}x), \quad 0 \leq t < T.$$

The argument  $x$  is an *offline occupation bundle*, not the realized history, not an observed parameter, and not an additional register made available to the machine.

**Theorem A.6.1** (Resource-exact dynamic value and supersolutions). *For the specified clocked profile and observable-row interface,  $B_0(x_0)$  is the exact maximum worst-case reward over all stochastic controllers. The maximum is attained by a sequence of legal common prescriptions. With the norm  $\|x - x'\| = \sup_\theta \sum_{h,s} |x_\theta(h, s) - x'_\theta(h, s)|$ , each  $B_t$  is 1-Lipschitz. Moreover,*

$$(33) \quad B_0(x_0) = \inf_H H_0(x_0),$$

where the infimum ranges over families of functions on occupation bundles satisfying

$$H_T \geq B_T, \quad H_t(x) \geq H_{t+1}(\mathcal{T}_{t,q}x) \quad (q \in \mathcal{Q}_t).$$

The infimum is attained by  $H = B$ . No convexification over retained controllers and no new adversarial choice after a report occurs in these identities.

*Proof.* For a fixed sequence  $q_0, \dots, q_{T-1}$ , iteration of the displayed transition gives its actual terminal law for every fixed  $\theta$ . The terminal minimum is therefore exactly its worst-case reward. A runtime randomized controller in this interface is precisely such a sequence of common conditional rows; independence of fresh randomization and the declared register specify all its conditional choices. Persistent random correlations are allowed only through that register.

The occupation bundle at the next stage is determined by the current bundle and the prescription, without drawing a realized history in the design problem. Hence optimizing over the remaining prescription sequence gives (32) by ordinary backward induction. This does not select a different continuation for each unrecorded history. Each maximizing  $q$  is still a single legal table common to all hidden histories and parameters. At  $x_0$  one follows the maximizing sequence of design prescriptions, computing their occupation bundles offline; the runtime controller only reads its allowed inputs.

Stochastic matrices contract the  $\ell^1$  norm. The terminal minimum is 1-Lipschitz in the displayed norm. Induction, using the same  $q$  when comparing two bundles and then taking the two maxima, proves the Lipschitz assertion. Joint continuity and compactness of  $\mathcal{Q}_t$  give attainment at each stage, and compactness of  $\Theta$  gives the terminal minimum. Any family  $H$  in (33) bounds the terminal reward along every prescription sequence. Backward induction therefore gives  $H_t \geq B_t$ . Equality is admissible, proving (33) and its attainment.  $\square$

This is a nonlinear supersolution dual, not a least-favorable-prior saddle theorem at fixed width. Its optimization can be large and nonconvex. The principle of dynamic programming is classical; the point of this formulation is that the common-row and memory constraints remain in the maximizations. If rows are shared across scheduled times, as for an autonomous controller, choose the shared rows once and hold them fixed in all subsequent transitions; equivalently augment the *design* problem by that immutable prescription. Maximizing a shared row anew at each time would solve a different problem. A finite union of allowed interfaces can be handled by taking their maximum, or by a fully wired interface with the prescribed profile and its legal observable inputs. Neither operation enlarges a runtime register invisibly.

**A.6.2. An exact informative-control bottleneck.** Fix integers  $m \geq 2$  and  $1 \leq K \leq m$ . The fixed parameter is  $\theta = (i, j) \in [m] \times \{0, 1\}$ . The first training experiment  $R$  reports  $i$ . Across the next cut the controller retains at most  $K$  labels, with an arbitrary stochastic encoder  $E(s | i)$ . It then chooses one of the  $m$  sensing actions with probabilities  $D(a | s)$ . The selected action is kept in a charged  $m$ -state action buffer and the old label is discarded. Action  $a$  reports  $j$  when  $a = i$  and reports  $\perp$  otherwise. The first report is no longer available.

The candidate validation law on  $\{0, 1\}$  is  $\delta_j$ ; the target is uniform. An event is frozen before one fresh candidate and one fresh target validation. Stopping before either training action is permitted. No independent persistent selector is given to the controller. The observation symbols are atomic; a bitwise input implementation would have additional cuts. Denote the maximum worst-case score by  $V_{m,K}$ .

**Theorem A.6.2** (Exact finite-memory control and its convexification gap). *In this protocol,*

$$(34) \quad V_{m,K} = \frac{1}{2\lceil m/K \rceil}.$$

*The value obtained by allowing an uncharged ex ante mixture of complete  $K$ -label controllers is instead*

$$(35) \quad \bar{V}_{m,K} = \frac{K}{2m}.$$

*The inequality is strict whenever  $K$  does not divide  $m$ . The matching controller for (34) has charged cut profile bounded by  $(1, K, m, 3, 6, 3)$ . The  $K$ -label cut controls both retention of the routing observation and the subsequent informative action choice.*

*Proof.* For a fixed  $i$ , let

$$p_i = \sum_s E(s | i) D(i | s).$$

This is the probability of taking the informative action. On its complement, all retained information is independent of  $j$ . Averaging over the two values of  $j$  makes the expected validation score zero there, for any frozen event or randomized response. On the informative part the score is at most  $\text{TV}(\text{Ber}(1/2), \delta_j) = 1/2$ . Thus the minimum over  $j$  at a given  $i$  is at most  $p_i/2$ . A stop before sensing is also uninformative about  $j$  and obeys the same bound; it can be padded by an ignored sensing operation.

Set  $L = \lceil m/K \rceil$ . Since  $p_i \leq \max_s D(i | s)$ , a value  $\min_i p_i > 1/L$  would require every  $i$  to have some row  $s$  with  $D(i | s) > 1/L$ . Each stochastic row has at most  $L - 1$  such indices. But  $K(L - 1) < m$ . This contradiction proves the upper bound. Partition  $[m]$  into at most  $K$  fibers of size at most  $L$ , retain the fiber label after  $R$ , and choose uniformly inside that fiber. On a successful report freeze  $\{1\}$  when  $j = 0$  and  $\{0\}$  when  $j = 1$ ; on  $\perp$  freeze the empty event. The score for every  $j$  is  $1/(2|\text{fiber}(i)|)$ , proving equality. The event alphabet has three labels. Storing the event and its candidate indicator requires at most six labels, and the final difference has three. The chosen sensing action was separately charged, proving the displayed profile.

For the convexified upper bound use the uniform prior on  $(i, j)$ . For any one controller,

$$\frac{1}{m} \sum_i p_i = \frac{1}{m} \sum_{i,s} E(s | i) D(i | s) \leq \frac{1}{m} \sum_{i,s} D(i | s) = \frac{K}{m}.$$

The same upper bound holds for mixtures. For the matching mixture, choose uniformly one of the  $m$  cyclic intervals of  $K$  indices. For that interval hardcode a deterministic  $K$ -label encoder which routes each included index to its own sensing action, and assigns other indices arbitrarily. Each  $i$  belongs to exactly  $K$  intervals. A successful action is followed by the complementary

singleton event and failure by the empty event, as above. Every fixed  $(i, j)$  has mean score  $K/(2m)$ . This proves (35).  $\square$

For example,  $V_{3,2} = 1/4$  whereas  $\bar{V}_{3,2} = 1/3$ . The mixture just constructed can be implemented with a retained interval selector and a local label, using at most  $mK$  labels at the bottleneck. It cannot be declared a  $K$ -label realization: when the displayed gap is positive, (34) proves that no such realization exists. The action buffer of size  $m$  is not part of the  $K$  coordinate and has not been omitted from the profile. The theorem is a multicut resource law, not an assertion that its uniform peak equals  $K$ .

The actions are statistically incomparable.  $R$  cannot distinguish the two values of  $j$  at any fixed  $i$ , while action  $a$  does distinguish them at  $i = a$ . For  $a \neq b$ , action  $a$  does not distinguish the pair with  $i = b$ , while  $b$  does. A parameter-independent garbling cannot create a distinction absent from its input experiment.

**Corollary A.6.3** (A strict gap with positive report probabilities). *Replace each of the two training kernels by a mixture with weight  $\epsilon > 0$  of the uniform law on its report alphabet. Let  $\Delta_{m,K} = K/(2m) - 1/(2\lceil m/K \rceil) > 0$ . For  $\epsilon < \Delta_{m,K}/8$  the resulting full-support model still has a strict gap between the genuine profile-constrained value and its free-selector converification.*

*Proof.* Each training row changes by at most  $\epsilon$  in total variation. Couple corresponding rows until the first disagreement. For any fixed controller or mixed controller the probability of such a disagreement is at most  $2\epsilon$ , and its conditional reward lies in  $[-1, 1]$ . Each of the two optimal values changes by at most  $4\epsilon$ . Their difference is therefore at least  $\Delta_{m,K} - 8\epsilon > 0$ . All row arguments and register alphabets are unchanged.  $\square$

The distinction between mixed and behavioral strategies without perfect recall is classical; it is not first asserted here. Contemporary polynomial formulations over behavioral simplices include [16]. Theorem A.6.2 evaluates the discrepancy in this specific frozen-validation experiment for every  $m, K$ , with a matching actual register and a noisy persistence statement. In particular, a single prior followed by an unrestricted policy-tree best response cannot be substituted for (32).

## APPENDIX A.7. SADDLE FACES AND CAUSAL REALIZATION

The statistical saddle and its implementation are different objects. The former is convex; the latter need not be. The purpose of this section is to retain that distinction while extracting memory obstructions from an unrestricted saddle. In particular, a zero Bayes coefficient must not be discarded before the contact conditions at the worst parameters have been imposed.

**A.7.1. A normal form over a finite causal interface.** Fix a finite horizon and finite action and report alphabets. An action  $a_t$  is chosen before report  $y_t$ . A terminal output is included as one last action, followed by a dummy report. Illegal actions can be removed from each protocol type; equivalently, use a fixed padding of the finite protocol tree and impose its zero constraints. Define a *causal response array*  $C(\mathbf{a} \mid \mathbf{y})$  by nonnegativity, normalization in  $\mathbf{a}$  for every  $\mathbf{y}$ , and the requirement that its marginal on  $a_1, \dots, a_t$  depends only on  $y_1, \dots, y_{t-1}$ . The resulting set  $\mathcal{C}$  is a finite polytope. Conditioning successive marginals realizes every such array by a full-history randomized controller; arbitrary versions on zero marginals do not change the array.

For a fixed parameter  $\theta$ , the environment has a history-dependent likelihood  $L_\theta(\mathbf{a}, \mathbf{y})$ , obtained by marginalizing its hidden states. The bounded reward has the linear form

$$(36) \quad g_\theta(C) = \sum_{\mathbf{a}, \mathbf{y}} L_\theta(\mathbf{a}, \mathbf{y}) r_\theta(\mathbf{a}, \mathbf{y}) C(\mathbf{a} \mid \mathbf{y}).$$

Assume its coefficient vector is continuous on a compact metric parameter space. The parameter is fixed once, not selected after a report. Protocol-specific equalities, including a frozen validation

choice, are represented by the corresponding finite protocol tree. A discarded protocol choice is not supplied again as a free input.

Here is an explicit positive realization of a response array. At cut  $t$  use  $k_t$  states, an initial distribution  $\alpha$ , and nonnegative matrices  $M_t^{a,y}$  of size  $k_{t-1}$  by  $k_t$  such that

$$(37) \quad M_t^{a,y} \mathbf{1} = p_t(a), \quad \sum_a p_t(a) = \mathbf{1}, \quad p_t(a) \text{ is independent of } y.$$

Then

$$(38) \quad C(\mathbf{a} \mid \mathbf{y}) = \alpha M_1^{a_1, y_1} \cdots M_T^{a_T, y_T} \mathbf{1}.$$

The independence in (37) is essential: otherwise an action could use its not-yet-observed report. If an action or an input must survive an intermediate cut, split this formula at that cut and include its buffer in the state alphabet. Likewise, impose any declared shared-row constraints before optimizing. An externally fixed clock permits time-dependent matrices; an autonomous implementation has to store its phase or use the prescribed shared rows.

**Proposition A.7.1** (Outer normal form and compatible continuations). *For the finite interface and declared cuts, the response arrays of all controllers with profile at most  $\mathbf{K}$  are exactly the arrays (38) with  $k_t \leq K_t$ , the normalization (37), and the declared interface constraints. This set, denoted  $\mathcal{C}_{\mathbf{K}}$ , is compact. The assertion is over all wirings of the allowed register, not one chosen transition graph.*

*Equivalently, there are at most  $K_t$  normalized continuation arrays  $B_{t,s}$  at each cut, with terminal continuation 1, and common nonnegative coefficients satisfying*

$$(39) \quad B_{t-1,s}(a\mathbf{a} \mid y\mathbf{y}) = \sum_{s'} M_t^{a,y}(s, s') B_{t,s'}(\mathbf{a} \mid \mathbf{y}), \quad C = \sum_s \alpha(s) B_{0,s}.$$

*Separate positive factorizations at the cuts are not sufficient without these common shift identities.*

*Proof.* In a controller, let  $p_t(a \mid s)$  be its action row and  $q_t(s' \mid s, a, y)$  its update row. Their product defines  $M_t^{a,y}$  and gives (37). Multiplication over a complete execution gives (38). Every finite wiring embeds into the fully connected register by assigning zero to unused transitions; smaller alphabets are padded by unused states. Thus no further maximization over graph presentations is necessary.

Conversely choose action  $a$  with probability  $p_t(a \mid s)$ , and, after observing  $y$ , use the row  $M_t^{a,y}(s, s')/p_t(a \mid s)$  when the denominator is positive. At a zero denominator the entire corresponding nonnegative row vanishes; choose an arbitrary legal update there. This gives exactly the required runtime arguments. It does not expose a posterior, the parameter, or an offline occupation array to the machine. Apply the same construction at each declared buffer cut. A product of finitely many stochastic row simplices is compact; closed legality and sharing constraints preserve compactness. Its continuous image is  $\mathcal{C}_{\mathbf{K}}$ .

The future execution starting at a state  $s$  defines  $B_{t,s}$  and satisfies (39). Conversely, induction from the terminal continuation and these identities gives the product formula. Thus the continuation description has exactly the same realizations. In particular, independently selected factorizations at different cuts cannot be spliced unless the shift equations hold.  $\square$

This is a finite controlled positive-realization statement. The role of positivity and invariant generating cones in stochastic realization is classical [17, 18, 19]. Ordinary linear rank need not be a state count. Here the additional statistical question is which positive realizations meet an optimal saddle face. Proposition A.7.1 provides a normal form, not an efficient factorization algorithm. It also does not compactify an unbounded number of observable operations.

**A.7.2. The realization theorem.** Let

$$U = \max_{C \in \mathcal{C}} \min_{\theta} g_{\theta}(C), \quad V_{\mathbf{K}} = \max_{C \in \mathcal{C}_{\mathbf{K}}} \min_{\theta} g_{\theta}(C).$$

By compact convex minimax there is a least-favorable prior  $\mu_*$  with  $U = \max_{C \in \mathcal{C}} \int g_{\theta}(C) d\mu_*$ . Put

$$\begin{aligned} \ell_*(C) &= \int g_{\theta}(C) d\mu_*, \\ F_* &= \{C \in \mathcal{C} : \ell_*(C) = U\}, \\ \mathcal{S}_* &= F_* \cap \bigcap_{\theta} \{C : g_{\theta}(C) \geq U\}. \end{aligned} \tag{40}$$

The set  $F_*$  is an exposed face. The second intersection is important: a Bayes best response to a least-favorable prior need not be minimax.

Here  $\mathcal{C}$  is the full-history convex reference for the finite protocol. A nonconvex restriction, such as reuse of one stochastic table at several visits, is imposed on  $\mathcal{C}_{\mathbf{K}}$ , not inserted into  $\mathcal{C}$  before invoking convex minimax. In that case  $U$  is a reference upper value unless exactness for the unrestricted physical class is separately known. In the reset applications below that exactness is supplied by Theorems A.4.1 and A.4.2.

**Proposition A.7.2** (Bayes loss and worst-case loss). *Under the preceding assumptions,*

$$U - V_{\mathbf{K}} = \min_{C \in \mathcal{C}_{\mathbf{K}}} \left\{ U - \ell_*(C) + \ell_*(C) - \min_{\theta} g_{\theta}(C) \right\}. \tag{41}$$

*Both summands are nonnegative and the minimum is attained.*

*Proof.* The prior average is at most  $U$  and at least the minimum over fixed parameters. The sum in braces equals  $U - \min_{\theta} g_{\theta}(C)$ . Minimizing on the compact realization set proves the assertion.  $\square$

**Theorem A.7.3** (Saddle-face contact and compatible realization). *Under the preceding assumptions,  $V_{\mathbf{K}} = U$  if and only if some array in  $\mathcal{S}_*$  has compatible positive continuation generators of profile at most  $\mathbf{K}$ . If no such generators exist,  $V_{\mathbf{K}} < U$  strictly.*

*For  $C \in \mathcal{S}_*$  one has  $g_{\theta}(C) = U$  on  $\text{supp } \mu_*$ . At an interior supporting parameter at which the payoff is differentiable,  $\nabla_{\theta} g_{\theta}(C) = 0$ . These equalities and stationarity conditions hold also in directions whose Bayes coefficient vanishes.*

*At any reset continuation cut, let  $R_h$  denote the conditional channel of future outputs under each externally specified future input word. It factors as*

$$R_h = \sum_{s=1}^{K_t} E(s \mid h) B_s, \quad E(\cdot \mid h) \in \Delta_{K_t}, \tag{42}$$

*with one common family of continuation channels  $B_s$ . Any obstruction to this positive factorization for every member of  $\mathcal{S}_*$  is therefore a memory obstruction for every admissible architecture, regardless of its training wiring.*

*Proof.* By Proposition A.7.2, the two nonnegative losses vanish exactly when  $C$  belongs to  $\mathcal{S}_*$ . Proposition A.7.1 then proves the realization criterion. Compactness makes nonintersection a strictly positive value loss, not merely failure of one optimizer.

For an optimal array,  $g_{\theta}(C) - U$  is continuous, nonnegative, and has zero  $\mu_*$  integral. It is zero on the support of that measure. Every interior zero is a local minimum, so its gradient vanishes. No strict-sign hypothesis on individual coordinates is needed. Finally condition on the actual retained state at a reset cut. Given that state, the future program receives the same

specified inputs and has the same output law, irrespective of the discarded past. Averaging gives (42). All persistent random variables are part of that state. The assertion can equivalently be checked on controller input tapes, using the generators in (39); it does not assume that a hidden physical state resets at a cut where the interface has not reset it.  $\square$

The identity (41) is an exact loss decomposition, not a new interchange of a minimum and maximum over nonconvex machines. Its use is that an unrestricted certificate identifies a finite face, while contact at its supporting parameters can determine the remaining coordinates. The resulting channels are then tested for causal realizability. This is stronger than choosing an arbitrary Bayes tie rule and counting the states of that one rule.

**Corollary A.7.4** (Explicit coefficient form for frozen validation). *In the reset experiment of (24), write*

$$C_{z\omega}^* = \int P_{\theta}^{\otimes N}(z)(Q(\omega) - P_{\theta}(\omega)) d\mu_*(\theta).$$

The first summand of (41) is exactly

$$(43) \quad \sum_{C_{z\omega}^* > 0} C_{z\omega}^*(1 - h_z(\omega)) + \sum_{C_{z\omega}^* < 0} |C_{z\omega}^*| h_z(\omega).$$

Thus optimality fixes every strict-sign coordinate, while the support contact and stationarity equations must still be imposed at the zeros. For  $K$  labels at the post-training decision cut, an arbitrary upstream encoder gives the compact relaxation

$$(44) \quad h_z(\omega) = \sum_{s=1}^K E(s | z) D_s(\omega), \quad E \in (\Delta_K)^{\Omega^N}, \quad D_s \in [0, 1]^{\Omega}.$$

If this relaxation misses the saddle set, its strictly positive gap bounds every smaller architectural class.

*Proof.* Maximizing each coefficient separately gives the sum of its positive part. Subtraction gives (43). Conditioning on the decision state gives (44); the post-cut randomization is independent of the discarded word. Conversely an arbitrary encoder and a response list realize this factorization when other memory is unrestricted. The parameter spaces in (44) are compact, so the final assertion follows from Theorem A.7.3.  $\square$

**A.7.3. Faces as memory witnesses.** For a finite input set  $\mathcal{Y}$  and output alphabet  $\mathcal{D}$ , continuation channels form the polytope  $\mathcal{P} = \prod_{y \in \mathcal{Y}} \Delta(\mathcal{D})$ . Its vertices are deterministic output functions. The analogous polytope for scalar test responses is  $[0, 1]^{\mathcal{Y}}$ .

**Lemma A.7.5** (Vertex and face packing). *Suppose channels to be factored through one common state alphabet include  $s$  distinct vertices  $v_1, \dots, v_s$  of a polytope  $\mathcal{P}$  and rows  $r_1, \dots, r_j$ . Suppose  $r_i \in F_i$ , the faces  $F_i$  are pairwise disjoint, and*

$$r_i \notin \text{conv}\{v_a : v_a \in F_i\}.$$

*Every factorization of these rows as stochastic mixtures of generators in  $\mathcal{P}$  needs at least  $s + j$  generators.*

*Proof.* A convex decomposition of a vertex uses that same vertex at every positive coefficient. Hence all  $s$  vertices must occur among the generators. If a convex combination belongs to a face, all generators with positive coefficients belong to that face. The stated exclusion therefore forces an additional generator in each  $F_i$ . Pairwise disjointness prevents any such generator from serving two faces.  $\square$

The lemma does not assert that a stochastic state must itself be a history residual. Its generator can be any channel in the ambient polytope. This is why the argument also excludes randomized encoders and randomized continuations. It is a positive-factorization argument, not ordinary matrix rank or a restriction to a deterministic compiler.

**Proposition A.7.6** (Resource equivalence and stable obstructions). *A causal, cut-preserving recoding with a causal inverse, both using only one transducer state and preserving the payoff, preserves every  $V_{\mathbf{K}}$ ,  $U$ , and the set of profiles attaining  $U$ . More generally suppose simulations in both directions have defect at most  $\epsilon$  and require at most  $R_t$  states at cut  $t$ . For rewards in  $[-1, 1]$ ,*

$$V_{\epsilon}(\mathbf{RK}) \geq V_{\mathfrak{F}}(\mathbf{K}) - 2\epsilon, \quad V_{\mathfrak{F}}(\mathbf{RK}) \geq V_{\epsilon}(\mathbf{K}) - 2\epsilon.$$

*For a common controller class and training-validation kernels whose values differ by at most  $\eta$ , a gap  $U - V_{\mathbf{K}} = \delta$  remains at least  $\delta - 2\eta$  after the perturbation.*

*Proof.* Transport a controller through each simulator and retain the product of its state and the simulator state. Apply the uniform bounded-reward variation bound and optimize. With an exact one-state inverse the two inequalities are equalities at the same profile. In the last assertion both the unrestricted and the constrained optimum change by at most  $\eta$ ; subtract their two bounds. The state products must be applied at the actual buffer cuts, not only at the terminal decision.  $\square$

These statements place the saddle face, the future-test quotient, and resource-aware causal morphisms in one theorem chain. The channel factorizations are presentation-independent under the stated causal recodings. The memory obstruction in the next section is derived from the experimental coefficients themselves, not from a metric dimension or a covering exponent supplied as an additional hypothesis.

#### APPENDIX A.8. FACIAL CERTIFICATES FOR SCHEDULE-OPTIMIZED MEMORY

A schedule is part of the resource problem. The following criterion extracts a whole family of schedule converses from a saddle, rather than minimizing the states of one selected program. Its hypotheses are finite identities of continuation functions and faces. Its conclusion applies to arbitrary stochastic state encoders.

Consider finitely many validation tapes, with a fixed internal order on each tape and finitely many symbols per slot. A *declared-clock schedule* is a word specifying which tape supplies each successive slot; it is fixed before training and is independent of all reports. Let  $\mathcal{G}$  be the finite acyclic graph of consumed-prefix counts. Its directed paths from the initial vertex to the final vertex are the legal schedules. This includes all interleavings, not only serial ones. The lower bound below does not give an adaptive scheduler free storage: a report-dependent choice of the next tape belongs to a different controlled interface and requires its own charged rows.

At a vertex  $v$  of  $\mathcal{G}$ , a retained state supplies a conditional channel on the unread tape suffixes. Assume in this section that every prefix and suffix combination used in a witness has positive probability under a supporting experiment. One may instead restrict to a stated common suffix subalphabet with this property. The channels form a product of probability simplices, denoted by  $\mathcal{P}_v$ .

**Definition A.8.1** (Contact-forced facial certificate). A certificate at  $v$  consists of distinct deterministic channels  $d_1, \dots, d_s$  and channels  $r_1, \dots, r_j$ , such that every minimax-optimal auditor has these rows among its conditional continuations, allowing parameter-independent averaging of specified past rows. Each  $r_i$  lies in a face  $F_i$  of  $\mathcal{P}_v$ , the faces are pairwise disjoint, and

$$r_i \notin \text{conv}\{d_a : d_a \in F_i\}.$$

Its certified capacity is  $s + j$ . Define  $c(v)$  to be the largest such capacity within a declared finite witness family. Conditional averaging must retain the same future-input coordinates and may not add the unknown parameter as an input. A channel of mean zero is not thereby a deterministic zero channel.

For an upper certificate choose a minimax-optimal finite randomization over frozen deterministic events, with the selected event retained at the decision cut. Let  $\mathcal{D}_v$  be its distinct future deterministic output functions after all possible supported prefixes at  $v$ . When the input support is a full product, equality of these functions is closed under every next-symbol restriction. Put  $r(v) = |\mathcal{D}_v|$ . More general supported experiments may use any explicitly supplied shift-compatible deterministic completion; merely minimizing separate partial-function covers at different cuts is insufficient.

**Theorem A.8.2** (Facial capacity and schedule realization). *Suppose contact with the unrestricted saddle supplies the preceding certificates. For each declared-clock path  $\pi$  and every stochastic auditor on that path attaining the unrestricted value,*

$$(45) \quad W(\pi) \geq \max_{v \in \pi} c(v).$$

*A shift-compatible deterministic residual family realizes the selected optimal event rule simultaneously with widths  $r(v)$  along any such path. If its training and selection peak is  $W_0$ , then*

$$(46) \quad \min_{\pi} \max_{v \in \pi} c(v) \leq W_{\text{clk}}^{\min} \leq \min_{\pi} \max \{W_0, \max_{v \in \pi} r(v)\}.$$

*In particular, a certificate and a realizing path with the same peak identify the exact minimum over all declared-clock schedules and all stochastic architectures on those schedules. If  $c(v) = r(v)$  at every vertex and  $W_0$  does not exceed the path peak, the entire minimum-profile problem reduces to the intrinsic capacity field on  $\mathcal{G}$ . The peak optimum of that field is computed by*

$$(47) \quad b(v_0) = c(v_0), \quad b(v) = \max\{c(v), \min_{u \rightarrow v} b(u)\}.$$

*The result is invariant under bijective, causal, slot-preserving recodings of the tape alphabets.*

*Proof.* Condition on a charged retained state at  $v$ . Every past row is a stochastic mixture of the same at most  $W(\pi)$  future channels. Parameter-independent averaging preserves this factorization. The face-packing lemma therefore gives at least  $s + j$  states for each certificate, proving (45). This step ranges over all state wirings and all stochastic encoders, not a specified graph.

For the upper bound retain the current residual output function. If two residuals agree on the future input product, their restrictions after each legal next symbol agree as well. Therefore the next retained label is determined by the old label and that symbol. At the last cut it is the output itself. This constructs all cuts compatibly in one machine. The initially sampled event and its training selector are charged in  $W_0$ . Optimizing the two bounds over the finite path set proves (46). The recursion follows by classifying paths according to their last edge and taking the maximum with the cost of the final vertex. Induction proves it on the acyclic graph. Finally, a bijective recoding induces an affine isomorphism of every channel polytope, preserving vertices, faces, conditional averages and restriction maps. It preserves both certificates and realizing paths.  $\square$

The general positive-realization normal form and residual quotient have classical antecedents [17, 18, 19]. The minimization of partially specified machines likewise requires compatible coverings, not unrelated cutwise minima [20]. The contribution used here is different: the witness rows are forced by *every member of the uniform saddle*, through contact on its Bayes-indifferent coordinates. This makes the lower field independent of a chosen optimal program.

The criterion is a certificate theorem for this class of experiments, not an assertion that arbitrary nonnegative-rank problems have become easy or that facial packing is always exact.

#### APPENDIX A.9. EXACT MINIMAX LAWS FOR A MARKED PRODUCT FAMILY

The posterior-predictive dual can be solved explicitly for a continuous family containing the collision target. Throughout this section, the training and candidate validation law is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

In the order 000, 001, 110, 111, let  $Q_\gamma$  have masses

$$((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4),$$

and zero mass elsewhere. Write  $U_1(\gamma) = U_1(b, Q_\gamma)$ , with exactly the training-validation convention of (24). Set

$$(48) \quad \gamma_* = 1 - 1/\sqrt{2}, \quad s_\gamma = \sqrt{\gamma^2 - 2\gamma + 5}, \quad u_\gamma = \gamma - 2 + s_\gamma, \quad \tau_\gamma = \frac{2u_\gamma}{u_\gamma + 2 - \gamma}.$$

**Theorem A.9.1** (Exact marked minimax family). *For every  $0 \leq \gamma \leq \gamma_*$ ,*

$$(49) \quad U_1(\gamma) = \frac{3 + u_\gamma^2}{8}.$$

*An optimal response depends on the training word only through the report count  $K = X_1 + X_2$ . On the four target atoms its rows are*

$$(50) \quad h_0 = (\tau_\gamma, 0, 1, 1), \quad h_1 = (1, 1, 1, 1), \quad h_2 = (1, 1, 0, \tau_\gamma),$$

*and all responses are zero off these atoms. A least-favorable prior is*

$$(51) \quad \mu_\gamma = \frac{1}{2}\delta_{(t_\gamma, t_\gamma)} + \frac{1}{2}\delta_{(1-t_\gamma, 1-t_\gamma)}, \quad t_\gamma = \frac{1 - \sqrt{u_\gamma}}{2}.$$

*The assertion optimizes over all stochastic responses to the full marked training word, not merely over count-based or symmetric responses.*

*Proof.* First,  $u_\gamma$  is the positive root of

$$(52) \quad u^2 + (4 - 2\gamma)u - (1 + 2\gamma) = 0.$$

On the asserted interval,  $0 < u_\gamma < 1$  and  $0 < \tau_\gamma < 1$ . Indeed the polynomial is negative at zero and positive at one; also  $u_\gamma < 2 - \gamma$  because  $\gamma < 1/2$ . Substitution of  $1 - 2\gamma$  into the polynomial gives  $8(\gamma^2 - 2\gamma + 1/2)$ , which is nonnegative precisely on the present interval. Monotonicity on  $[0, \infty)$  therefore gives

$$(53) \quad u_\gamma \leq 1 - 2\gamma.$$

Put  $a = (1 - p)(1 - q)$ ,  $c = pq$ , and  $z = 1 - a - c$ . The probabilities of the three training counts are  $a, z, c$ . The independent training mark may be discarded by the displayed construction. Let  $G_\gamma(p, q)$  denote its score. With  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ , direct expansion gives

$$(54) \quad G_\gamma(p, q) - \frac{3 + u_\gamma^2}{8} = \frac{2 - \tau_\gamma}{16} \{(u - v - u_\gamma)^2 + 4v\}.$$

For clarity, this identity follows by substituting the three rows of (50) into

$$a(Q_\gamma - b)h_0 + z(Q_\gamma - b)h_1 + c(Q_\gamma - b)h_2,$$

using  $a + c = (1 + u - v)/2$ ,  $a - c = -(p + q - 1)$ , and then eliminating  $u_\gamma^2$  by (52). The coefficient of the resulting square is  $(2 - \tau_\gamma)/16$  and that of  $v$  is four times this coefficient. Both

are nonnegative. Equality holds at both points of (51), since there  $v = 0$  and  $u = u_\gamma$ . This proves the lower bound and identifies its equality set.

It remains to bound every response, including nonsymmetric ones. Use (51) in Theorem A.4.1. At  $t = t_\gamma$  put  $a = (1 - t)^2$ ,  $c = t^2$ , and  $T = a + c = (1 + u_\gamma)/2$ . For the training report pair 00, the four dual coefficients, apart from a common positive factor, are

$$(55) \quad \left( Q_H T - \frac{a^2 + c^2}{2}, \quad Q_L T - \frac{a^2 + c^2}{2}, \quad Q_L T - ac, \quad Q_H T - ac \right),$$

where  $Q_H = (1 + \gamma)/4$  and  $Q_L = (1 - \gamma)/4$ . The first coordinate is zero by (52); the second is  $-\gamma T/2 \leq 0$ . The last two are positive:  $T \geq 1/2$ ,  $ac \leq 1/16$ , and  $\gamma < 1/2$  imply  $Q_L T > 1/16 \geq ac$ . Thus  $(\tau_\gamma, 0, 1, 1)$  maximizes this linear functional. For the training pair 11, reversing all report bits and the mark reverses the four coordinates and gives the row  $h_2$ .

For either training pair 01 or 10, the two prior support points have the same likelihood  $t(1 - t)$ . The posterior is still equally weighted, and the candidate predictive mass at each target atom is  $T/4$ . Every one of the four coefficients is therefore nonnegative by  $Q_L - T/4 = (1 - 2\gamma - u_\gamma)/8 \geq 0$ . The response  $h_1$  is optimal. At off-diagonal validation atoms the target mass vanishes and the coefficient is nonpositive. Finally, conditioning on either training mark multiplies all these coefficients by  $1/2$ ; it creates no further optimizing choice. We have therefore optimized every coordinate of the full marked-word response space.

The prior average of the displayed response equals its value at either support point, namely  $(3 + u_\gamma^2)/8$ , by (54). Every other response has prior average at most this number and hence has minimum over fixed  $(p, q)$  at most this number. Together with the lower bound this proves (49), optimality of the response, and least favorability of the prior.  $\square$

**Corollary A.9.2** (The exact one-preparation collision value). *For  $Q_* = Q_{1/4}$ ,*

$$(56) \quad U_1(b, Q_*) = u_{\text{ex}} := \frac{85 - 7\sqrt{73}}{64}, \quad u_{1/4} = \frac{\sqrt{73} - 7}{4}, \quad \tau_{1/4} = 2 - \frac{14}{\sqrt{73}}.$$

*If only the target changes to  $Q$ , then  $|U_1(b, Q) - u_{\text{ex}}| \leq \text{TV}(Q, Q_*)$ .*

*Proof.* Substitute  $\gamma = 1/4$  in Theorem A.9.1. For a fixed trained response the target perturbation is at most total variation, uniformly in  $(p, q)$ . Taking first the minimum and then the maximum preserves this bound in both directions.  $\square$

**A.9.1. Complementary slackness and the event alphabet.** The tie in the first coordinate of (55) explains the randomization. Any value of that response coordinate is Bayes-optimal for the two-point prior. The minimax choice makes the uniform payoff stationary at its two support points; solving this condition gives  $\tau_\gamma$  and the square identity (54). This derives the prior and response together, rather than postulating that a numerically effective prior is optimal.

Operationally, for  $K = 0$  one draws once between the events with indicator vectors  $(0, 0, 1, 1)$  and  $(1, 0, 1, 1)$ , with probabilities  $1 - \tau_\gamma$  and  $\tau_\gamma$ . For  $K = 2$  one draws between  $(1, 1, 0, 0)$  and  $(1, 1, 0, 1)$ . For  $K = 1$  the event is  $(1, 1, 1, 1)$ . The resulting event identity is retained and used for both fresh validations. These are exactly the five events in the two-preparation construction below. The one-preparation theorem supplies their complementary-slackness interpretation; it does not prove that the two-preparation selector is optimal. The four-point rational prior retained below is a useful rational certificate, not a least-favorable prior.

The exact response uses an atomic stochastic row. It does not receive free persistent randomness. Replacing  $\tau_\gamma$  by a dyadic number within  $2^{-b}$  changes each conditional response, and hence the score, by at most  $2^{-b}$ . A sequential fair-bit implementation must retain its bit

prefix and event identity. None of these implementation costs is needed by the deterministic two-preparation physical audit.

**Proposition A.9.3** (The zero-preparation endpoint). *For  $0 \leq \gamma \leq 1$ ,  $U_0(b, Q_\gamma) = \gamma/2$ .*

*Proof.* The fixed event  $\{000, 111\}$  has score  $(1 + \gamma)/2 - (a + c)/2 \geq \gamma/2$  because  $a + c \leq 1$ . Conversely, the equally weighted prior on  $b(0, 0)$  and  $b(1, 1)$  has predictive validation law uniform on the four target atoms. Its total variation from  $Q_\gamma$  is  $\gamma/2$ . Theorem A.4.1 with  $N = 0$  gives the matching upper bound.  $\square$

#### APPENDIX A.10. A SELF-CONTAINED COLLISION INTERFACE

We give the preparation, mechanical estimate, observation law and private simulator class needed for the physical specialization. The following argument does not appeal to an unpublished physical lemma. It retains the same positive-volume preparation and positive sensor noise as the earlier collision construction.

**Definition A.10.1** (The reset row–event architecture). A preparation supplies two sequential report slots and, afterwards, an actual mark. The source reports in the two slots are constant. A private width-one simulator has no retained information between those slots and no persistent hidden seed. It may use fresh independent coins. Its first emission is  $X_1 \sim \text{Ber}(p)$ ; after receiving the current gate  $A \in \{0, 1\}$ , its second emission has a fixed Bernoulli kernel with parameter  $q_A$ . The parameters  $(p, q_0, q_1)$  are fixed throughout the audit. The simulator does not observe the actual mark. All its coins are independent of that mark. Different preparations reset all unretained variables and are independent conditional on the parameters.

The auditor observes the first report, chooses a gate using its retained state and that report, observes the second report, and then observes the mark. During training it may choose rows and stop adaptively, using at most the declared number of candidate preparations. It next freezes one gate policy and one event, with any retained random choice included in its register. It uses that same row–event continuation on one fresh candidate preparation and one independent target preparation and returns the difference of their event indicators, target minus candidate. It may not reselect the event after either validation. Independent target-only calibration is allowed but all retained calibration and randomness are charged. Peak width counts every bit, mark, event and validation-accumulator cut. Clocked schedules are declared externally; an autonomous implementation must retain its phase. An unretained transcript, seed or stopping-time value is not available to a continuation.

In the all-on row the complete private law is  $b(p, q_1)$ , with an independent fair actual mark. For lower bounds it suffices to restrict the adversary to  $q_0 = 0$ ,  $q_1 = q$ . In this subfamily every deterministic gate policy is the pushforward

$$T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$$

of  $b(p, q)$ . The gate, when included in the transcript, is another function of these same coordinates. Randomized gate policies are covered by averaging their independent random tables. This proves both the all-on product characterization for the upper construction and the common-garbling subfamily used for the outer converse. The width-one constraint is a simulator constraint; it is not an uncharged restriction on the auditor’s register.

**A.10.1. Preparation and elastic scattering.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$ , with no walls and contact distance  $d$ . Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ ,  $V = (v_1 + v_2)/2$ , and let the center of mass position range over any fixed rational box of positive volume. Prepare

$(B, W) \in \{0, 1\}^2$  with probability  $5/16$  at  $B = W$  and  $3/16$  at  $B \neq W$ . Conditional on  $(B, W)$ , use the uniform product preparation on the following boxes:

$$(57) \quad \begin{aligned} r &= (-a_0, (2B-1)b_0, c_0), & a_0 &\in [29/10, 31/10], & b_0 &\in [9/20, 11/20], \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & & & |V_z - (2W-1)| &\leq 1/100. \end{aligned}$$

Thus the actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ , preserved by momentum conservation. Set

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector, identically zero on the incoming transverse-velocity range.

**Lemma A.10.2** (Uniform collision signal). *For every preparation in (57) and every  $9/10 \leq d \leq 11/10$ , exactly one collision occurs and its time lies in  $(4/5, 3/2)$ . Afterwards*

$$(2B-1)v_{1,y} > 1/2, \quad (2B-1)h(v_{1,y}) > 1/4.$$

For  $0 < d \leq 2/5$  no collision occurs on  $[0, 3]$  and the detector is zero throughout that interval.

*Proof.* Before contact,  $r(t) = r + tg$ . At  $t \leq 4/5$  its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At  $t = 3/2$  its absolute coordinate bounds are  $1/4, 113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . The first contact therefore occurs in the claimed interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$ . Hence the entry contact has  $n_x < 0$ , where  $n = r(t_c)/d$ . Its remaining coordinates give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B-1)n_y \geq 87/220.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The elastic rule gives

$$v_1^+ = V + g/2 - (g \cdot n)n, \quad g^+ = g - 2(g \cdot n)n.$$

Consequently

$$(2B-1)v_{1,y}^+ > -3/200 + (1443/1000)(87/220) > 1/2.$$

The definition of  $h$  implies the signal bound. Since  $r(t_c) \cdot g^+ > 0$ , squared separation increases strictly afterwards; there is no second collision. Finally, for  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . There is no contact, and the incoming  $|v_{1,y}| \leq 3/200$  makes  $h$  zero.  $\square$

**A.10.2. Positive noise and the actual mark.** Let  $\mathcal{B}_t$  be Brownian motion independent of the preparation and set

$$Y_t = \int_0^t h(v_{1,y}(s)) ds + \sigma \mathcal{B}_t, \quad 0 < \sigma \leq 1/24.$$

The two potential all-on reports are

$$Z_1 = \mathbf{1}_{\{2(Y_2 - Y_{3/2}) > 0\}}, \quad Z_2 = \mathbf{1}_{\{2(Y_3 - Y_{5/2}) > 0\}}.$$

The actual second report is  $AZ_2$ . The gate changes acquisition, not the mechanical path. The continuous path is implemented by the target sensor; it is not made available to the private simulator or supplied as an uncharged auditor buffer. Denote the law of  $(Z_1, Z_2, W)$  by  $Q_{d,\sigma}$ .

**Theorem A.10.3** (Uniform physical presentation). *For  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ ,*

$$(58) \quad \text{TV}(Q_{d,\sigma}, Q_*) < 1/300.$$

*The same estimate holds after every declared feedback gate, including its observable gate value. The all-on private product family and the common-garbling subfamily in Definition A.10.1 apply to this very experiment.*

*Proof.* Every collision occurs before  $3/2$ . Conditional on the preparation, the two normalized sensor windows are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . Lemma A.10.2 makes their means have sign  $2B - 1$  and magnitude greater than  $1/4$ . Each potential report therefore differs from  $B$  with probability less than  $\Phi(-3)$ . The Gaussian tail estimate

$$\Phi(-x) \leq \frac{e^{-x^2/2}}{x\sqrt{2\pi}}$$

gives  $\Phi(-3) < 1/600$ :  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$  suffice. Couple the ideal and noisy reports using the same preparation, actual mark and gate random table. Except on a set of probability less than  $2\Phi(-3) < 1/300$ , both potential reports equal  $B$  and the entire gated transcript agrees. The ideal marked law is precisely  $Q_*$ , by the prepared  $(B, W)$  table. This proves (58) and the feedback-uniform version. Finally, the source is blind, its actual mark is unobserved by the simulator, and the gate is its only current input at the second emission. The product and subfamily assertions follow from the two independent private-emission kernels specified above.  $\square$

For  $d \leq 2/5$ , the two windows instead contain only independent centered Gaussian noise. Their signs are independent fair bits, independent of  $W$ , and a private width-one simulator reproduces every gated row exactly. Thus the informative regime and its no-collision control use the same detector, preparation convention and actual mark.

#### APPENDIX A.11. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1-p)(1-q)$  and  $c = pq$ . On the ordered atoms

$$(59) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(60) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \longrightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (60). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in Definition A.10.1 and Theorem A.10.3, explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem A.11.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (18). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(61) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

*from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.*

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

#### A.11.1. An exact rational certificate against one preparation.

**Lemma A.11.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem A.4.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (25) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (59), the signed coefficients in (25), after grouping by  $K$ , are the entries of

$$(62) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1 - p_i)^{2-k} \left( Q_{*,j} - \frac{(1 - p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (62) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (62) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ .

A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**A.11.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (59) and with indicator zero at every off-diagonal atom:

$$(63) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma A.11.3** (Exact uniform score of the selector). *Against the ideal target, the selector (63) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (63) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(64) \quad \begin{aligned} G(p, q) = H(u, v) = & -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} \\ & + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}. \end{aligned}$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

### A.11.3. Causal compilation and the full register profile.

**Lemma A.11.4.** *The selector and its two validations admit the deterministic profile (61). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event–function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2 w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (63). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem A.11.1.* Lemma A.11.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas A.11.3 and A.11.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary A.11.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the local microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem A.11.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in Theorem A.10.3; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark A.11.6* (The part of the frontier determined here). The deterministic theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . Theorem A.12.1 and Corollary A.12.2 below additionally determine the ideal maximum score with two preparations on this width range. The least peak width over all validation orders and the full boundary for  $3 \leq W \leq 11$  remain separate questions. Theorem A.14.3 below determines the peak for forward serial validation, and

Theorem A.14.1 determines the order-independent decision cut. The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by (2, 12) in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

**Corollary A.11.7** (The enlarged physical preparation segment). *With the full architecture of Definition A.10.1,*

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

Here  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$  is the exact one-preparation all-on value, rather than the older rational upper bound.

*Proof.* Restrict the adversary to the common-garbling subfamily in Definition A.10.1. Theorem A.4.2 and Corollary A.9.2 bound every at-most-one-preparation auditor, even with unlimited memory, by  $u_{\text{ex}} + \beta$ . The same deterministic two-preparation machine in Lemmas A.11.3 and A.11.4 has score at least  $m_2 - \beta$  against the full private candidate family. These inequalities prove the assertion. The four-preparation total, peak twelve and positive-noise specialization are unchanged.  $\square$

#### APPENDIX A.12. THE EXACT TWO-PREPARATION MARKED SADDLE

The one-preparation saddle has an exact successor. A new zero coefficient of the least-favorable predictive measure makes it necessary to randomize at the two extreme training counts. This randomization changes the value, but does not enlarge the alphabet of frozen validation events.

Let  $b(p, q)$  and  $Q_*$  be as in Section A.11. Let  $r$  be the unique root in  $(1/3, 7/20)$  of

$$(65) \quad 2r^3 + 25r^2 - 3 = 0,$$

and define

$$(66) \quad \tau = \frac{6(-r^2 + 4r - 1)}{r(3r + 25)}, \quad v_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad p_{\pm} = \frac{1 \pm \sqrt{r}}{2}.$$

The polynomial in (65) is strictly increasing on the positive half-line and has opposite signs at the indicated endpoints. These observations prove the asserted existence, uniqueness and isolating interval. That interval also gives  $0 < \tau < 1$ .

**Theorem A.12.1** (Exact two-preparation value). *For the full marked-word response class of (24),*

$$U_2(b, Q_*) = v_2.$$

*A least-favorable prior gives mass 1/2 to each of  $(p_-, p_-)$  and  $(p_+, p_+)$ . An optimal response discards the two training marks, retains the total number  $S$  of ones in the four training report bits, and uses*

$$(67) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & \tau & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & \tau \end{array}$$

with zero response at off-diagonal validation atoms. Numerically,  $r = 0.3417694155\dots$ ,  $\tau = 0.1688236447\dots$  and  $v_2 = 0.4261127787\dots$ . The exact value is determined by (65)–(66), not by these decimals.

*Proof.* Write  $a = (1-p)(1-q)$ ,  $c = pq$ ,  $u = (p+q-1)^2$  and  $v = (p-q)^2$ . Both  $u$  and  $v$  belong to  $[0, 1]$ . The score of the deterministic five-event selector is the polynomial  $H(u, v)$  in (64). Only counts zero and four are changed by (67). Their probabilities are  $a^2$  and  $c^2$ . Consequently the new score is

$$G(u, v) = H(u, v) + \tau J(u, v), \quad J = a^2(5/16 - a/2) + c^2(5/16 - c/2).$$

Expansion gives the polynomial identity

$$(68) \quad \begin{aligned} J(u, v) = & -\frac{u^3}{64} + \frac{3u^2v}{64} - \frac{25u^2}{128} - \frac{3uv^2}{64} + \frac{13uv}{64} \\ & + \frac{v^3}{64} - \frac{v^2}{128} - \frac{v}{32} + \frac{3}{128}. \end{aligned}$$

Thus

$$H(u, 0) = \frac{-u^3 + 6u^2 - 3u + 14}{32}, \quad J(u, 0) = \frac{3 - 25u^2 - 2u^3}{128}.$$

Equation (65) says  $J(r, 0) = 0$ , and the choice of  $\tau$  says  $\partial_u G(r, 0) = 0$ . Direct factorization, using these two identities, yields

$$(69) \quad G(u, 0) - v_2 = \frac{(u-r)^2\{75 + 12r + 6u - 37r^2 - 74ru\}}{64r(3r + 25)}.$$

The expression in braces is strictly positive for  $0 \leq u \leq 1$ : it is at least  $75 - 37(7/20)^2 - 74(7/20) > 0$ . Moreover,

$$\partial_v H = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}, \quad \partial_v J = \frac{3(u-v)^2 + 13u - v - 2}{64} \geq -\frac{3}{64}.$$

Because  $0 < \tau < 1$ ,  $\partial_v G \geq 11/64$  on the unit square. It follows that  $G(u, v) \geq G(u, 0) \geq v_2$ , with equality precisely when  $v = 0$  and  $u = r$ . Both equality points are feasible and are the two parameters in the asserted prior. This proves the global lower bound.

It remains to prove an upper bound against every response, not only those depending on  $S$ . Under the asserted prior the four training report bits are independent Bernoulli variables with common parameter  $p_-$  or  $p_+$ . Conditional on  $S = s$ , their arrangements and the two independent training marks have parameter-independent distributions. The signed predictive coefficients can therefore be grouped by  $S$  without restricting any response coordinate. For the four displayed validation atoms put

$$C_{s,j} = \frac{1}{2} \sum_{p \in \{p_-, p_+\}} \binom{4}{s} p^s (1-p)^{4-s} \{Q_{*,j} - b_j(p, p)\}.$$

The first three rows of  $256C$  are

$$\begin{aligned} s = 0 : & \quad (-(2r^3 + 25r^2 - 3), -(2r^3 + 27r^2 + 12r - 1), \\ & \quad -(2r^3 - 5r^2 - 20r - 1), -(2r^3 - 7r^2 - 32r - 3)), \\ s = 1 : & \quad 4(r-1)(2r^2 + 7r - 3, 2r^2 + 9r - 1, \\ & \quad 2r^2 - 7r - 1, 2r^2 - 9r - 3), \\ s = 2 : & \quad -6(r-1)^2(2r-3, 2r-1, 2r-1, 2r-3). \end{aligned}$$

Rows three and four are the reversals of rows one and zero, respectively. Their signs, using  $1/3 < r < 7/20$ , are

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Every off-diagonal validation coefficient is nonpositive because its target mass is zero. Hence (67) maximizes every signed coefficient: it is one at positive coefficients, zero at negative ones, and arbitrary at the two zeros. The lower-bound equality at both prior points shows that this Bayes maximum is exactly  $v_2$ . The posterior-predictive dual, Theorem A.4.1, now gives the matching upper bound for the full response class.  $\square$

**Corollary A.12.2** (Exact physical score on the peak-twelve segment). *Use the atomic stochastic-row convention and the original marked interface of Definition A.10.1. At two candidate training preparations, every peak budget  $W \geq 12$  has exact ideal worst-case score  $v_2$ . For a target  $Q$  with  $\text{TV}(Q, Q_*) \leq \beta$ , the corresponding value lies in  $[v_2 - \beta, v_2 + \beta]$ . In particular, with  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$ ,*

$$(70) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad u_{\text{ex}} + \beta \leq c < v_2 - \beta.$$

*Proof.* Let  $h_0, \dots, h_4$  be the five deterministic events in (63). At count zero select  $h_1$  with probability  $\tau$  and  $h_0$  otherwise; at count four select  $h_3$  with probability  $\tau$  and  $h_4$  otherwise. At the other counts retain the indicated event. Discard the count and retain the selected event for both validations. This realizes (67); the event alphabet remains five. The full charged profile, now including the separate event-selection update, is

$$(1, 2, 3, 3, 4, 5, 5, 5, 10, 12, 10, 10, 7, 3).$$

The common residual-function compiler in Lemma A.11.4 applies unchanged. In particular, no persistent random selector is outside the register. The all-on law for every private candidate is  $b(p, q)$ , so Theorem A.12.1 proves the constructive lower bound. For the converse restrict to the admissible common-garbling product subfamily and apply Theorem A.4.2 followed by Theorem A.12.1. This bounds all architectures, including those using feedback, stopping and more memory. Target perturbation changes each frozen-event expectation by at most  $\beta$ . Finally the exact one-preparation theorem excludes a strict score above  $c$  at  $N \leq 1$ , whereas the displayed machine achieves it at  $N = 2$  under (70).  $\square$

The root  $r$  is larger than  $2 - \sqrt{3}$ . The old diagonal polynomial  $H(u, 0)$  is strictly increasing between these points, whence  $v_2 > m_2$ . The deterministic theorem, including its zero-random-bit implementation, remains valid; the new exact score uses an additional stochastic row.

**Proposition A.12.3** (Finite precision for the new row). *Replacing  $\tau$  by a dyadic  $\tau_b = k/2^b \in [0, 1]$  with  $|\tau_b - \tau| \leq 2^{-b}$  loses at most  $(5/16)2^{-b}$  in uniform score. A clocked fair-bit implementation uses  $b$  extra random bits and at most  $\max\{12, 6(b+1) + 5\}$  persistent states, including their phase, in addition to the unchanged preparation count.*

*Proof.* At each affected training word the response changes at a single atom;  $|5/16 - a/2|$  and  $|5/16 - c/2|$  are at most  $5/16$ . The two affected word probabilities sum to at most one. This gives the score estimate. To implement the dyadic coin, compare  $b$  fresh fair bits lexicographically with the fixed  $b$ -bit integer  $k$ . Retain the origin (count zero or four), one of the three comparison flags, and a phase in  $\{0, \dots, b\}$ . Once the comparison ends retain its chosen one of five events. Unaffected counts can wait in their event states. These states total at most  $6(b+1) + 5$ ; the other cuts have peak twelve. The cases  $k = 0, 2^b$  are deterministic. Exact atomic randomization and a finite fair-bit implementation are therefore distinct resource claims.  $\square$

## APPENDIX A.13. A CONTINUOUS TWO-PREPARATION MARKED FAMILY

The preceding saddle persists on an explicit interval of target laws, with exact rather than perturbative values. Use the target  $Q_\gamma$  from Section A.9 and write  $U_2(\gamma) = U_2(b, Q_\gamma)$ .

**Theorem A.13.1** (A two-preparation saddle family). *For  $6/25 \leq \gamma \leq 13/50$ , let  $r_\gamma$  be the unique root in  $(1/3, 7/20)$  of*

$$(71) \quad f_\gamma(r) = r^3 + (13 - 2\gamma)r^2 + (3 - 12\gamma)r - (1 + 2\gamma) = 0.$$

Set

$$D_\gamma(r) = 3r^2 + (26 - 4\gamma)r + 3 - 12\gamma, \quad t_\gamma = -\frac{2\{3r_\gamma^2 + (8\gamma - 14)r_\gamma + 3\}}{D_\gamma(r_\gamma)}.$$

Then  $0 < t_\gamma < 1$ , and

$$(72) \quad U_2(\gamma) = \frac{-r_\gamma^3 + (7 - 4\gamma)r_\gamma^2 - 3r_\gamma + 13 + 4\gamma}{32}.$$

The response (67), with  $\tau = t_\gamma$ , is optimal. A least-favorable prior gives equal masses to the two diagonal parameters  $p = q = (1 \pm \sqrt{r_\gamma})/2$ . The response has the same five-event, peak-twelve atomic realization. At  $\gamma = 1/4$  these formulas reduce to Theorem A.12.1.

*Proof.* For brevity write  $r = r_\gamma$ ,  $D = D_\gamma(r)$  and  $t = t_\gamma$ . The derivative  $D_\gamma$  is positive on the rectangle  $\gamma \in [6/25, 13/50]$ ,  $r \in [1/3, 7/20]$ . For example its lower bound is  $1/3 + (26 - 52/50)/3 - 3/25 > 8$ . The polynomial  $f_\gamma$  decreases with  $\gamma$  at a fixed positive argument. Direct rational evaluations give  $f_{6/25}(1/3) < 0$  and  $f_{13/50}(7/20) > 0$ . Monotonicity therefore gives the root and its uniqueness in this interval. The numerator of  $t$  is  $-16\gamma r - 6r^2 + 28r - 6$ . It is bounded below by  $28/3 - 6 - 16(13/50)(7/20) - 6(7/20)^2 > 0$ , and above by  $28(7/20) - 6 < 4 < D$ . Thus  $0 < t < 1$ .

Let  $H, J$  be the polynomials from (64) and (68). Changing the target masses linearly in  $\gamma$  gives

$$\begin{aligned} H_\gamma(u, v) &= H(u, v) + (\gamma - 1/4) \frac{1 - (u - v)^2}{8}, \\ J_\gamma(u, v) &= J(u, v) + (\gamma - 1/4) \frac{(u - v)^2 + 6u - 2v + 1}{32}. \end{aligned}$$

The response's full-parameter score is  $G_\gamma = H_\gamma + tJ_\gamma$ . One has  $J_\gamma(r, 0) = -f_\gamma(r)/64 = 0$  and  $\partial_u G_\gamma(r, 0) = 0$ . Algebraic division gives

$$(73) \quad G_\gamma(u, 0) - H_\gamma(r, 0) = \frac{(u - r)^2 A_\gamma(r, u)}{16D},$$

where

$$\begin{aligned} A_\gamma(r, u) &= 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru \\ &\quad + 12\gamma r + 6\gamma u - 51\gamma + 30. \end{aligned}$$

For  $0 \leq u \leq 1$  this is at least  $30 - 10(7/20)^2 - 20(7/20) - 51(13/50) > 0$ . The transverse derivatives satisfy

$$\begin{aligned} 32\partial_v H_\gamma &= 3(u - v)^2 + (8\gamma - 10)u + (6 - 8\gamma)v + 15 \geq 5, \\ 64\partial_v J_\gamma &= 3(u - v)^2 + (14 - 4\gamma)u + (4\gamma - 2)v - 4\gamma - 1 \geq -3 \end{aligned}$$

on  $0 \leq u, v \leq 1$ . Consequently  $\partial_v G_\gamma \geq 7/64$ . Equation (73) proves a lower bound  $H_\gamma(r, 0)$ , with equality precisely at the proposed prior points. This quantity is the right side of (72).

For the upper bound group the full training words by  $S$ , as in the preceding theorem. Put  $L(r) = r^2 + 6r + 1$ . Using  $f_\gamma(r) = 0$ , the first three rows of  $256C$  are

$$\begin{aligned} 0 : & (0, -8\gamma L(r), 32r(r+1) - 8\gamma L(r), 32r(r+1)), \\ 1 : & 8(r-1)(r^2 + 4r - 1 - 2\gamma(r+1), \\ & \quad r^2 + 4r - 1 + 2\gamma(r+1), \\ & \quad r^2 - 4r - 1 + 2\gamma(r+1), r^2 - 4r - 1 - 2\gamma(r+1)), \\ 2 : & -12(r-1)^2(r-1-2\gamma, r-1+2\gamma, r-1+2\gamma, r-1-2\gamma). \end{aligned}$$

The other rows are their reversals. The sign pattern is again

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Here are explicit interval checks for the potentially small margins. In row zero the third coordinate is bounded below by  $32(1/3)(4/3) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 0$ . The first parenthesis of row one is at most  $(7/20)^2 + 4(7/20) - 1 - 2(6/25)(4/3) < 0$ ; the third is at most  $(7/20)^2 - 4/3 - 1 + 2(13/50)(27/20) < 0$ . The second parenthesis is positive already from  $r > 1/3$  and  $\gamma > 0$ , and the fourth is negative. Finally  $r - 1 + 2\gamma \leq -13/100 < 0$ . All off-diagonal validation coefficients are nonpositive. Thus the stated response is a Bayes best response for this prior, including its two zero coefficients. Its score at both supporting parameters equals the lower bound. The full posterior-predictive dual proves (72).  $\square$

This interval is a uniform certificate region for the displayed saddle, not a claim that the same masks remain optimal for every mark bias. The theorem supplies a continuous family at genuinely growing training history  $N = 2$ ; it does not infer a recurrence for every  $N$  from the one-preparation formulas.

#### APPENDIX A.14. EXACT MEMORY FROM A MARKED SADDLE

The realization criterion is now applied to a saddle with genuine Bayes indifference. The zero coefficients in the two-preparation problem are not harmless: their values are fixed by contact with the parameter family. This supplies a converse for all optimal audits, rather than for a preselected response table.

Put  $I = [6/25, 13/50]$ . Throughout this section  $r = r_\gamma$ ,  $t = t_\gamma$ , and  $v = U_2(\gamma)$  are those of Theorem A.13.1. Denote the five deterministic events in (63) by  $e_0, \dots, e_4$ . Responses displayed below are ordered on 000, 001, 110, 111 and vanish at the other four atoms.

**Theorem A.14.1** (Contact rigidity and exact decision memory). *For every  $\gamma \in I$ , every minimax optimal full-word response with two training preparations has, after averaging the independent training marks at the two extreme report counts, the five rows*

$$(74) \quad (t, 0, 1, 1), \quad (1, 0, 1, 1), \quad (1, 1, 1, 1), \quad (1, 1, 0, 1), \quad (1, 1, 0, t).$$

*At the three interior counts the displayed response is forced at each individual training word, not merely after averaging.*

*In the original reset row–event interface, the least number of states at the post-training cut that permits the exact ideal score  $v$  is five. This converse allows arbitrary upstream finite memory, randomized encoding, adaptive training gates, stopping, independent target-only calibration, and all legal post-cut randomizations. Other cuts are unrestricted in this decision-memory assertion.*

*Proof.* First consider a response to the full two-preparation word. Under the least-favorable prior of Theorem A.13.1, every training word has positive probability. The strict coefficient signs force  $e_1, e_2, e_3$  at report counts 1, 2, 3. At count zero only the 000 coordinate is free; at count

four only the 111 coordinate is free. All off-diagonal validation coefficients are strictly negative: the prior parameters are interior, each word likelihood is positive, and the target assigns zero mass to those atoms. Thus those coordinates are zero for every optimal response.

Let  $a$  and  $b$  be the averages of the two free coordinates over the four equiprobable training mark words at their respective extreme counts. On the diagonal parameter  $(p, p)$  the score is

$$(75) \quad H_\gamma((2p-1)^2, 0) + aA_\gamma(p) + bB_\gamma(p),$$

where

$$A_\gamma(p) = (1-p)^4 \left( \frac{1+\gamma}{4} - \frac{(1-p)^2}{2} \right), \quad B_\gamma(p) = p^4 \left( \frac{1+\gamma}{4} - \frac{p^2}{2} \right).$$

Here  $H_\gamma$  is the deterministic five-event score in the proof of Theorem A.13.1. At  $p_+ = (1+\sqrt{r})/2$ ,  $A_\gamma(p_+) + B_\gamma(p_+) = J_\gamma(r, 0) = 0$  and  $A_\gamma(p_+) > 0$ . The latter follows from  $p_+ > 1/2$  and  $(1+\gamma)/4 > 1/4$ . Reflection exchanges  $A$  and  $B$  at  $p_- = 1 - p_+$ . Also  $H_\gamma(r, 0) = v$ . Optimality forces contact at both prior points, by Theorem A.7.3. Subtracting  $v$  from (75) therefore gives  $(a-b)A_\gamma(p_+) = 0$ , hence  $a = b$ .

With this common value the diagonal score is  $H_\gamma(u, 0) + aJ_\gamma(u, 0)$ , where

$$H_\gamma(u, 0) = \frac{-u^3 + (7-4\gamma)u^2 - 3u + 13 + 4\gamma}{32}, \quad J_\gamma(u, 0) = -\frac{f_\gamma(u)}{64}.$$

The supporting value  $r$  lies in  $(0, 1)$ , so the derivative at  $r$  vanishes. Since  $f'_\gamma(r) = D_\gamma(r) > 8$ , the derivative equation has the unique solution

$$a = b = \frac{64 \partial_u H_\gamma(r, 0)}{D_\gamma(r)} = t_\gamma.$$

This proves (74). Individual extreme mark words may still use different tie values; no unnecessary uniqueness is asserted.

Now take an arbitrary audit with  $K$  states at the decision cut. Restrict the candidate to the common-garbling subfamily in Definition A.10.1. Generate two all-on words and simulate the adaptive training and its stopping with independent coins. The retained state is a parameter-independent stochastic function of those two words. Conditional on that state, the frozen row-event continuation pulls back to a response  $D_s \in [0, 1]^8$  on the all-on alphabet. Any calibration is part of the same encoding and retained state. Thus (44) holds without increasing  $K$ . If the audit attains  $v$  against the full physical class, its pullback attains  $v$  against this subfamily, since the unrestricted upper bound is  $v$ . Averaging selected rows preserves their factorization.

The three interior rows in (74) are distinct vertices of  $[0, 1]^8$ , so the generators must include  $e_1, e_2, e_3$  themselves. The first row lies in the face

$$F_0 = \{d : d(001) = 0, d(110) = d(111) = 1, d = 0 \text{ off the diagonal}\}.$$

Of those three obligatory vertices only  $e_1$  lies in  $F_0$ ; since  $t < 1$ , this row is not  $e_1$ . It needs another generator in  $F_0$ . Similarly the last row needs another generator in

$$F_4 = \{d : d(000) = d(001) = 1, d(110) = 0, d = 0 \text{ off the diagonal}\}.$$

Only  $e_3$  among the obligatory vertices lies there. The two faces are disjoint. Lemma A.7.5 gives  $K \geq 3 + 2 = 5$ . Conversely the optimal response mixes  $e_0, e_1$  at count zero and  $e_4, e_3$  at count four and otherwise selects the indicated event. Only its five-valued event label survives the cut. The inherited compiler realizes its subsequent validation with finite memory and attains  $v$ . This proves exactness of the decision count.  $\square$

The contact argument is essential. Setting both free coordinates equal to one gives a Bayes best response with only the three events  $e_1, e_2, e_3$ , but its derivative at  $r$  is nonzero because  $t < 1$ . It is not minimax. Counting the states of a Bayes best response alone would give an incorrect resource conclusion.

**Corollary A.14.2** (A strict gap and its physical persistence). *There is  $\delta_* > 0$ , uniform for  $\gamma \in I$ , such that every two-preparation audit with at most four states at the decision cut has ideal worst-case score at most  $U_2(\gamma) - \delta_*$ . In particular, this bound holds for every original-interface audit of whole-schedule peak at most four. If only the target changes by total variation at most  $\beta < \delta_*/2$ , the five-state decision construction still strictly outperforms this class.*

*Proof.* Let  $W_4(\gamma)$  be the maximum worst-case score over the relaxed factorizations (44) with  $K = 4$  and two full training words. Their encoder and decoder spaces are compact and fixed, independently of  $\gamma$ . The score is jointly continuous in these variables, the target bias, and  $(p, q)$ . Consequently  $W_4$  is continuous. By Theorem A.14.1 it is strictly less than  $U_2(\gamma)$  for each  $\gamma \in I$ . The minimum of this positive continuous gap on compact  $I$  is positive. This defines  $\delta_*$  without pretending to have evaluated it numerically. The domination argument in that theorem makes it an upper bound for every original-interface audit in question. Changing only the target changes any fixed audit's mean score by at most  $\beta$ . The difference between the two classes therefore decreases by at most  $2\beta$ .  $\square$

For the microscopic family at  $\gamma = 1/4$ , the signal is larger than  $1/4$  and the standard deviation of each normalized sensor noise is  $\sqrt{2}\sigma$ . The Gaussian tail bound used in Theorem A.10.3 gives the sharper, vanishing estimate

$$(76) \quad \text{TV}(Q_{d,\sigma}, Q_*) \leq \frac{8\sigma}{\sqrt{\pi}} \exp\{-1/(64\sigma^2)\}, \quad 9/10 \leq d \leq 11/10.$$

Thus Corollary A.14.2 holds uniformly in  $d$  for all sufficiently small positive  $\sigma$ . This is an existence statement with the displayed physical modulus. The present proof does not certify that every  $\sigma \leq 1/24$  lies below the unknown gap threshold.

**A.14.1. The sharp serial-validation peak.** A decision cut and the whole execution have different resource costs. We now determine the latter in a declared validation schedule. In the *forward serial class*, both training preparations finish before validation; the candidate validation's two report slots and mark are read before any target validation report is read. The same frozen row-event continuation is used on both preparations, as in Definition A.10.1. Training gates, stochastic state updates and frozen gate policies are unrestricted within that interface. No intermediate output can be reread as external memory.

**Theorem A.14.3** (Sharp forward serial peak). *For every  $\gamma \in I$ , the least whole-schedule peak width attaining  $U_2(\gamma)$  in the forward serial class is twelve. In particular, a peak of at most eleven in this class incurs a strictly positive loss, which can be chosen uniformly for  $\gamma \in I$ .*

*Proof.* Use the common-garbling subfamily and the two raw all-on training words as in Theorem A.14.1. Any optimal audit must finish both training preparations almost surely under its least-favorable prior. Indeed a stopped branch after a first preparation would have a response independent of the unused second word. For each first report count 0, 1, 2, two choices of the unused word force two different interior vertices from  $e_1, e_2, e_3$ . Each has positive conditional probability. A positive stopped component cannot be a convex component of two distinct vertices. The same argument excludes stopping before the first draw. Null branches may be completed arbitrarily.

Consider the cut after the candidate's second report slot and before its mark. On a canonical raw input tape its continuation is a channel from  $(w, y) \in \{0, 1\} \times \{000, 001, 110, 111\}$  to  $\{-1, 0, 1\}$ , where  $w$  is the unread candidate mark and  $y$  the fresh target word. All these target words have positive probability. Each retained state supplies one such continuation channel, common to every past leading to it. Hence the rows indexed by selected pasts factor through at most the peak number of generators.

For the strict interior training counts, the following eight rows are forced deterministic channels:

$$(77) \quad e_1(y) - f(w), \quad f \in \{0, 1 - w, 1\}; \quad e_2(y) - f(w), \quad f \in \{0, 1\}; \quad e_3(y) - f(w), \quad f \in \{0, w, 1\}.$$

For example  $e_1$  has candidate residual 0 after an off-diagonal report pair,  $1 - w$  after 00, and 1 after 11. The other cases follow by restriction of their masks. Each listed past has positive probability under both supporting candidate parameters. The eight functions are distinct: subtracting two with the same mask compares their distinct  $w$  functions; for different masks their difference depends nontrivially on  $y$  and cannot equal a function of  $w$  alone. They are eight distinct vertices of the product of output simplices.

There are four additional required rows. Average the extreme training marks as in Theorem A.14.1, and take the candidate raw report pair to be, respectively, off diagonal and 11 at count zero, and off diagonal and 00 at count four. Independence of a fresh raw candidate preparation from the frozen continuation preserves the averaged tie probability  $t$ . On the four target words these rows have means

$$(78) \quad (t, 0, 1, 1), \quad (t - 1, -1, 0, 0), \quad (1, 1, 0, t), \quad (0, 0, -1, t - 1),$$

for both values of  $w$ . More precisely, each integer coordinate here is a point mass at that integer, and the remaining coordinate is the Bernoulli mixture between the two neighboring integers. This stronger channel statement, not a statement about a zero mean alone, follows because the candidate indicator is fixed at 0 or 1 on the selected raw pair, while the target indicator is a bit. Fresh gate randomness is already part of this channel; it supplies no additional past-dependent argument to a retained state.

The four rows lie in four pairwise disjoint faces of the product of output simplices. These faces fix, for both  $w$ , respectively,

|           | 000 | 001 | 110 | 111 |
|-----------|-----|-----|-----|-----|
| $F_{0,+}$ | *   | 0   | 1   | 1   |
| $F_{0,-}$ | *   | -1  | 0   | 0   |
| $F_{4,+}$ | 1   | 1   | 0   | *   |
| $F_{4,-}$ | 0   | 0   | -1  | *   |

where a number specifies a point mass and  $*$  is unrestricted. Among the eight vertices (77), each face contains exactly one:  $e_1$ ,  $e_1 - 1$ ,  $e_3$ , and  $e_3 - 1$ , respectively. Since  $t < 1$ , none of the four required rows is that vertex. Face packing forces four more generators, for a total of twelve. This argument uses conditional future-output laws and not the continued storage of an event name after a residual has replaced it.

The optimal five-event selection followed by the inherited forward compiler has peak twelve, including its stochastic selection cut. It proves the matching upper bound. To see strictness below twelve, use the finite-protocol normal form of Proposition A.7.1 with all logical cuts bounded by eleven, including selection and frozen-continuation buffers. Unobserved internal random computations can be collapsed to common transition kernels on the same register; an unretained random duration cannot be supplied as a later input. The normalized row spaces and closed frozen-interface restrictions are compact. If the constrained value equalled  $U_2$ , the

preceding face obstruction would apply. Continuity and compactness in  $\gamma$  give a uniform strictly positive gap, just as in Corollary A.14.2.  $\square$

Theorem A.14.3 is a minimum-width theorem for a specified serial order, not a claim that an arbitrary validation order has the same minimum. The ideal target has support restrictions that can change future residuals when the target is read first. Reverse-order and interleaved validations require their own continuation analysis. The decision-memory converse in Theorem A.14.1 does not make this serial-order assumption. Neither statement replaces the original physical interface by an uncharged atomic validation.

#### APPENDIX A.15. A FULL-SUPPORT MARKED SADDLE

The support restriction of the ideal target can be removed without replacing the private simulator or changing the training experiment. This section identifies an explicit region of positive targets on which both the statistical saddle and its decision-memory number are exact. The next section shows that the original Brownian sensor belongs to this region throughout its previously stated noise range.

Put

$$\mathcal{R} = [6/25, 13/50] \times [0, 1/1000].$$

For  $(\gamma, \kappa) \in \mathcal{R}$ , define  $Q_{\gamma, \kappa}$  on  $\{0, 1\}^3$  by the masses

$$(79) \quad \frac{\omega}{Q_{\gamma, \kappa}(\omega)} \left| \begin{array}{cccc|c} 000 & 001 & 110 & 111 & \text{each other atom} \\ a & b & b & a & \kappa \end{array} \right|, \quad a = \frac{1+\gamma}{4} - \kappa, \quad b = \frac{1-\gamma}{4} - \kappa.$$

These masses sum to one. For  $\kappa > 0$  every atom has positive mass. The candidate is still  $b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2)$ ; there is no additional candidate parameter.

**Theorem A.15.1** (Full-support saddle and contact rigidity). *For every  $(\gamma, \kappa) \in \mathcal{R}$ , there is a unique  $r = r_{\gamma, \kappa}$  in  $(33/100, 7/20)$  satisfying*

$$(80) \quad f(r) = r^3 + (13 - 2\gamma + 8\kappa)r^2 + (3 - 12\gamma + 48\kappa)r - 1 - 2\gamma + 8\kappa = 0.$$

Set  $D = f'(r)$  and

$$(81) \quad t = \frac{2\{-3r^2 + (14 - 8\gamma - 16\kappa)r - 3 + 48\kappa\}}{D},$$

$$(82) \quad v = \frac{-r^3 + (7 - 4\gamma - 8\kappa)r^2 + (-3 + 48\kappa)r + 13 + 4\gamma - 104\kappa}{32}.$$

Then  $8 < D < 10$ ,  $1/10 < t < 1/4$ , and

$$U_2(b, Q_{\gamma, \kappa}) = v.$$

The optimal five response rows are (74), with this value of  $t$ , and zero at all off-diagonal atoms. The equal prior on  $p = q = (1 \pm \sqrt{r})/2$  is least favorable. The same averaged rows are forced for every full-word minimax response. At the three interior counts the entire deterministic event is forced word by word.

The least post-training decision width attaining  $v$  is exactly five, including in the original gate interface with arbitrary stochastic training, stopping and independently acquired calibration.

*Proof.* On the indicated rectangle in  $(\gamma, \kappa, r)$ , direct monotonicity gives  $8 < f'(r) < 10$ . The polynomial decreases with  $\gamma$  and increases with  $\kappa$ . Its two endpoint evaluations are bounded by

$$f_{6/25, 1/1000}(33/100) = -81619/5000000 < 0, \quad f_{13/50, 0}(7/20) = 387/40000 > 0.$$

This proves existence and uniqueness in the stated interval. The numerator of  $t$  is  $-16\gamma r - 32\kappa r + 96\kappa - 6r^2 + 28r - 6$ . Bounding its negative and positive terms separately gives a lower

bound  $10378/10000 > 1$  and an upper bound  $19754/10000 < 2$ . Together with  $8 < D < 10$  these prove the asserted interval for  $t$ .

Let  $u = (p + q - 1)^2$ ,  $z = (p - q)^2$ , and retain the polynomials  $H_\gamma, J_\gamma$  from Theorem A.13.1. The probabilities of the five training counts give

$$E(u, z) = \frac{(u - z)^2 - 6u + 2z + 13}{4},$$

$$L(u, z) = \frac{(u - z)^2 + 6u - 2z + 1}{8}.$$

Here  $E$  is the expected cardinality of the deterministic selected four-atom event, and  $L$  is the probability of an extreme training count. The score of the proposed response is therefore

$$G = H_{\gamma, \kappa} + tJ_{\gamma, \kappa}, \quad H_{\gamma, \kappa} = H_\gamma - \kappa E, \quad J_{\gamma, \kappa} = J_\gamma - \kappa L.$$

This is an identity in the actual training probabilities, not an estimate. On the diagonal,  $J_{\gamma, \kappa}(u, 0) = -f(u)/64$  and  $H_{\gamma, \kappa}(r, 0) = v$ . Polynomial division, using  $f(r) = 0$ , gives

$$(83) \quad G(u, 0) - v = \frac{(u - r)^2 A(\gamma, \kappa, r, u)}{16D},$$

where

$$A = 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru + 12\gamma r + 6\gamma u - 51\gamma + 30$$

$$- 384\kappa^2 - 96\kappa r - 48\kappa u - 144\kappa.$$

For  $0 \leq u \leq 1$  the negative terms alone give  $A > 8$  throughout  $\mathcal{R}$ . Moreover, on  $0 \leq u, z \leq 1$  the bounds in the preceding family theorem yield

$$\partial_z H_{\gamma, \kappa} \geq 5/32 - \kappa, \quad \partial_z J_{\gamma, \kappa} \geq -3/64.$$

Indeed the additional derivatives are respectively  $\kappa(u - z - 1)/2$  and  $\kappa(u - z + 1)/4$ . Since  $t < 1/4$ , one has  $\partial_z G > 1/8$ . Thus (83) is a global lower certificate on the parameter square, with equality at exactly the two proposed prior points.

For the Bayes upper bound, group the four report bits by their total  $S$ ; the independent training marks and arrangements conditional on  $S$  are parameter independent under this prior. Put  $L_r = r^2 + 6r + 1$ . The first three rows of 256 times the signed coefficient table on 000, 001, 110, 111 are

$$S = 0 : \quad (0, -8\gamma L_r, 32r(r + 1) - 8\gamma L_r, 32r(r + 1)),$$

$$S = 1 : \quad 8(r - 1)(r^2 + 4r - 1 - 2\gamma(r + 1) + 8\kappa(r + 1),$$

$$r^2 + 4r - 1 + 2\gamma(r + 1) + 8\kappa(r + 1),$$

$$r^2 - 4r - 1 + 2\gamma(r + 1) + 8\kappa(r + 1),$$

$$r^2 - 4r - 1 - 2\gamma(r + 1) + 8\kappa(r + 1)),$$

$$S = 2 : \quad -12(r - 1)^2(r - 1 - 2\gamma + 8\kappa, r - 1 + 2\gamma + 8\kappa,$$

$$r - 1 + 2\gamma + 8\kappa, r - 1 - 2\gamma + 8\kappa).$$

The other rows are their reversals. For example the potentially small first parenthesis in row one is at most

$$(7/20)^2 + 4(7/20) - 1 - 2(6/25)(133/100) + 8(1/1000)(27/20) < -1/10.$$

The third parenthesis is negative by the same endpoint bounds; the second is positive and the fourth negative. In row two,  $r - 1 + 2\gamma + 8\kappa \leq -61/500 < 0$ . Row zero's third entry is positive since  $32(33/100)(133/100) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 7$ . Consequently the signs are

exactly those of the previous two-preparation saddle. At each off-diagonal atom the candidate mass on both prior points equals  $(1-r)/8 > 13/160$ , whereas  $\kappa \leq 1/1000$ . Every off-diagonal coefficient is strictly negative. Coordinatewise Bayes maximization therefore selects the proposed response, including its two indifferent coordinates. Its equal score at the prior support closes the minimax match against the full response class.

For completeness the contact argument persists, not just the sign pattern. If  $a_0, b_0$  are the averaged extreme response coordinates, their extra diagonal contributions are

$$a_0(1-p)^4\{a - (1-p)^2/2\} + b_0p^4\{a - p^2/2\}.$$

At either support point their sum with  $a_0 = b_0 = 1$  is zero by (80); the first term is positive at  $p_+$ . Contact at both supports gives  $a_0 = b_0$ . Interior stationarity gives  $a_0 = b_0 = 64\partial_u H_{\gamma,\kappa}(r, 0)/D = t$ . All strict coordinates are forced individually. Thus the three vertices and two disjoint faces used in Theorem A.14.1 are unchanged. That theorem's positive-factorization argument gives five states for every admissible stochastic encoder, while the same five-event selection attains it. The common-garbbling reduction is unchanged because the candidate interface is unchanged.  $\square$

The rectangle  $\mathcal{R}$  is an explicit stability region for the *saddle and its exact decision-memory number*. It is not a claim that arbitrary nonsymmetric total-variation perturbations have the same optimizer. At  $\kappa = 0$  every formula reduces to the retained ideal theorem. Positive off-diagonal target masses do not destroy the strict negative Bayes coefficients at those atoms: their magnitude relative to the candidate, rather than their being zero, is what is needed.

#### APPENDIX A.16. EXACT STATISTICAL FORM OF THE BROWNIAN COLLISION SENSOR

The full-support theorem applies to the original microscopic target, not only to an independently constructed contamination model. The preparation symmetries supply the required form exactly.

**Theorem A.16.1** (Physical symmetry and a quantitative noise region). *Use exactly the preparation boxes, elastic collision, detector and Brownian windows of Section A.10. Conditional on the preparation put*

$$Z = |h(v_{1,y}^+)|, \quad e = \Phi\left(-\frac{Z}{\sqrt{2}\sigma}\right), \quad \mu_1 = \mathbb{E}e, \quad \mu_2 = \mathbb{E}e^2.$$

For every  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$  the exact all-on target law is

$$(84) \quad Q_{d,\sigma} = Q_{\gamma_{d,\sigma}, \kappa_{d,\sigma}}, \quad \gamma_{d,\sigma} = \frac{1}{4} - \frac{\mu_1}{2}, \quad \kappa_{d,\sigma} = \frac{\mu_1 - \mu_2}{2}.$$

In particular

$$\frac{1}{4} - \frac{1}{1200} < \gamma_{d,\sigma} < \frac{1}{4}, \quad 0 < \kappa_{d,\sigma} < \frac{1}{1200},$$

so the entire physical range lies inside  $\mathcal{R}$ , and every target atom has strictly positive probability. The physical two-preparation value in the unrestricted-memory original gate interface equals (82) at these parameters. Its exact decision-memory number is five.

*Proof.* The collision estimate gives  $Z > 1/4$  for every prepared point. The conditional two window noises are independent, of equal variance, and the deterministic signal is constant after the collision. Thus, given  $(B, W, Z)$ , the two report bits are independent copies of  $B$  flipped with probability  $e$ .

We justify the distribution of  $Z$  rather than assume a noise symmetry. Reflection in the spatial  $y$  coordinate sends  $(r_y, g_y, V_y)$  to their negatives, interchanges the two  $B$  boxes, and preserves their uniform product laws and the elastic equations. It negates  $v_{1,y}^+$  and leaves  $Z$

unchanged. The only box that depends on  $W$  is the one for  $V_z$ ; changing this center-of-mass velocity cannot change the relative collision or the outgoing  $y$  velocity. All other box coordinates are independent of  $W$ . Consequently  $Z$ , and hence  $e$ , has the same conditional law for all four  $(B, W)$  labels. The Brownian increments are independent of these labels and of the preparation.

The prepared masses of  $(B, W)$  are  $5/16$  for equality and  $3/16$  otherwise. Direct averaging therefore gives

$$\begin{aligned} Q(000) &= Q(111) = 5/16 - 5\mu_1/8 + \mu_2/2, \\ Q(001) &= Q(110) = 3/16 - 3\mu_1/8 + \mu_2/2, \\ Q(010) &= Q(011) = Q(100) = Q(101) = (\mu_1 - \mu_2)/2. \end{aligned}$$

These are precisely (79) with (84). This calculation uses both the common signal and the actual mark; replacing the common signal by independent unconditional report errors would in general replace  $\mu_2$  incorrectly by  $\mu_1^2$ .

The Gaussian bound already proved in the physical bridge yields  $0 < e < 1/600$  uniformly in this physical range. Thus  $0 < \mu_2 < \mu_1 < 1/600$ , proving the parameter bounds. Positivity follows also directly from  $0 < e < 1$  and positive prepared label masses. The all-on construction works against every private candidate in Definition A.10.1; its score is the product-family score. Conversely the common-garbling private subfamily gives the architecture-uniform upper bound. Theorem A.15.1 therefore supplies both exact value and exact decision count for the original interface, not for an auxiliary sensor.  $\square$

*Remark A.16.2* (Known target and acquired calibration). The exact value and exact atomic stochastic realization are statements for a specified target law. Their event-selection probability depends on that target, not on the unknown candidate. When  $d, \sigma$  and the preparation are known, the expectations in (84) are defined integrals of that known physical law. They are not free information about the private parameter. An auditor that must acquire the target instead uses finite calibration and a precision allowance. The following explicit bound makes this separation operational.

**Proposition A.16.3** (Acquisition and finite row precision). *Let the fixed physical target be in the preceding theorem. From  $n$  independent all-on target calibration words define*

$$\hat{\kappa} = \frac{1}{4n} \sum_{i=1}^n \mathbf{1}_{\{X_{1i} \neq X_{2i}\}}, \quad \hat{\gamma} = \frac{1}{n} \sum_{i=1}^n (\mathbf{1}_{\{000,111\}} - \mathbf{1}_{\{001,110\}})(X_i).$$

*Clip these separately to the two intervals of  $\mathcal{R}$ . With probability at least  $1 - 4\exp(-na^2/2)$ , both coordinate errors are at most  $a$ . Choose the optimal response for this clipped target and replace its tie probability by a dyadic number with error at most  $2^{-b}$ . Conditional on that calibration event, its worst-case score against the true target is at least*

$$(85) \quad U_2(b, Q_{d,\sigma}) - 9a - 2^{-b}.$$

*The calibration can be acquired with at most  $(n+1)^3$  counter states and at most  $4(n+1)^3$  states including the current report buffer; retaining the calibration output during the audit gives the conservative product bound  $12(n+1)^3$  at logical report cuts. A sequential fair-bit realization of the tie coin, with its origin and bit phase retained, has a finite explicit bound  $12(n+1)^3 + 8(b+2)(n+1)^3$ .*

*Proof.* The off-diagonal indicator has mean  $4\kappa$  and range one. The signed diagonal indicator has mean  $2a - 2b = \gamma$  and range two. Hoeffding's inequality and a union bound give the displayed failure probability; clipping to an interval containing the truth cannot increase coordinate error. The two target laws have total variation at most  $|\Delta\gamma|/2 + 4|\Delta\kappa| \leq 9a/2$ . Every fixed trained

response changes score by at most this amount when only the target changes, and so does the unrestricted optimal value. Using an optimizer for the estimated target therefore loses at most  $9a$  against the true one. Only the two extreme-count event choices are rounded. Their score contribution changes by at most the coin error, because their total probability is at most one and the change in a single indicator expectation has magnitude at most one. This proves (85).

Three nonnegative category counts, each bounded by  $n$ , compute the two statistics; they also fix the clipped estimates and the subsequent program choice. Keeping this count triple with the twelve-state audit costs at most the stated product. At an extreme count, sample the dyadic coin using  $b$  fair bits and comparison with its binary threshold, retaining the two-valued origin, the comparison flag and the phase. At most  $8(b+2)$  additional states suffice per calibration choice. All other counts select deterministic events. The bound includes the coin workspace instead of identifying an algebraic row with a finite random-bit primitive. The  $n$  target calibrations and the four audit preparations are all charged.  $\square$

#### APPENDIX A.17. OPTIMAL VALIDATION ORDERS AND A POSITIVE-NOISE MEMORY JUMP

We now optimize the order in the original two-tape, bit-level validation interface. Each tape has slots  $1, 2, w$  in that order. Write  $X$  for the candidate tape and  $Y$  for the target tape. There are twenty declared-clock interleavings. A fixed clock is common to all executions; its phase is not a report-dependent side channel. Gate choices, state updates, training and frozen-event selection remain stochastic and otherwise unrestricted as before.

Let  $e_0, \dots, e_4$  be the five events (63). A full raw validation word has output  $e_i(Y) - e_i(X)$ . For the strict training counts, contact forces  $i = 1, 2, 3$  respectively. At either extreme only one raw-event coordinate is indifferent; Theorem A.15.1 fixes its mark-averaged probability to  $t \in (1/10, 1/4)$ .

One precaution is needed. A freshly randomized gate need not couple its two validation coins as one stored event mask would. When both raw validation words equal the indifferent atom, their difference may be random with mean zero. None of the lower certificates below uses that coordinate as a forced deterministic zero. For every additional mixed witness, the known prefix excludes at least one validation word from the indifferent atom, so at least one of the two event indicators is already deterministic. Its future output law is then fixed by the remaining indicator's marginal. This covers both stored-mask and fresh gate implementations.

**Theorem A.17.1** (The minimum over all declared-clock validation orders). *For every  $(\gamma, \kappa) \in \mathcal{R}$  with  $\kappa > 0$ , the least whole-schedule peak attaining  $U_2(b, Q_{\gamma, \kappa})$ , minimized over all twenty declared-clock interleavings, is twelve. The only minimizing orders are the two serial orders*

$$XXXYYY, \quad YYYXXX.$$

*Every nonserial declared order requires peak at least fourteen. The lower bounds permit the full stochastic gate and event interface, not merely an all-on deterministic compiler. These conclusions apply to  $Q_{d, \sigma}$  for every  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ .*

*Proof.* Every raw validation prefix has positive probability at either supporting candidate and at the target. Thus all cut witnesses may be compared on a common full future alphabet. Generate all-on words to simulate training gates as in Theorem A.14.1. The post-training response is an unrestricted optimizer on the supporting subfamily, hence has the contact-forced rows of Theorem A.15.1. Stopping before the two training preparations cannot occur with positive supporting probability: for each retained first-word branch, two possible unused second words force different strict vertices. A positive stopped component cannot belong to both vertices. The witnesses below therefore concern actual post-training validation cuts.

At a cut with two slots consumed from one tape and none from the other, the eight deterministic vertices and four disjoint additional faces from Theorem A.14.3 give twelve. That argument required only the four positive target diagonal words. It is still valid with full target support. Exchanging the two raw tapes negates the output and gives exactly the same channel-polytope certificate at the reversed cut. Thus either serial order needs twelve.

We give explicit certificates at the two possible nonserial entrance cuts. After one slot of each tape, write  $x = X_1$ ,  $y = Y_1$ , and use suffix coordinates  $(u, w, v, z) = (X_2, X_w, Y_2, Y_w)$ . Define

| $i$ | $g_i^0(u, w)$    | $g_i^1(u, w)$ |
|-----|------------------|---------------|
| 1   | $(1 - u)(1 - w)$ | $u$           |
| 2   | $1 - u$          | $u$           |
| 3   | $1 - u$          | $uw$          |

and let  $d_i^{xy} = g_i^y(v, z) - g_i^x(u, w)$ . The twelve expressions with  $i = 1, 2, 3$  and  $x, y \in \{0, 1\}$  give ten distinct deterministic vertices. The only repetitions are  $d_2^{11} = d_1^{11}$  and  $d_3^{00} = d_2^{00}$ , as is seen by substituting  $u, w, v, z \in \{0, 1\}$  in the displayed functions.

There are four more required channels. Use count zero at prefixes  $(x, y) = (0, 1), (1, 0)$  and count four at these same two prefixes. Their endpoints are respectively the continuations of  $(e_0, e_1)$  and  $(e_4, e_3)$ , with nontrivial weights  $1 - t, t$ . Each excludes simultaneous occurrence of the indifferent atom. The minimal face of each such channel consists of distributions supported, at each suffix, on the two endpoint output values. Among the ten mandatory vertices it contains only  $d_1^{01}, d_1^{10}, d_3^{01}, d_3^{10}$ , respectively. These four faces are pairwise disjoint. In their listed order, suffixes separating their six pairs are

| pair           | 12   | 13   | 14   | 23   | 24   | 34   |
|----------------|------|------|------|------|------|------|
| $(u, w, v, z)$ | 0110 | 0010 | 0000 | 0000 | 0001 | 0000 |

At each listed suffix the two sets of permitted output integers are disjoint; this follows directly from the displayed  $g_i^x$  and the masks  $e_0, e_4$ . None of the required mixed rows is the sole mandatory vertex in its face, because  $0 < t < 1$ . Face packing gives  $10 + 4 = 14$ .

Suppose instead two slots of  $X$  and one of  $Y$  have been consumed. A deterministic continuation is indexed by  $(i, X_1X_2, Y_1)$ . The following twelve choices are distinct and include every strict-count continuation:

| $i$ | $(X_1X_2, Y_1)$                                        |
|-----|--------------------------------------------------------|
| 1   | $(00, 0), (00, 1), (01, 0), (01, 1), (11, 0), (11, 1)$ |
| 2   | $(00, 0), (01, 0)$                                     |
| 3   | $(00, 1), (01, 1), (11, 0), (11, 1)$                   |

They are verified by the formula  $e_i(Y_1, Y_2, Y_w) - e_i(X_1, X_2, X_w)$  on the eight suffixes  $(X_w, Y_2, Y_w)$ . At training count zero take additionally prefixes  $(01, 0)$  and  $(11, 0)$ . The corresponding two faces have endpoints  $(0, (1 - Y_2)(1 - Y_w))$  and  $(-1, -1 + (1 - Y_2)(1 - Y_w))$ , respectively. Each contains just its listed  $i = 1$  vertex, and they are disjoint at any suffix with  $Y_2 = 1$ . Both mixtures are nontrivial. Thus this cut also requires fourteen. Swapping  $X, Y$  proves the same result at the cut with one and two slots consumed.

Any nonserial interleaving either reads one slot from each tape first, or starts with two slots of one tape and then switches before its mark. It therefore passes one of the preceding cuts and needs fourteen. Every serial order has an upper realization of peak twelve: select the same five-valued frozen event and use its future residual functions. For full-support raw words the validation widths in either serial order are

$$(5, 10, 12, 10, 10, 7, 3).$$

These counts follow by restriction of the five masks, exactly as in Lemma A.11.4; for the reverse order negate all output residuals and exchange the tapes. Training and the charged stochastic selection cut have width at most five. Therefore both serial orders attain twelve, proving all assertions by Theorem A.8.2. The physical specialization follows from Theorem A.16.1.  $\square$

This theorem optimizes the externally declared schedule; it does not optimize a report-dependent scheduler that changes which tape is read next. Such a scheduler has a different action interface, and its protocol state cannot be supplied for free. The phrase “all orders” in Theorem A.17.1 refers to all twenty declared interleavings, with this quantifier fixed explicitly.

**Theorem A.17.2** (A singular support transition in reverse serial memory). *For every  $\gamma \in [6/25, 13/50]$ , the exact minimum peak in the reverse serial order  $YYYXXX$  for the ideal target  $Q_{\gamma,0}$  is ten. For every  $0 < \kappa \leq 1/1000$  it is twelve. In particular the reverse-serial exact memory of the physical collision experiment jumps from ten at its zero-noise target to twelve at every positive  $\sigma \leq 1/24$ , although its target laws converge in total variation as  $\sigma \downarrow 0$ .*

*Proof.* For the upper bound at the ideal target, ignore its first report bit; its second bit equals the first almost surely, so this does not remove any needed information. After its second bit and mark, retain the residual  $c - e_i(X)$ , where  $c = e_i(Y)$ . Event  $e_2$  has  $c = 1$  surely; each other event permits two values of  $c$ . The compatible reverse validation profile is

$$(5, 5, 9, 9, 10, 7, 3).$$

After the second target bit the nine functions are, with the unread mark denoted by  $z$ ,

$$-e_0, 1 - e_0, 1 - z - e_1, 1 - e_1, 1 - e_2, 1 - e_3, z - e_3, 1 - e_4, -e_4.$$

Restricting after the target mark gives nine functions  $c - e_i$ . After the first candidate bit they give ten distinct functions of  $(X_2, X_w)$ ; after its second bit they give the seven scalar mark functions in Lemma A.11.4. Equality of residual functions is preserved by restriction, so these counts describe one compatible machine, not independent cutwise colorings. Training remains of peak five and the terminal score is correct almost surely for every candidate. On target words of zero probability, choose arbitrary legal transitions.

For the converse examine the cut after all three target slots and the first candidate bit. Write suffixes  $(X_2, X_w)$  in the order 00, 01, 10, 11. The three strict training events force the following eight distinct deterministic output channels:

$$\begin{aligned} (0, 1, 1, 1), & \quad (-1, 0, 0, 0), \quad (1, 1, 0, 0), \quad (0, 0, -1, -1), \\ (0, 0, 1, 1), & \quad (-1, -1, 0, 0), \quad (1, 1, 1, 0), \quad (0, 0, 0, -1). \end{aligned}$$

At training count zero take  $X_1 = 0$  and target words 001 and 110. They force the channels with output means

$$(-t, 0, 0, 0), \quad (1 - t, 1, 1, 1).$$

Every integer coordinate is a point mass, and the remaining coordinate is the indicated mixture of neighboring output integers, because the target event indicator is fixed on these words. Their faces each contain exactly one of the eight mandatory vertices. They are disjoint at suffix 01, which requires output zero in the first and one in the second. Thus two additional generators are required, giving ten. All these prefixes have positive supporting probability. The full-support value twelve follows from the preceding theorem. Formula (84) gives the physical assertion and  $\mu_1, \mu_2 \rightarrow 0$  by the uniform Gaussian bound.  $\square$

The discontinuity concerns exact attainment. It neither contradicts continuity of the optimal score nor prevents a lower-memory device from approximating that score. It also explains why a

support-zero compiler cannot be transferred to the noisy physical target by simply keeping its state count unchanged.

#### APPENDIX A.18. PREPARATION LIMITS AND LOCALIZATION OF LEAST-FAVORABLE PRIORS

The contact structure has a second consequence, now for an arbitrary number of training preparations. We separate a general localization principle from the special geometry of the marked product family. An exact finite- $N$  two-point prior is not assumed.

**Theorem A.18.1** (Nearest-experiment limit and prior localization). *Let  $P_\theta$  be a continuous family on a finite alphabet of size  $d$ , with compact metric parameter space, and let  $Q$  be fixed. Put*

$$d_Q(\theta) = \text{TV}(Q, P_\theta), \quad d_* = \min_{\theta} d_Q(\theta), \quad C_* = \{\theta : d_Q(\theta) = d_*\}.$$

*For  $N \geq 1$ , the unrestricted frozen-validation values satisfy*

$$(86) \quad d_* - \sqrt{(d-1)/N} \leq U_N(P, Q) \leq d_*, \quad U_N \uparrow d_*.$$

*Every least-favorable prior  $\mu_N$  in Theorem A.4.1 satisfies*

$$(87) \quad \int (d_Q - d_*) d\mu_N \leq \sqrt{(d-1)/N}.$$

*Consequently every weak limit of such priors is supported on  $C_*$ . For every  $a > 0$  their mass on  $\{d_Q - d_* \geq a\}$  is at most  $\sqrt{(d-1)/N}/a$ . More generally, an upper bound  $b_N$  on twice the expected total-variation error of a common empirical reconstruction replaces  $\sqrt{(d-1)/N}$  in both conclusions.*

*Proof.* Let  $\hat{P}$  be the empirical law of the  $N$  reports, and choose the indicator  $h_{\hat{P}}$  maximizing  $(Q - \hat{P})h$ . If  $h_\theta$  maximizes  $(Q - P_\theta)h$ , the two event inequalities give

$$(Q - P_\theta)h_{\hat{P}} \geq d_Q(\theta) - 2 \text{TV}(\hat{P}, P_\theta).$$

This inequality holds for the same parameter-independent response rule at every parameter. For any law  $P$  on  $d$  atoms,

$$\mathbb{E} \text{TV}(\hat{P}, P)^2 \leq \frac{d}{4N} \left( 1 - \sum_x P(x)^2 \right) \leq \frac{d-1}{4N}.$$

Thus its expected score is at least  $d_Q(\theta) - \sqrt{(d-1)/N}$ . Every response has score at most  $d_Q(\theta)$  at that parameter, which proves the upper bound at a minimizing parameter. Ignoring the last observation proves monotonicity and hence the limit.

Against a minimizing prior, the Bayes optimum is  $U_N$ . It is at least the prior average of the same empirical rule. Therefore

$$U_N \geq \int d_Q d\mu_N - \sqrt{(d-1)/N}.$$

Combine this with  $U_N \leq d_*$  to get (87). Markov's inequality proves the mass estimate. The function  $d_Q - d_*$  is nonnegative and continuous on the compact parameter space, so its integral under any weak limit is zero. Such a limit is supported on its zero set. The proof uses only the common reconstruction bound, which proves the last assertion.  $\square$

The empirical estimate in (86) is the same finite-alphabet mechanism underlying the retained decision-spectrum classification. Its role here is different: it controls every least-favorable prior, not merely a constructive selector. In particular, finite-preparation saddle supports cannot remain far from the closest candidate experiments as the preparation number grows.

**Theorem A.18.2** (Intrinsic marked contact geometry). *For every  $\gamma \in I$ , set  $s_\gamma = \sqrt{(1+\gamma)/2}$  and*

$$d_\gamma = 2s_\gamma - 1 - \gamma/2, \quad C_\gamma = \{(s_\gamma, s_\gamma), (1 - s_\gamma, 1 - s_\gamma)\}.$$

*Then*

$$(88) \quad \min_{p,q} \text{TV}(Q_\gamma, b(p, q)) = d_\gamma, \quad \operatorname{argmin}_{p,q} \text{TV}(Q_\gamma, b(p, q)) = C_\gamma.$$

*Moreover, for Euclidean distance in  $[0, 1]^2$ ,*

$$(89) \quad \text{TV}(Q_\gamma, b(p, q)) - d_\gamma \geq \frac{7}{2300} \operatorname{dist}((p, q), C_\gamma)^2.$$

*The constant is uniform on  $I$  and is derived from the experiment's atom probabilities, not from a metric-entropy or small-ball assumption.*

*Proof.* Put  $a = (1-p)(1-q)$ ,  $c = pq$ ,  $l = (1-\gamma)/2$  and  $h = (1+\gamma)/2$ . The common mass of target and candidate is  $\psi(a) + \psi(c)$ , where

$$\psi(z) = \begin{cases} z, & 0 \leq z \leq l, \\ z/2 + (1-\gamma)/4, & l \leq z \leq h, \\ 1/2, & h \leq z \leq 1. \end{cases}$$

This follows by summing the smaller mass on each of the two marked atoms corresponding to the report pair. Reflection  $(p, q) \mapsto (1-p, 1-q)$  exchanges  $a, c$ ; assume  $c \geq a$ . If  $c < 1/4$ , both terms are in the first segment of  $\psi$ , and their sum is at most  $1/2$ .

For  $c \geq 1/4$ , put  $x = \sqrt{c} \geq 1/2$ . By the arithmetic-geometric mean inequality,

$$a \leq (1-x)^2 \leq 1/4 < l.$$

Consequently the common mass is at most  $F(x) = (1-x)^2 + \psi(x^2)$ , with equality only when  $p = q = x$ . On the three consecutive intervals with endpoints  $1/2, \sqrt{l}, \sqrt{h}, 1$ , this function is respectively

$$(1-x)^2 + x^2, \quad (1-x)^2 + x^2/2 + (1-\gamma)/4, \quad (1-x)^2 + 1/2.$$

The first two are strictly convex and the last strictly decreases. The first increases away from  $1/2$ . Thus a maximum must occur at  $\sqrt{l}$  or  $\sqrt{h}$ . Their difference is

$$(90) \quad F(\sqrt{h}) - F(\sqrt{l}) = \gamma \left( \frac{3}{2} - \frac{2}{\sqrt{h} + \sqrt{l}} \right) > \frac{7}{575}.$$

Indeed  $\sqrt{h} > 39/50$ ,  $\sqrt{l} > 3/5$ , and  $\gamma \geq 6/25$ , so the right side is greater than  $(6/25)(3/2 - 100/69) = 7/575$ . The unique maximizing diagonal point on this side is  $x = \sqrt{h}$ . Its common mass is  $(1 - \sqrt{h})^2 + 1/2 > 1/2$ , also excluding  $c < 1/4$ . Subtracting it from one gives  $d_\gamma$ . Reflection proves (88) and the assertion about all minimizers.

We record a uniform quantitative form. Write  $s = \sqrt{h}$  and  $\Delta = 7/575$ . For  $1/2 \leq x \leq \sqrt{l}$ , the common mass is at most  $F(\sqrt{l})$ , so its deficit from  $F(s)$  is at least  $\Delta$ . For  $\sqrt{l} \leq x \leq s$ , convexity puts  $F$  below the chord between its endpoint values. Since this interval has length at most one, its deficit is at least  $\Delta(s-x)$ . For  $s \leq x \leq 1$  the deficit is

$$(1-s)^2 - (1-x)^2 = (x-s)(2-s-x) \geq (1-s)(x-s).$$

Since  $s < 4/5$ , this too is at least  $\Delta|x-s|$ . Together the three intervals give  $F(s) - F(x) \geq \Delta|x-s|$ .

Let  $z = (p-q)^2$ . At fixed  $c = x^2$  the additional loss from the nondiagonal candidate is exactly

$$(1-x)^2 - a = p + q - 2x = \frac{z}{p+q+2x} \geq z/4.$$

The geometric mean  $x$  lies between  $p$  and  $q$ , and hence

$$(p - s)^2 + (q - s)^2 \leq 4z + 4(x - s)^2 \leq 4z + 4|x - s|.$$

It follows that the total deficit is at least  $(\Delta/4)((p - s)^2 + (q - s)^2)$ , proving (89) in this case. If  $c < 1/4$ , the total variation is at least  $1/2$ , whereas  $d_\gamma < 12/25$  from  $s < 4/5$  and  $\gamma \geq 6/25$ . The excess is therefore greater than  $1/50$ ; Euclidean squared distance in the square is at most two, and  $1/50 > 2(7/2300)$ . This proves the remaining case. Reflection completes the proof.  $\square$

**Corollary A.18.3** (An all-preparation law and a limiting two-point prior). *For all  $N \geq 1$  and  $\gamma \in I$ ,*

$$(91) \quad d_\gamma - \sqrt{3/N} \leq U_N(b, Q_\gamma) \leq d_\gamma, \quad U_N(b, Q_\gamma) \uparrow d_\gamma.$$

*Every least-favorable prior  $\mu_{N,\gamma}$  satisfies*

$$(92) \quad \int \text{dist}(\theta, C_\gamma)^2 d\mu_{N,\gamma}(\theta) \leq \frac{2300}{7} \sqrt{3/N}.$$

*A least-favorable prior can be chosen invariant under simultaneous complementation of the two parameters. Every such symmetric choice satisfies, for the Euclidean quadratic transport distance,*

$$(93) \quad W_2 \left( \mu_{N,\gamma}, \frac{1}{2} \delta_{(s_\gamma, s_\gamma)} + \frac{1}{2} \delta_{(1-s_\gamma, 1-s_\gamma)} \right) \leq \sqrt{2300/7} (3/N)^{1/4}.$$

*In particular, the limiting symmetric least-favorable law is unique.*

*Proof.* Estimate the four-atom report-pair law from training and tensor it with the known fair mark. Tensoring with a common probability preserves total variation. The proof of Theorem A.18.1 therefore uses  $d = 4$  rather than eight, proving (91) and an excess bound  $\sqrt{3/N}$ . Combining the latter with (89) gives (92).

Simultaneously complement both report bits and the mark in every training and validation word. This leaves  $Q_\gamma$  invariant and sends  $b(p, q)$  to  $b(1 - p, 1 - q)$ . The Bayes objective in (25) is invariant under this transformation and convex in the prior. Averaging a minimizing prior with its reflected image is therefore again minimizing and is symmetric.

Map each parameter to a closest point of  $C_\gamma$ , choosing the two points with equal probabilities at a tie. This is a Borel kernel, equivariant under reflection. A symmetric prior is pushed forward to the equal two-point law in (93); the induced coupling has squared transport cost exactly the left side of (92). Taking square roots proves the assertion.  $\square$

These conclusions identify the endpoint and limiting contact geometry for every preparation number. They do not assert that the exact prior has two atoms at every finite  $N$ , or that the displayed convergence rates and constants are sharp. The finite- $N = 1, 2$  saddles are preserved as exact results. The new theorem explains their relationship to an intrinsically determined limiting contact set without extrapolating their particular event tables to unproved values of  $N$ .

#### APPENDIX A.19. AN EXACT PREPARATION–DECISION–MEMORY LAW

A second solvable family separates a genuine joint resource law from an implementation bound. Here the memory coordinate is the number of states at the training–validation cut. It is not identified with the bit-level peak width of the collision audit.

Fix  $m = 2^d$ ,  $0 < \alpha < 1$ , and an unknown parameter  $\theta \in \{1, \dots, m\}$ . A fresh training preparation reports  $\theta$  with probability  $\alpha$  and an erasure  $\perp$  otherwise. Conditional on  $\theta$ , the preparations are independent. Candidate validation has law  $\delta_\theta$  and target validation is uniform on  $\{1, \dots, m\}$ . At the decision cut the auditor retains at most  $K = 2^k$  states,  $0 \leq k \leq d$ . Its subsequent response may depend only on that state, current validation observations and fresh

independent randomness. In particular, a calibration table, remembered seed or stopping time outside the retained state is not available. Upstream and downstream memory are otherwise unrestricted for the converse. Let  $V_N^{\text{er}}(K)$  be the best worst-case expected signed validation score with at most  $N$  training preparations.

**Theorem A.19.1** (Exact joint law). *For every  $N \geq 0$  and  $K = 2^k \leq m$ ,*

$$(94) \quad V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N) \left(1 - \frac{1}{K}\right).$$

*The converse covers stochastic encoders and arbitrary legal stopping. The value is attained by a clocked machine with  $K$  training states. With atomic preparation and validation outcomes, the complete audit has peak at most  $\max\{2K, 3\}$  and uses at most  $N + 2$  preparations.*

*Proof.* Write  $q = (1 - \alpha)^N$  and pre-generate  $N$  potential training reports. A stopped auditor ignores the unused reports; this does not disclose extra information to it. On the event that all  $N$  reports are erasures, its retained-state law  $r = (r_j)_{j=1}^K$  is independent of  $\theta$ . After padding any smaller register with unused states, its channel to the decision register has the form

$$(95) \quad C(j \mid \theta) = qr_j + (1 - q)S(j \mid \theta)$$

for a stochastic channel  $S$ . This identity remains valid with randomized stopping and randomized state updates.

Use the uniform prior on parameters as an upper certificate. The part  $qr_j$  has zero expected score for every response: averaging  $\delta_\theta$  under this prior gives the target itself. For the other part, optimizing over all responses gives a convex function of  $S$ , a sum of positive parts of linear functions. Every stochastic channel is a convex combination of deterministic channels  $j = g(\theta)$ ; therefore its value is at most the largest deterministic-channel value. This convexification is used only to bound a channel. It does not presuppose that a mixture of width- $K$  machines is realizable at width  $K$ .

If the fibers of  $g$  have sizes  $n_1, \dots, n_K$ , a nonempty fiber has posterior uniform on that fiber, so its total variation from the uniform target is  $1 - n_j/m$ . The prior-averaged optimal score is

$$\sum_j \frac{n_j}{m} \left(1 - \frac{n_j}{m}\right) = 1 - \sum_j (n_j/m)^2 \leq 1 - 1/K.$$

Empty fibers contribute zero. Cauchy–Schwarz proves the inequality. This is an upper bound on the average score and hence on its minimum over fixed parameters. Multiplying by  $1 - q$  proves the upper bound in (94).

For attainment, partition the parameter alphabet into  $K$  equal groups and let  $g(\theta)$  denote its group. Initialize the register uniformly on the  $K$  group labels. On an erasure leave it unchanged; on a revealed parameter overwrite it by  $g(\theta)$ . No extra “revelation occurred” flag is needed. At the decision cut its law is  $q \text{Unif}[K] + (1 - q)\delta_{g(\theta)}$ . For register  $j$ , freeze the event which is the complement of group  $j$ . On a revelation its score is  $1 - 1/K$ . Under a uniformly random initial label, the mean score is zero for each fixed  $\theta$ : one of the  $K$  labels has score  $1 - 1/K$  and the others have score  $-1/K$ . This proves the exact worst-case value.

The  $k$  initialization bits can be accumulated in the  $K$ -state register; all earlier prefix counts are at most  $K$ . Thus no persistent seed lies outside it. Candidate validation retains the group label and its event indicator, using at most  $2K$  states. Target validation produces one of the three values  $-1, 0, 1$ . This proves the atomic-outcome peak bound. The controller uses a declared external schedule; an autonomous stopping implementation must additionally retain its phase. A phase-tagged implementation is finite, but its cost is not included in  $K$ .  $\square$

**Corollary A.19.2** (Thresholds and matching resource scales). *For  $K \geq 2$  and  $0 \leq c < 1 - 1/K$ , the least integer number of training preparations giving a score strictly greater than  $c$  is*

$$(96) \quad N_c^{\text{er}}(K) = \left\lfloor \frac{\log(1 - c/(1 - 1/K))}{\log(1 - \alpha)} \right\rfloor + 1.$$

*If  $c \geq 1 - 1/K$ , no finite  $N$  suffices. For  $0 < \varepsilon < 1$ , achieving  $V_N^{\text{er}}(K) \geq 1 - \varepsilon$  requires*

$$K \geq \varepsilon^{-1}, \quad N \geq \frac{\log(1/\varepsilon)}{-\log(1 - \alpha)}.$$

*Conversely, whenever an allowed  $K \leq m$  satisfies  $K \geq 2/\varepsilon$ , the choice  $N \geq \log(2/\varepsilon)/[-\log(1 - \alpha)]$  suffices.*

*Proof.* The strict threshold is equivalent to  $(1 - \alpha)^N < 1 - c/(1 - 1/K)$ . Since the denominator logarithm is negative, the least integer satisfying this strict inequality is (96), including equality cases of the real quotient. Also

$$1 - V_N^{\text{er}}(K) = q + (1 - q)/K.$$

This is at least  $q$  and at least  $1/K$ , and is at most  $q + 1/K$ . These three inequalities prove the necessary and sufficient bounds.  $\square$

The exact law concerns an entire  $(N, K, \alpha, m)$  family, not a single finite diagnostic. Its mechanism is a parameter-independent erasure component followed by the convex geometry of the decision channel. It demonstrates how a preparation obstruction and a memory obstruction can be matched in one theorem. It does not identify the least physical peak width at two collision preparations. Encoding the  $m$ -symbol reports bit by bit also introduces cuts not present in this atomic model; the physical bit-level accounting is given separately.

#### APPENDIX A.20. INTEGER MEMORY AND THE FAILURE OF A NAIVE PARTITION FORMULA

The divisibility assumptions in Theorem A.19.1 can be removed, but a balanced-partition Bayes bound must not be mistaken for a minimax equality when a persistent random partition is not free. This distinction leads to another exact finite-resource transition.

Keep the revelation interface, but allow any integers  $m \geq 2$  and  $1 \leq K \leq m$ . Put  $\rho = 1 - (1 - \alpha)^N$ , and denote the genuine  $K$ -label minimax value by  $V_{N,m}^{\text{er}}(K)$ . Write  $m = Kq + s$ ,  $0 \leq s < K$ , and set

$$(97) \quad B_{m,K} = 1 - \frac{(K - s)q^2 + s(q + 1)^2}{m^2}.$$

Here and below all-erasure initialization randomness is a state initialization, not an unrecorded seed used again at validation.

**Proposition A.20.1** (Arbitrary integer alphabet bounds and low-reveal equality). *The optimal uniform-prior Bayes score is  $\rho B_{m,K}$ . The minimax value satisfies*

$$(98) \quad V_{N,m}^{\text{er}}(K) \leq \min \left\{ \rho B_{m,K}, 1 - \frac{\lceil m/K \rceil}{m} \right\}.$$

*If  $\rho \leq m/(m + s)$ , equality with the first term holds. At perfect revelation  $\rho = 1$  the exact value is the second term. In particular, when  $s > 0$  the uniform-prior Bayes optimum at perfect revelation is strictly larger than the minimax value.*

*Proof.* The all-erasure decomposition (95) holds without any divisibility condition. Its parameter-independent part has zero uniform-prior score. Optimizing the other part over responses gives a convex function of its stochastic channel. A deterministic channel with fiber sizes  $n_j$  has Bayes score  $1 - \sum_j (n_j/m)^2$ . If two nonempty fiber sizes differ by at least two, moving one index from the larger to the smaller strictly decreases the sum of squares. Allowing empty fibers and repeating gives sizes  $q$  and  $q + 1$ , proving the Bayes bound. It is attained by this partition and its complementary events, with any parameter-independent initialization. This proves the first upper bound as well as the asserted Bayes optimum.

For perfect revelation, fix any  $K$  response vectors. For each known parameter choose a response maximizing its score; this deterministic assignment cannot decrease any parameter's payoff, even when the original encoder was randomized. Some assigned fiber has size at least  $\lceil m/K \rceil$ . Averaging its parameters, the score of their common response is at most the total variation between the uniform target and the uniform law on that fiber, namely  $1 - |\text{fiber}|/m$ . The minimum is no larger. Balanced fibers with their complementary events attain the resulting upper bound. A perfectly informed encoder can simulate any less informative encoder, so this is an upper bound at every  $\rho$ .

For the low-reveal equality let balanced fibers have weights  $w_j = n_j/m$ . When  $\rho < 1$ , initialize their label register with probabilities

$$(99) \quad r_j = \frac{\rho w_j + (1 - 2\rho)/K}{1 - \rho}.$$

These sum to one, and are nonnegative precisely throughout the stated range: the smallest numerator is  $\rho q/m + (1 - 2\rho)/K$ . On a revealed parameter overwrite the label by its fiber; on erasure do nothing. No revelation flag is retained. For a parameter in fiber  $i$ , the complementary-event score is

$$\begin{aligned} g_i &= \rho(1 - w_i) + (1 - \rho) \left( r_i - \sum_j r_j w_j \right) \\ &= \rho \left( 1 - \sum_j w_j^2 \right) = \rho B_{m,K}. \end{aligned}$$

This matches the upper bound uniformly in the fixed parameter. If  $\rho = 1$  and  $s = 0$ , the deterministic revealed label already attains that value, so the singular denominator in (99) is not used. Finally, with unequal balanced fibers the weighted average of their sizes is strictly smaller than the largest size; equivalently  $B_{m,K} > 1 - \lceil m/K \rceil/m$ . This proves the last assertion.  $\square$

**Theorem A.20.2** (The complete two-label revelation law). *For every  $m \geq 2$ , every  $N \geq 0$ , and  $0 < \alpha < 1$ , set  $w = \lfloor m/2 \rfloor/m$  and  $b = \lceil m/2 \rceil/m$ . Then*

$$(100) \quad V_{N,m}^{\text{er}}(2) = \min\{2wb\rho, w\}, \quad \rho = 1 - (1 - \alpha)^N.$$

*The same formula holds at the limiting endpoints  $\rho = 0, 1$ . For odd  $m$  it changes regime at  $\rho = m/(m + 1)$ ; for even  $m$  it reduces to  $\rho/2$ . The attaining machine uses two training labels, a frozen two-event alphabet, and atomic peak at most four.*

*Proof.* Proposition A.20.1 gives the upper bound and its attainment for  $\rho \leq 1/(2b)$ . Above this threshold, partition into fibers of weights  $w, b$  and initialize deterministically in the larger fiber's label. Continue to overwrite on a reveal and leave the state unchanged on an erasure. A parameter in the larger fiber has score  $w$ ; a parameter in the smaller fiber has score  $(2\rho - 1)b$ . The latter is at least  $w$  exactly when  $\rho \geq 1/(2b)$ . This attains the second upper bound. For even  $m$  the threshold is one, so the low-reveal construction suffices. The endpoint  $\rho = 0$  may instead

freeze a constant event. Candidate validation retains the selected label and its indicator, with at most four states; target validation produces the difference. Initialization is atomic randomization when its probabilities are not dyadic.  $\square$

For example,  $m = 3, K = 2$  gives  $V_{N,3}^{\text{er}}(2) = \min\{4\rho/9, 1/3\}$ , rather than  $4\rho/9$  for all  $\rho$ . The balanced-integer expression is therefore not the unqualified replacement of the divisible minimax formula. For  $K \geq 3$  outside the low-reveal range, (98) remains a bound rather than an asserted equality. The compatible dynamic formulation of Section A.6 retains the exact optimization in that regime. These results strengthen the revelation example without identifying its decision-cut coordinate with the collision model's bit-level peak.

#### APPENDIX A.21. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows, and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r-1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(101) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma A.21.1** (Causal interpretation of the coefficients). *Every coefficient in (101) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (101) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at

most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem A.21.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_{\theta} g_{\theta}(q^C), \quad u_C = \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(102) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_{\alpha} (u_C - b_{\theta_C, C, \alpha}) B_{\alpha}(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .*

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (101) implies

$$\min_{\theta} g_{\theta}(q) \leq \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma A.21.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (102). Choose  $\theta_C$  attaining the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

**Remark A.21.3.** The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem A.4.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

## APPENDIX A.22. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [6]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma A.22.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-}(L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem A.22.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(103) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(104) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma A.22.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ , and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (104).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_{\pm}^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ .

Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_{\pm}^n(i, \cdot), \pi_{\pm}) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (104). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (103). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (104) is an observation time at which an external analyst reads the autonomous machine, not a free input clock used by its transitions. The adversarial model of [10] is not covered by the independent-report proof above.

#### APPENDIX A.23. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary A.23.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\overline{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\overline{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\overline{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding’s inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition A.23.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (25); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem. This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

#### APPENDIX A.24. A SHARPENED PHYSICAL CONSUMER AND ITS SIMULATION BUDGET

The exact two-preparation theorem has a downstream use with explicit hypotheses, rather than a merely renamed dependency arrow. It sharpens the mean margin of a raw-interface confidence test, and the causal morphism theorem transfers that test, with its full memory and calibration costs, to another executable interface.

**Theorem A.24.1** (Confidence and transported resource certificate). *Let  $Q$  be a physical marked target with  $\text{TV}(Q, Q_*) \leq \beta$ . Use the two-preparation event selector with a dyadic coin  $\tau_b$  satisfying  $|\tau_b - \tau| \leq 2^{-b}$ , and put*

$$a_b = v_2 - \beta - \frac{5}{16}2^{-b}, \quad W_b = \max\{12, 6(b+1) + 5\}.$$

*If  $0 < c < a_b$ ,  $R$  independent four-preparation blocks, followed by the test  $\overline{D}_R > c$ , have error bounds*

$$(105) \quad \sup_{\text{private}} \mathbb{P}(\overline{D}_R \leq c) \leq \exp\{-R(a_b - c)^2/2\},$$

$$(106) \quad \sup_{\text{equal}} \mathbb{P}(\overline{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*They use  $4R$  preparations, at most  $bR$  fresh random bits, and at most  $W_b(2R+1)$  persistent states under a clocked schedule. With an exact atomic coin, replace  $a_b, W_b$  by  $v_2 - \beta, 12$ .*

*Suppose a source interface simulates this entire repeated audit under Theorem A.2.4, uniformly over the private and equal-law families, with path defect  $\Delta_R$ . Then the corresponding source error bounds are the right sides of (105)–(106) plus  $\Delta_R$ , capped at one. At aligned cuts its state bound is  $C_{\text{cal}}R_tM_tW_b(2R+1)$ , and its preparation count is  $N_{\text{cal}}$  plus all source calls required to supply the  $4R$  audit preparations. Calibration is acquired and retained, not supplied as a free real-valued table.*

*Proof.* Corollary A.12.2 and Proposition A.12.3 give mean block score at least  $a_b$  under every fixed private parameter. Independent fresh preparations and independent coins give independent block scores in  $[-1, 1]$ . Hoeffding's inequality proves (105). Under the equal-law null, conditional on training and the frozen event, the two validation indicators have the same mean. Each block therefore has mean zero, proving (106) by the same inequality. Retain the integer sum in

$\{-R, \dots, R\}$  alongside the current block register. Updating the sum and resetting the block is a deterministic boundary operation. This proves the raw resource bounds.

Apply Theorem A.2.4 to the whole repeated experiment, including its stopping and validation fields. Its defect bound applies to each of the two terminal error events, whose indicators have range one; each probability therefore changes by at most  $\Delta_R$ , not  $2\Delta_R$ . The same theorem gives the state product and preparation count. The source blocks need not be independent after a shared calibration stage: independence was used only for the reference audit, and path-law comparison transfers its final event probability.  $\square$

The first part uses the exact saddle, the original microscopic bridge and the compiled residual machine. The second additionally needs the uniform acquired causal simulation theorem. A source which does not satisfy that theorem's stability and calibration hypotheses is not covered. Likewise this consumer supplies no reverse simulation and therefore does not transfer an optimal-width lower bound to an arbitrary source. It is an actual conditional theorem interface for subsequent models, not an assertion that the independent geometric A2 chain or the unbounded B4/C2 operator obligations have already been discharged.

#### APPENDIX A.25. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section A.21 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section A.22 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (62), polynomial identity (64), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: ROBUST SADDLES, CAUSAL MEMORY, AND VALIDATION ORDER

QIAN QI

**ABSTRACT.** We relate minimax contact geometry to the memory of causal statistical experiments. For a two-parameter family of full-support marked targets, we determine the exact two-preparation saddle and prove that five states are necessary and sufficient at the decision cut. The original positive-noise hard-sphere sensor is shown, by its preparation and reflection symmetries, to belong to this family throughout the explicit range  $0 < \sigma \leq 1/24$ . A facial scheduling criterion supplies converses uniform over stochastic encoders and over the declared validation order. Among all twenty clocked interleavings of the two three-slot validation tapes, the exact minimum peak is twelve; precisely the two serial orders attain it, and every nonserial order requires at least fourteen states. At zero noise, reverse serial validation instead has exact peak ten. Thus exact causal memory can jump at a support boundary while the statistical value varies continuously. We also retain the causal foundations, controlled minimax duality, exact ideal saddles, all-preparation localization, and resource-accounted transport results that enter this theorem chain.

## 1. INTRODUCTION

An optimal statistical decision and a minimum-memory realization of that decision are different objects. A least-favorable prior exposes a face of Bayes-optimal responses. Uniform minimax optimality imposes additional contact conditions, including on coordinates to which that prior assigns zero coefficient. Once those conditions have determined an optimal response, its realizability depends on common positive continuations across every charged cut. The order in which independent validation preparations are read is then a mathematical part of the memory problem, not a harmless implementation convention.

The present paper develops this connection from prepared causal experiments to an exact positive-noise physical theorem. We use finite registers, count all persistent selectors and report buffers, and freeze one row–event continuation before independent candidate and target validation. The unknown candidate parameter is fixed through the audit. The target is a specified law; acquisition of unknown target calibration has a separate resource charge. A clocked validation schedule is declared before data are observed. Report-dependent scheduling is a distinct controlled interface and is not treated as an uncharged clock.

**1.1. The principal theorem chain.** Let the private all-on experiment be  $b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2)$ . On the four diagonal marked atoms 000, 001, 110, 111, give the target masses

$$\frac{1+\gamma}{4} - \kappa, \quad \frac{1-\gamma}{4} - \kappa, \quad \frac{1-\gamma}{4} - \kappa, \quad \frac{1+\gamma}{4} - \kappa,$$

and give each other atom mass  $\kappa$ . For  $(\gamma, \kappa) \in [6/25, 13/50] \times [0, 1/1000]$ , the full-support saddle theorem determines the exact value by the unique root  $r \in (33/100, 7/20)$  of

$$r^3 + (13 - 2\gamma + 8\kappa)r^2 + (3 - 12\gamma + 48\kappa)r - 1 - 2\gamma + 8\kappa = 0.$$

A global polynomial factorization proves the lower bound. Every signed posterior coefficient is checked for the matching two-point prior. Support contact and stationarity determine the two Bayes-indifferent response coordinates in an interval strictly inside  $(0, 1)$ . Consequently the minimum post-training decision width is exactly five, not merely at the ideal target but throughout this explicit rectangle. See Theorem 16.1.

The physical identification is exact. In the original collision model, the two Brownian report windows have one common random signal amplitude and conditionally independent noises. If  $e$  is their conditional sign error probability, put  $\mu_1 = \mathbb{E}e$ ,  $\mu_2 = \mathbb{E}e^2$ . Preparation reflection and center-of-mass independence give

$$\gamma = \frac{1}{4} - \frac{\mu_1}{2}, \quad \kappa = \frac{\mu_1 - \mu_2}{2}.$$

The previously proved mechanical and Gaussian estimates place these parameters in the saddle rectangle for every contact distance  $9/10 \leq d \leq 11/10$  and every  $0 < \sigma \leq 1/24$ . Theorem 17.1 thus proves exact physical memory on a quantified positive-noise range. It does not infer exact counts from an unevaluated compactness gap.

Theorem 9.2 gives a general schedule certificate. Contact-forced vertices and disjoint faces supply a capacity at each consumed-prefix configuration. Compatible residual functions supply an upper realization. A matching path in the finite schedule graph identifies the exact minimum across schedules and stochastic architectures. The distinction between expected responses and complete output channels is essential: two independent gate coins can produce a random output with mean zero. Our certificates do not replace such a channel by a deterministic zero.

For the full-support marked family the certificates imply

$$W_{\text{clk}}^{\min} = 12, \quad \text{argmin}_{\text{clock orders}} W = \{XXXXYYY, YYYXXX\}.$$

Here each letter reads the next slot of its tape, preserving the order of the two report bits and the mark. All other eighteen interleavings need at least fourteen states. At the ideal target the exact reverse serial peak is instead ten. Theorems 18.1 and 18.2 therefore show how a support change can alter exact memory even when the law and its minimax value change continuously. They do not identify a feedback scheduler with the fixed-clock class.

**1.2. Foundations and retained results.** The object-level route is the prepared causal experiment, its future-test quotient, an executable causal morphism, and the attainable resource profile. The first sections give A0–A5, conditional-mean and entropy identities, checkpoint resolution, online implementation, and joint calibration/model-error transport. The classical mechanisms are stated with their hypotheses rather than taken as a universal geometric law. The unrestricted controlled dual uses a single adversarial prior; the finite-memory occupation formulation does not convexify persistent selectors for free. The informative routing example remains a sharp multicut result.

The ideal marked values  $U_1$  and  $U_2$ , their continuous target family, and the self-contained microscopic bridge are included in full. For arbitrary preparation number the closest-experiment endpoint and least-favorable-prior localization remain as proved, including the explicit contact geometry of the ideal marked family. The present positive-noise and scheduling results do not assert a sharp large- $N$  expansion or a finite- $N$  support law. Revelation, finite-architecture certification, autonomous testing and transported confidence results are retained with their

distinct resource conventions. No result is removed to obtain the new memory theorem. For reference, the deterministic precursor constants retain their notation:

$$(1) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

The sensor moments  $\mu_1, \mu_2$  used above are different quantities.

**1.3. Relation to earlier work.** Classical experiment comparison and minimax supply the convex statistical ingredients [2, 3]. Controlled sensing, sequential experimental design and finite-horizon belief control are established subjects [13, 1, 14, 15]. Positive stochastic realization, invariant generating cones and nonnegative-rank geometry have a substantial literature [17, 18, 19]. Partial-input state minimization requires compatible coverings [20]. Finite-memory testing and the role of stochastic policies are likewise classical [6, 7, 8, 9], and the recent settings of [10, 16] have their own objectives and adversaries.

We do not claim the matrix-product normal form, the elementary loss identity, residual minimization, or dynamic programming as new. The loss identity is recorded separately as Proposition 8.2. The realization theorem retains its substantive contact and compatibility statements. The new consequences under consideration are the full-support saddle region containing the original Brownian model, the all-declared-order physical memory theorem, and the exact support-boundary jump. They use contact-forced channels common to every optimizer rather than the state count of an arbitrarily selected Bayes tie rule. The comparison with general filtered experiments [11] is not represented as a completed proof-level priority audit.

The historical geometric and unbounded-operator pipelines retain their own assumptions and derivations. In particular no finite-state argument here proves the Fourier/LLT, stopped-LDP, nonlinear semigroup or strict/form-response gates of A2, B4 or C2. The new physical memory converse is a genuine proof consumer of the foundations layer, not a replacement label for those independent analyses.

## 2. CAUSAL EXPERIMENTS AND THEIR PREDICTIVE QUOTIENTS

We begin with the object and morphism structure. Its elementary probability statements fix the meaning of later resource theorems; classical kernel construction, conditional expectation and quantization are not assigned a new priority. The substantive comparisons below retain their preparation, memory and approximation coordinates simultaneously.

**2.1. The experimental object.** An experiment has a fixed unknown parameter  $\theta \in \Theta$ , hidden states  $X_t$ , visible actions  $A_t$ , reports  $Y_{t+1}$ , and preparation laws  $\mu_\theta$ . We impose the following six conventions.

**A0 (types and visibility).** These spaces are standard Borel. Visible histories include actions, reports and publicly recorded resource increments. A legal-action set and its remaining budget are part of the visible protocol type. Two histories with different legal continuations are not identified.

**A1 (positive kernels).** There are jointly measurable normalized nonnegative kernels  $K_t^\theta(dx', dy, dc | x, a)$ , with  $c$  a nonnegative resource increment. An absorbing symbol represents termination or failure. Dirac kernels are allowed. Positivity here does not require every outcome to have strictly positive probability. A hidden state can contain the necessary physical past; this notation does not assume a finite-dimensional physical closure.

**A2 (causality).** A policy is a kernel  $\alpha_t(da | h_t)$  depending only on visible past data and allowed independent randomization. It cannot read the unknown parameter. Stopping is with respect to the visible filtration.

**A3 (executable tests).** The specified bounded future tests include constants, required report events and their legal one-step continuations. For discrete reports the one-step instrument is

$$(\mathbb{T}_{t,a,y}f)(\theta, x) = \int f(\theta, x') K_t^\theta(dx', \{y\}, dc \mid x, a).$$

The test spaces are closed under the required instruments, finite linear combinations and the bounded monotone limits needed to recover the stated event laws. For general reports one uses event instruments and regular conditional distributions, not division by the probability of a continuous singleton.

**A4 (actual preparation).** Average risks and acquired state laws refer to the specified preparation and exploration protocol. Failed trials, calibration, resets and conditioning events retain their probabilities and implementation costs. A convenient measure on a reachable set does not replace its acquired law.

**A5 (executable resources).** Persistent labels, temporary buffers, program constants, calibration precision, preparations and clocks are distinguished. A retained selector is a state. A parameter-dependent table is not a known program constant. A simulator with  $R_t$  labels composed with a controller with  $K_t$  labels has the direct product bound  $R_t K_t$ , before any justified quotient is taken. Atomic stochastic rows and fair-bit implementations are separately specified.

**Proposition 2.1** (Prepared path laws). *For every fixed parameter and causal policy, the preparation and kernels uniquely determine their finite-dimensional path laws. On a finite horizon they are the iterated kernel product*

$$\mu_\theta(dx_0) \prod_{t < T} \alpha_t(da_t \mid h_t) K_t^\theta(dx_{t+1}, dy_{t+1}, dc_t \mid x_t, a_t).$$

*These laws are consistent under marginalization. For a countable horizon they determine the usual kernel extension. Deterministic dynamics give their original trajectory laws when represented by Dirac kernels.*

*Proof.* Successive integration constructs each finite law. Normalization of the last two kernels gives its preceding marginal, and induction proves consistency and uniqueness on cylinder events. The countable kernel extension gives the full law; equivalently one applies the standard extension theorem to these consistent iterated kernels. Integration against a Dirac transition is evaluation along that transition, which proves the last assertion.  $\square$

**2.2. Prepared predictive equivalence.** For Bayesian predictions additionally fix a prior on the parameter, and regard  $(\theta, X_t)$  as the hidden variable. A prepared posterior  $\pi$  at a given protocol type evaluates the future tests. Define  $\pi \sim_t \tilde{\pi}$  if their evaluations agree on every specified future test. This definition concerns one prepared experiment; it does not identify a prior-dependent posterior with a statistic sufficient simultaneously for all fixed parameters.

**Theorem 2.2** (Predictive quotient and causal closure). *For finite report alphabets, predictive equivalence is preserved by every legal positive-probability report update. Its class determines the laws of all specified future experiments. Every deterministic history statistic that determines those laws factors onto this quotient. For a measurable realization it is sufficient that a countable separating test family gives a measurable evaluation map with standard Borel image, and that the chosen statistic admits a measurable factor. In finite history spaces the latter conditions are automatic.*

*Proof.* For a legal action and report, Bayes' rule gives

$$\pi'(f) = \frac{\pi(\mathbb{T}_{t,a,y}f)}{\pi(\mathbb{T}_{t,a,y}1)}.$$

Both numerator and denominator depend only on the old class by A3. Equivalent posteriors assign the same probability to the report, so updates agree on the next test space whenever that probability is positive. Null reports do not affect the prepared law and may be assigned a fixed admissible version. Induction determines every finite future report word; the monotone-class extension gives the required future events. Conversely those event laws determine the tests. If two histories have the same sufficient statistic, they have the same future evaluations; the quotient is therefore constant on its fibers. This gives the factor set-theoretically. The stated measurable factor assumption supplies its measurable version; no claim that every abstract quotient of a standard Borel space is standard Borel is used.  $\square$

**Proposition 2.3** (Barycenters, entropy and normalized response). *In a fixed preparation, suppose a hidden target  $Z$ , observation  $Y$  and postprocessing  $W$  form a Markov chain  $Z \rightarrow Y \rightarrow W$ . For any bounded vector of tests  $f$ ,*

$$p_W = \mathbb{E}[p_Y | W], \quad p_Y = \mathbb{E}[f(Z) | Y], \quad \mathbb{E}\varphi(p_W) \leq \mathbb{E}\varphi(p_Y)$$

*for every convex  $\varphi$  for which these expectations exist. For a parameter-independent kernel  $G$ ,  $P \ll Q$ , and finite  $D(P\|Q)$ , regular conditional laws give*

$$\begin{aligned} D(P\|Q) &= D(PG\|QG) \\ &\quad + \int D(P(dx | w)\|Q(dx | w)) (PG)(dw). \end{aligned}$$

*Finally, if  $f, g$  are bounded and  $\pi_u(dx) = e^{ug(x)}\pi(dx)/\pi(e^{ug})$ , then*

$$\left. \frac{d}{du} \pi_u(f) \right|_{u=0} = \text{Cov}_\pi(f, g).$$

*Proof.* The Markov property and the tower rule give the conditional barycenter; conditional Jensen gives convex order. The joint laws  $P(dx)G(dw | x)$  and  $Q(dx)G(dw | x)$  have relative entropy  $D(P\|Q)$ . Disintegrating by  $w$  and applying the entropy chain rule gives the identity, and hence data processing. The last equality follows by quotient differentiation; boundedness justifies differentiation under the integral.  $\square$

The barycenter statement concerns a law of predictions, not a pointwise map between reachable sets. Likewise the covariance in the last formula is a normalized response, not an independently postulated Fisher matrix or a global sufficiency theorem.

### 3. ATTAINABLE RESOLUTION AND RESOURCE-AWARE SIMULATION

**3.1. Checkpoint and online prediction.** Fix an actual exploration protocol and its history law. Let  $p(h)$  be a bounded  $d$ -dimensional conditional prediction vector, with law  $\nu$ . For instance, a future test is sampled independently after encoding, and the coordinates include its sampling weights. Squared excess prediction loss is then  $\mathbb{E}\|p(h) - \hat{p}\|^2$ .

**Proposition 3.1** (Checkpoint resolution). *For at most  $M$  retained labels the least checkpoint excess loss is*

$$(2) \quad \inf_{c_1, \dots, c_M} \int \min_{1 \leq j \leq M} \|p - c_j\|^2 \nu(dp).$$

*Independent randomized encoders or decoders cannot improve it. This formula concerns the stated preparation and does not provide a common codebook by separately optimizing at each unknown true parameter.*

*Proof.* Conditional squared loss decomposes into its Bayes loss and squared distance from the conditional mean. For each retained label replace a random decoder by its mean. Random assignment to the resulting centers cannot do better than a nearest center. Conversely a nearest-center assignment attains the infimum over codebooks arbitrarily closely. Conditioning on an independent shared random seed, if such a seed is allowed, gives a codebook for each seed, each with risk at least (2). Averaging cannot improve the bound. The formula does not charge the computation of a checkpoint assignment as an online algorithm; online compatibility is a separate condition.  $\square$

**Theorem 3.2** (A matched online resolution law). *Suppose a fixed prepared experiment has a predictive state  $s_t$  in a compact metric space  $S$ , a known initial state, and updates  $s_{t+1} = F_{t,a,y}(s_t)$ . Assume every permitted update is  $\rho$ -Lipschitz for one  $0 \leq \rho < 1$ , and the prediction map  $p : S \rightarrow \mathbb{R}^d$  is  $L$ -Lipschitz. Suppose  $S$  has a  $\delta$ -net of at most  $C\delta^{-d}$  points for all sufficiently small  $\delta$ . At a checkpoint  $T$ , assume the actual law  $\nu$  of  $p(s_T)$  satisfies the small-ball bound  $\nu(B(z,a)) \leq Aa^d$  for every center  $z$  and all sufficiently small  $a > 0$ . Then for all sufficiently large  $M$ , the minimum online excess prediction loss with  $M$  retained predictive labels satisfies*

$$(3) \quad c_0 M^{-2/d} \leq R_M^{\text{on}} \leq C_0 M^{-2/d}.$$

Here one may take

$$c_0 = \frac{1}{2}(2A)^{-2/d}, \quad C_0 = \frac{L^2 C^{2/d}}{(1-\rho)^2},$$

Any separate exploration controller, report buffer or clock is charged in addition to these  $M$  labels. The exploration protocol and the preparation are fixed before optimizing the encoder.

*Proof.* Any online  $M$ -label state is also a checkpoint encoder, so Proposition 3.1 applies. For any  $M$  centers, the union of balls of radius  $a = (2AM)^{-1/d}$  has  $\nu$ -mass at most one half. On its complement squared distance is at least  $a^2$ . Integration gives  $c_0 M^{-2/d}$ . This argument also permits randomized online encoders.

For the upper bound take a  $\delta$ -net with  $\delta = (C/M)^{1/d}$ , and a fixed measurable nearest-net assignment (with a fixed tie rule). Quantize the known initial state and, after each legal update, quantize again. The state error obeys  $e_{t+1} \leq \rho e_t + \delta$ ,  $e_0 \leq \delta$ , and hence  $e_t \leq \delta/(1-\rho)$ . The prediction error is at most  $Le_t$ . Squaring proves the upper bound, uniformly in time. Each update uses only the current net label and the current permitted input, so the construction is online. It does not grant the encoder free access to the original discarded history. If the exploration policy needs another register, that register is combined by a product construction.  $\square$

For example, a Lebesgue density bounded above by  $B$  gives the small-ball hypothesis with  $A = Bv_d$ , where  $v_d$  is unit-ball volume. The lower hypothesis is a condition on the *acquired prediction law*. A reachable set of dimension  $d$  without a mass condition does not imply the lower bound. Similarly, the contraction assumption is additional dynamics, not a consequence of kernel positivity.

**3.2. Causal morphisms and simultaneous error budgets.** A causal simulator  $\Gamma : \mathfrak{E} \rightarrow \mathfrak{F}$  is a parameter-independent executable transducer that uses source preparations to supply the target interface under every allowed target policy. Its defect  $\varepsilon$  is a uniform total-variation bound on the resulting path laws, including the fields required by the task. Its resource map  $\rho_\Gamma$  bounds the source resources of the transducer composed with a target controller.

**Proposition 3.3** (Composition and risk transfer). *Causal simulators compose. Their uniform defects add, capped at one, and their resource maps compose in the order  $\rho_{\Gamma_1} \circ \rho_{\Gamma_2}$ . For a terminal loss in  $[0, L]$  and a common target task,*

$$\mathcal{R}_{\mathfrak{E}}(\rho_{\Gamma}(B)) \leq \mathcal{R}_{\mathfrak{F}}(B) + L\varepsilon.$$

*For reward in  $[-1, 1]$ , the corresponding maximum worst-case rewards satisfy the reverse inequality with an error  $2\varepsilon$ .*

*Proof.* Interleave the two transducers; their pair of internal states is a causal implementation. Total variation contracts under a kernel and obeys the triangle inequality, proving the defect sum. If their state counts are  $R_t$  and  $M_t$ , the pair has at most  $R_t M_t$  states. Other declared resource bounds compose by execution of the two protocols. A bounded loss changes expectation by at most its range times total variation. Apply this bound to every fixed parameter and target controller and take the appropriate infimum or supremum. Uniformity in the controller is essential to this step.  $\square$

**Theorem 3.4** (Acquisition, quantization and model-error transport). *Suppose an exact source transducer has predictive state  $s_t \in S_t$  and additional charged buffers of size  $R_t$ , supplies  $T$  target operations, and has uniform model defect at most  $\varepsilon_{\text{mod}}$ . Its initialization and update depend on a calibration quantity  $\xi$ . From  $N_{\text{cal}}$  source preparations acquire an estimate  $\hat{\xi}$  with at most  $C_{\text{cal}}$  retained labels, such that*

$$\sup_{\theta} \mathbb{P}_{\theta}(d(\hat{\xi}, \xi) > a) \leq \eta.$$

*Subsequent preparation noises are independent of calibration conditional on the fixed parameter. Let finite nets of sizes  $M_t$  have radii  $\delta_t$ . Assume, on matching input/output histories and on the good calibration event, that the quantized transducer's state error satisfies*

$$(4) \quad e_0 \leq d_0 + a_0 a + \delta_0, \quad e_{t+1} \leq \rho_t e_t + d_{t+1} + a_{t+1} a + \delta_{t+1}.$$

*Assume its next output kernel and the exact transducer's output kernel differ in total variation by at most  $\epsilon_t + L_t e_t + b_t a$ , uniformly in the fixed parameter and legal policy. All constants and nets are declared independently of that unknown parameter. Then the quantized acquired transducer has defect at most*

$$(5) \quad \Delta = \min \left\{ 1, \varepsilon_{\text{mod}} + \eta + \sum_{t < T} (\epsilon_t + L_t e_t + b_t a) \right\}.$$

*Composing it with any target controller of cut widths  $K_t$  requires at most  $C_{\text{cal}} R_t M_t K_t$  labels at aligned execution cuts and transfers its bounded reward with loss at most  $2\Delta$ . Its preparations are  $N_{\text{cal}}$  plus all source preparations specified by the transducer; no successful-trial conditioning removes the failures.*

*Proof.* On the good calibration event, iterate (4). More explicitly, with  $D_0 = d_0 + a_0 a + \delta_0$  and  $D_j = d_j + a_j a + \delta_j$ ,

$$e_t \leq \sum_{j=0}^t D_j \prod_{k=j}^{t-1} \rho_k.$$

Couple each pair of output kernels maximally while their external histories agree. On agreement the target controller sees the same inputs, so it uses the same legal action and may use the same independent randomization. Its discontinuous action choices require no Lipschitz assumption: before a disagreement their arguments are identical. The chance of a first discrepancy is bounded by the sum in (5). Add the probability of bad calibration and the exact transducer's model defect. This proves the path bound, including stopping after padding by absorbing states.

The executable approximate transducer stores its calibration label, additional buffer, and net index. Combine these with the actual target register, not its full history or an uncharged belief. The resulting product gives the state count. If an operation contains further buffer cuts, apply the same product at each such cut;  $R_t$  was assumed to include them. Preparation costs add by execution. Finally apply Proposition 3.3.  $\square$

**Corollary 3.5** (A finite acquisition register). *Suppose  $r_0$  calibration rows have at most  $d$  outcomes, and take  $n$  independent preparations from each row on a fixed schedule. Their empirical rows satisfy, with probability at least  $1 - \eta$  uniformly in the row probabilities,*

$$\max \text{TV}(\hat{P}, P) \leq \frac{dz}{2}, \quad \eta = \min\{1, 2r_0d \exp(-2nz^2)\}.$$

*Their counts can be retained in at most  $(n+1)^{r_0(d-1)}$  labels. Thus Theorem 3.4 can use  $N_{\text{cal}} = r_0n$ ,  $a = dz/2$  and this finite calibration register when its calibration metric is the maximum row total variation.*

*Proof.* For each outcome the empirical frequency is the mean of independent Bernoulli indicators. Hoeffding's bound and a union bound over at most  $r_0d$  coordinates give the event stated. The total-variation estimate is half the sum of coordinate errors. Retain  $d - 1$  counts per row; the last is reconstructed from the known number of draws at that stage of the clocked schedule. Each retained count takes at most  $n + 1$  values. An autonomous implementation must additionally charge its schedule.  $\square$

These results separate exact predictive equivalence, average checkpoint resolution, online realizability, and uniform simulation risk. In particular, neither an optimal checkpoint codebook nor the proof-state bundle of Section 7 is automatically an executable finite register.

#### 4. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition 4.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{s_r}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller's random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(6) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition 4.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (6) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row. Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section 22 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

## 5. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(7) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z) (Q - P_\theta) h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem 5.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(8) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_\theta^{\otimes N}(z) \{Q(\omega) - P_\theta(\omega)\} d\mu(\theta) \right]_+$$

$$(9) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_\mu(z) \text{TV}(Q, \bar{P}_\mu(\cdot | z)).$$

Here  $m_\mu(z) = \int P_\theta^{\otimes N}(z) d\mu(\theta)$  and, when  $m_\mu(z) > 0$ ,

$$\bar{P}_\mu(\omega | z) = \frac{\int P_\theta^{\otimes N}(z) P_\theta(\omega) d\mu(\theta)}{m_\mu(z)}.$$

A zero-mass term in (9) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (7) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [3] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (8). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_\mu(z)$  it equals  $m_\mu(z)(Q - \bar{P}_\mu(\cdot | z))$ , proving (9). If  $m_\mu(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem 5.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_\theta$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^\Omega$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (7). This proves the upper bound for the union of all architectures. Conversely, retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (7).  $\square$

*Remark 5.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_\theta^{\otimes N} d\mu(\theta)$ , not  $(\int P_\theta d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (9) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary 5.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (8) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (8) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory's theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

## 6. CONTROLLED EXPERIMENTS WITHOUT A DOMINATING ACTION

The reduction to one dominating row is not needed for a statistical dual, provided causal action choice is retained in the dual recursion. We give the finite-action theorem with a compact parameter space and an explicit protocol state. Its equality is an unrestricted-memory statement; its upper certificates apply to every smaller-memory class.

Let  $\Theta$  be compact metric and  $E$  a finite set of protocol states. At  $e \in E$  let  $\mathcal{A}_e$  be a finite set of training actions. Action  $a$  produces  $x$  in a finite alphabet  $X_a$  with law  $P_\theta^a$  and changes the protocol state to  $T(e, a, x)$ . The functions  $\theta \mapsto P_\theta^a(x)$  are continuous. An unknown  $\theta$  is fixed throughout the experiment. Conditional on it, each requested preparation uses a fresh independent draw from the selected row. Legal validation designs form a nonempty finite set  $\mathcal{B}_e$ . Design  $b$  has a finite outcome alphabet  $Y_b$ , target law  $Q^b$  and continuous candidate law  $V_\theta^b$ . A policy may stop after at most  $N$  training actions. It then freezes  $b \in \mathcal{B}_e$  and an event on  $Y_b$ , before one candidate and one target validation. Randomization is independent of  $\theta$ . No training action is assumed to dominate another.

For a finite nonnegative measure  $\nu$  on  $\Theta$  write  $\nu_{a,x}(d\theta) = P_\theta^a(x)\nu(d\theta)$  and set

$$(10) \quad \begin{aligned} \Phi_e(\nu) &= \max_{b \in \mathcal{B}_e} \sum_{y \in Y_b} \left[ Q^b(y)\nu(\Theta) - \int V_\theta^b(y) d\nu \right]_+, \\ F_0(e, \nu) &= \Phi_e(\nu), \end{aligned}$$

$$(11) \quad F_n(e, \nu) = \max \left\{ \Phi_e(\nu), \max_{a \in \mathcal{A}_e} \sum_{x \in X_a} F_{n-1}(T(e, a, x), \nu_{a,x}) \right\}.$$

If no training action is legal, only the stopping term is retained. All the functions vanish at the zero measure, so no posterior division is required on null histories. For positive mass, (10) is the mass times the largest posterior-predictive total variation.

**Theorem 6.1** (Controlled posterior-predictive dual). *Let  $\mathcal{U}_N(e_0)$  be the maximum worst-case expected validation score over all randomized causal policies in the declared protocol, with at most  $N$  training preparations and no memory cap. Then*

$$(12) \quad \mathcal{U}_N(e_0) = \min_{\mu \in \mathcal{P}(\Theta)} F_N(e_0, \mu).$$

*Both extrema are attained. Each  $F_n(e, \cdot)$  is the maximum of finitely many continuous linear functionals on the cone of measures; in particular it is convex, continuous and positively homogeneous. For every prior  $\mu$ ,  $F_N(e_0, \mu)$  bounds the worst-case score of every finite-memory architecture implementing this protocol.*

*Proof.* There are finitely many histories of length at most  $N$  and finitely many event masks at each stopping history. Consequently there are finitely many deterministic policy trees, denoted by  $\Pi_N(e_0)$ . For  $\pi \in \Pi_N(e_0)$  its payoff  $g_\pi(\theta)$  is a finite sum of finite products of continuous primitive probabilities and is continuous in  $\theta$ .

A randomized causal policy induces the same outcome laws as a probability distribution on these trees: sample its finite random decision table in advance and condition on it. Conversely,

with no memory cap, a sampled tree can be retained and followed. Thus the unrestricted payoff vectors are exactly the convex hull of the  $g_\pi$ . This step is not an assertion that mixing machines preserves a specified register width.

The simplex on  $\Pi_N(e_0)$  and  $\mathcal{P}(\Theta)$  are compact and convex. The expected payoff is continuous and bilinear. Minimax therefore gives

$$\max_{\lambda \in \Delta(\Pi_N)} \min_{\theta} \sum_{\pi} \lambda_{\pi} g_{\pi}(\theta) = \min_{\mu} \max_{\pi \in \Pi_N} \int g_{\pi} d\mu.$$

For a fixed measure, the terminal maximum is (10), because an event includes precisely the positive coordinates of its signed predictive measure. At a training node one selects an action and, after its observed outcome, selects a continuation tree separately on that branch. The unnormalized branch measure is exactly  $\nu_{a,x}$ . Backward induction proves (11) and identifies the right side with (12). It also proves the finite-linear-functional representation. Compactness gives an optimizing prior and an optimizing mixed tree. Finally, the minimum over fixed parameters of any policy is at most its average under  $\mu$ , which is at most  $F_N(e_0, \mu)$ . This remains true after restricting its memory or architecture.  $\square$

The minimization in (12) occurs once, outside the recursion. It cannot be replaced by fresh adversarial choices after observations. The posterior carries dependence on one fixed unknown parameter. Also, a Bayes-optimal tree for a minimizing prior need not by itself be a minimax policy; the saddle-point mixture is supplied by the finite game in the proof.

**Corollary 6.2** (Bellman upper certificates). *Suppose functions  $\Psi_n(e, \nu)$  satisfy  $\Psi_0 \geq \Phi$  and, for  $n \geq 1$ , satisfy*

$$\Psi_n(e, \nu) \geq \Phi_e(\nu), \quad \Psi_n(e, \nu) \geq \sum_x \Psi_{n-1}(T(e, a, x), \nu_{a,x}) \quad (a \in \mathcal{A}_e).$$

*Then  $\Psi_N(e_0, \mu)$  is an upper certificate for every admissible architecture and every prior  $\mu$ . The family  $F_n$  is the least such family. An optimal prior can be chosen with at most  $d + 1$  support points, where  $d$  is the affine dimension of  $\{(g_{\pi}(\theta))_{\pi \in \Pi_N} : \theta \in \Theta\}$ .*

*Proof.* Induction in (11) gives  $F_n \leq \Psi_n$ . The equality case is the recursion itself. The objective depends on a prior only through its vector of integrals of the finitely many  $g_{\pi}$ . An optimal such vector belongs to the convex hull of their compact evaluation image. Carathéodory's theorem gives the stated support bound while preserving every pure-tree payoff.  $\square$

**Proposition 6.3** (Causal stability). *Consider two models with the same protocol, alphabets and policy class. Suppose their training rows differ uniformly in total variation by at most  $\epsilon$ , their candidate validation rows by at most  $\eta$ , and their target validation rows by at most  $\beta$ . Their unrestricted values, or their values in any common specified memory class, differ by at most  $2N\epsilon + \eta + \beta$ .*

*Proof.* Use the same policy randomization and couple corresponding training rows while the histories agree. The probability of a first discrepancy is at most  $N\epsilon$ , even with feedback and stopping. Conditional expected validation rewards lie in  $[-1, 1]$ , so differing training histories contribute at most  $2N\epsilon$ . On agreeing histories the same frozen design and event are used, and their conditional mean rewards differ by at most  $\eta + \beta$ . The bound is uniform in the fixed parameter and in the policy. Taking minima and suprema preserves it, with the reverse inequality obtained by interchanging the models.  $\square$

**6.1. An informative action choice.** The following calculation distinguishes the controlled theorem from a common-row reduction. Let  $\Theta = \{(i, j) : i, j \in \{0, 1\}\}$ . Action  $R$  reports  $i$ . Action  $L$  reports  $j$  when  $i = 0$  and otherwise reports an independent fair bit. Action  $H$  reports  $j$  when  $i = 1$  and otherwise reports an independent fair bit. The candidate validation is  $\delta_{(i,j)}$  and the target is uniform on  $\Theta$ .

**Proposition 6.4** (Strict adaptive advantage). *With two training preparations, the unrestricted adaptive value is  $3/4$  and the best nonadaptive value is  $5/8$ . Nonadaptive policies here include mixtures of schedules, with their random schedule retained. No available single training action dominates all the others.*

*Proof.* Take  $R$  first, and then  $L$  or  $H$  according to the observed  $i$ . The parameter is recovered exactly. The complement of its validation atom has score  $3/4$ . No policy can exceed  $\text{TV}(Q, \delta_\theta) = 3/4$  even with full information.

For the converse for fixed schedules, use the uniform prior. For a pair of actions  $a, b$  its Bayes value is explicitly

$$(13) \quad \sum_{x,y,\theta} \left[ \frac{1}{16} \sum_{\vartheta} P_{\vartheta}^a(x) P_{\vartheta}^b(y) - \frac{1}{4} P_{\theta}^a(x) P_{\theta}^b(y) \right]_+.$$

Substitution of the three displayed kernels gives

|     | $R$   | $L$    | $H$    |
|-----|-------|--------|--------|
| $R$ | $1/2$ | $5/8$  | $5/8$  |
| $L$ | $5/8$ | $7/16$ | $1/2$  |
| $H$ | $5/8$ | $1/2$  | $7/16$ |

This is an exact finite sum, not a parameter-grid estimate. It bounds any mixture of fixed schedules by  $5/8$ ; an early stop can be padded with an ignored observation. To attain the bound uniformly in  $\theta$ , choose with equal probabilities the schedules  $(R, L)$  and  $(R, H)$ . When the chosen branch-specific action matches  $i$ , the parameter is known and the score is  $3/4$ . Otherwise only  $i$  is known, and the complement of its two-atom fiber gives score  $1/2$ . Each fixed parameter therefore has mean score  $5/8$ .

Action  $R$  cannot distinguish parameters differing only in  $j$ . Action  $L$  cannot distinguish  $(1, 0)$  and  $(1, 1)$ , and  $H$  cannot distinguish  $(0, 0)$  and  $(0, 1)$ . An experiment which fails to distinguish such a pair cannot garble to one that distinguishes it. Hence no action is a common dominating row.  $\square$

If every binary report is additionally passed through an independent binary symmetric channel of crossover  $\epsilon$ , the primitive training rows change by at most  $\epsilon$  and have full support for  $0 < \epsilon < 1/2$ . Proposition 6.3, applied to both policy classes, leaves an adaptive advantage at least  $1/8 - 8\epsilon$ , which is positive for  $0 < \epsilon < 1/64$ . Thus the distinction is not confined to disjoint observation supports. The finite-horizon belief recursion and its piecewise-linear structure are classical [1]. The contribution here is their explicit integration with the frozen validation score, one fixed adversarial parameter, outer certificates, and the resource conventions; no priority for Bellman recursion itself is claimed.

## 7. CONTROLLED EXPERIMENTS AT A PRESCRIBED MEMORY PROFILE

An unrestricted posterior is a useful information state for a proof, but it is not a free runtime state. We first give a resource-exact dynamic formulation and then solve a controlled family in which replacing that formulation by a policy-tree mixture changes the value strictly.

**7.1. A parameterwise occupation state.** Fix a finite horizon  $T$ , a compact metric parameter space  $\Theta$ , finite hidden execution spaces  $H_t$ , and register alphabets  $S_t$  of sizes at most  $K_t$ . The visible inputs to each stochastic row and all legal actions are specified. Any input that must survive a cut belongs to  $S_t$ : this includes a chosen action, an unread report buffer, a stop flag, a selected validation event and a validation accumulator. One may subdivide an operation into several cuts to expose these costs. The scheduled time is available only in the clocked convention.

For now rows at different scheduled times are independently prescribed. Let  $\mathcal{Q}_t$  be the finite product of legal row simplices at stage  $t$ . A prescription  $q \in \mathcal{Q}_t$  is a table, chosen at design time, whose runtime arguments are exactly the declared visible inputs. After summing the fixed environmental kernels its one-stage transition is a stochastic matrix  $M_{t,\theta}^q$  on the hidden-state/register pairs. We assume this matrix is jointly continuous in  $(q, \theta)$ . Both action selection and state updating occur in this matrix, in their specified causal order; it is not an arbitrary matrix chosen separately for each hidden state or each parameter.

For a continuous bundle of probability vectors  $x = (x_\theta(h, s))_{\theta \in \Theta}$  define

$$(\mathcal{T}_{t,q}x)_\theta(h', s') = \sum_{h,s} x_\theta(h, s) M_{t,\theta}^q((h, s), (h', s')).$$

The initial bundle  $x_0$  is fixed by preparation. Terminal rewards  $r_\theta(h, s) \in [-1, 1]$  are continuous in  $\theta$ . Absorbing stopped states and frozen validation phases are included in this execution, not added afterwards without charge. Put

$$(14) \quad B_T(x) = \min_{\theta \in \Theta} \sum_{h,s} x_\theta(h, s) r_\theta(h, s),$$

$$(15) \quad B_t(x) = \max_{q \in \mathcal{Q}_t} B_{t+1}(\mathcal{T}_{t,q}x), \quad 0 \leq t < T.$$

The argument  $x$  is an *offline occupation bundle*, not the realized history, not an observed parameter, and not an additional register made available to the machine.

**Theorem 7.1** (Resource-exact dynamic value and supersolutions). *For the specified clocked profile and observable-row interface,  $B_0(x_0)$  is the exact maximum worst-case reward over all stochastic controllers. The maximum is attained by a sequence of legal common prescriptions. With the norm  $\|x - x'\| = \sup_\theta \sum_{h,s} |x_\theta(h, s) - x'_\theta(h, s)|$ , each  $B_t$  is 1-Lipschitz. Moreover,*

$$(16) \quad B_0(x_0) = \inf_H H_0(x_0),$$

where the infimum ranges over families of functions on occupation bundles satisfying

$$H_T \geq B_T, \quad H_t(x) \geq H_{t+1}(\mathcal{T}_{t,q}x) \quad (q \in \mathcal{Q}_t).$$

The infimum is attained by  $H = B$ . No convexification over retained controllers and no new adversarial choice after a report occurs in these identities.

*Proof.* For a fixed sequence  $q_0, \dots, q_{T-1}$ , iteration of the displayed transition gives its actual terminal law for every fixed  $\theta$ . The terminal minimum is therefore exactly its worst-case reward. A runtime randomized controller in this interface is precisely such a sequence of common conditional rows; independence of fresh randomization and the declared register specify all its conditional choices. Persistent random correlations are allowed only through that register.

The occupation bundle at the next stage is determined by the current bundle and the prescription, without drawing a realized history in the design problem. Hence optimizing over the remaining prescription sequence gives (15) by ordinary backward induction. This does not select a different continuation for each unrecorded history. Each maximizing  $q$  is still a single legal table common to all hidden histories and parameters. At  $x_0$  one follows the maximizing sequence

of design prescriptions, computing their occupation bundles offline; the runtime controller only reads its allowed inputs.

Stochastic matrices contract the  $\ell^1$  norm. The terminal minimum is 1-Lipschitz in the displayed norm. Induction, using the same  $q$  when comparing two bundles and then taking the two maxima, proves the Lipschitz assertion. Joint continuity and compactness of  $\mathcal{Q}_t$  give attainment at each stage, and compactness of  $\Theta$  gives the terminal minimum. Any family  $H$  in (16) bounds the terminal reward along every prescription sequence. Backward induction therefore gives  $H_t \geq B_t$ . Equality is admissible, proving (16) and its attainment.  $\square$

This is a nonlinear supersolution dual, not a least-favorable-prior saddle theorem at fixed width. Its optimization can be large and nonconvex. The principle of dynamic programming is classical; the point of this formulation is that the common-row and memory constraints remain in the maximizations. If rows are shared across scheduled times, as for an autonomous controller, choose the shared rows once and hold them fixed in all subsequent transitions; equivalently augment the *design* problem by that immutable prescription. Maximizing a shared row anew at each time would solve a different problem. A finite union of allowed interfaces can be handled by taking their maximum, or by a fully wired interface with the prescribed profile and its legal observable inputs. Neither operation enlarges a runtime register invisibly.

**7.2. An exact informative-control bottleneck.** Fix integers  $m \geq 2$  and  $1 \leq K \leq m$ . The fixed parameter is  $\theta = (i, j) \in [m] \times \{0, 1\}$ . The first training experiment  $R$  reports  $i$ . Across the next cut the controller retains at most  $K$  labels, with an arbitrary stochastic encoder  $E(s \mid i)$ . It then chooses one of the  $m$  sensing actions with probabilities  $D(a \mid s)$ . The selected action is kept in a charged  $m$ -state action buffer and the old label is discarded. Action  $a$  reports  $j$  when  $a = i$  and reports  $\perp$  otherwise. The first report is no longer available.

The candidate validation law on  $\{0, 1\}$  is  $\delta_j$ ; the target is uniform. An event is frozen before one fresh candidate and one fresh target validation. Stopping before either training action is permitted. No independent persistent selector is given to the controller. The observation symbols are atomic; a bitwise input implementation would have additional cuts. Denote the maximum worst-case score by  $V_{m,K}$ .

**Theorem 7.2** (Exact finite-memory control and its convexification gap). *In this protocol,*

$$(17) \quad V_{m,K} = \frac{1}{2 \lceil m/K \rceil}.$$

*The value obtained by allowing an uncharged ex ante mixture of complete  $K$ -label controllers is instead*

$$(18) \quad \bar{V}_{m,K} = \frac{K}{2m}.$$

*The inequality is strict whenever  $K$  does not divide  $m$ . The matching controller for (17) has charged cut profile bounded by  $(1, K, m, 3, 6, 3)$ . The  $K$ -label cut controls both retention of the routing observation and the subsequent informative action choice.*

*Proof.* For a fixed  $i$ , let

$$p_i = \sum_s E(s \mid i) D(i \mid s).$$

This is the probability of taking the informative action. On its complement, all retained information is independent of  $j$ . Averaging over the two values of  $j$  makes the expected validation score zero there, for any frozen event or randomized response. On the informative part the score is at most  $\text{TV}(\text{Ber}(1/2), \delta_j) = 1/2$ . Thus the minimum over  $j$  at a given  $i$  is at

most  $p_i/2$ . A stop before sensing is also uninformative about  $j$  and obeys the same bound; it can be padded by an ignored sensing operation.

Set  $L = \lceil m/K \rceil$ . Since  $p_i \leq \max_s D(i | s)$ , a value  $\min_i p_i > 1/L$  would require every  $i$  to have some row  $s$  with  $D(i | s) > 1/L$ . Each stochastic row has at most  $L - 1$  such indices. But  $K(L - 1) < m$ . This contradiction proves the upper bound. Partition  $[m]$  into at most  $K$  fibers of size at most  $L$ , retain the fiber label after  $R$ , and choose uniformly inside that fiber. On a successful report freeze  $\{1\}$  when  $j = 0$  and  $\{0\}$  when  $j = 1$ ; on  $\perp$  freeze the empty event. The score for every  $j$  is  $1/(2|\text{fiber}(i)|)$ , proving equality. The event alphabet has three labels. Storing the event and its candidate indicator requires at most six labels, and the final difference has three. The chosen sensing action was separately charged, proving the displayed profile.

For the convexified upper bound use the uniform prior on  $(i, j)$ . For any one controller,

$$\frac{1}{m} \sum_i p_i = \frac{1}{m} \sum_{i,s} E(s | i) D(i | s) \leq \frac{1}{m} \sum_{i,s} D(i | s) = \frac{K}{m}.$$

The same upper bound holds for mixtures. For the matching mixture, choose uniformly one of the  $m$  cyclic intervals of  $K$  indices. For that interval hardcode a deterministic  $K$ -label encoder which routes each included index to its own sensing action, and assigns other indices arbitrarily. Each  $i$  belongs to exactly  $K$  intervals. A successful action is followed by the complementary singleton event and failure by the empty event, as above. Every fixed  $(i, j)$  has mean score  $K/(2m)$ . This proves (18).  $\square$

For example,  $V_{3,2} = 1/4$  whereas  $\bar{V}_{3,2} = 1/3$ . The mixture just constructed can be implemented with a retained interval selector and a local label, using at most  $mK$  labels at the bottleneck. It cannot be declared a  $K$ -label realization: when the displayed gap is positive, (17) proves that no such realization exists. The action buffer of size  $m$  is not part of the  $K$  coordinate and has not been omitted from the profile. The theorem is a multicut resource law, not an assertion that its uniform peak equals  $K$ .

The actions are statistically incomparable.  $R$  cannot distinguish the two values of  $j$  at any fixed  $i$ , while action  $a$  does distinguish them at  $i = a$ . For  $a \neq b$ , action  $a$  does not distinguish the pair with  $i = b$ , while  $b$  does. A parameter-independent garbling cannot create a distinction absent from its input experiment.

**Corollary 7.3** (A strict gap with positive report probabilities). *Replace each of the two training kernels by a mixture with weight  $\epsilon > 0$  of the uniform law on its report alphabet. Let  $\Delta_{m,K} = K/(2m) - 1/(2\lceil m/K \rceil) > 0$ . For  $\epsilon < \Delta_{m,K}/8$  the resulting full-support model still has a strict gap between the genuine profile-constrained value and its free-selector convexification.*

*Proof.* Each training row changes by at most  $\epsilon$  in total variation. Couple corresponding rows until the first disagreement. For any fixed controller or mixed controller the probability of such a disagreement is at most  $2\epsilon$ , and its conditional reward lies in  $[-1, 1]$ . Each of the two optimal values changes by at most  $4\epsilon$ . Their difference is therefore at least  $\Delta_{m,K} - 8\epsilon > 0$ . All row arguments and register alphabets are unchanged.  $\square$

The distinction between mixed and behavioral strategies without perfect recall is classical; it is not first asserted here. Contemporary polynomial formulations over behavioral simplices include [16]. Theorem 7.2 evaluates the discrepancy in this specific frozen-validation experiment for every  $m, K$ , with a matching actual register and a noisy persistence statement. In particular, a single prior followed by an unrestricted policy-tree best response cannot be substituted for (15).

## 8. SADDLE FACES AND CAUSAL REALIZATION

The statistical saddle and its implementation are different objects. The former is convex; the latter need not be. The purpose of this section is to retain that distinction while extracting memory obstructions from an unrestricted saddle. In particular, a zero Bayes coefficient must not be discarded before the contact conditions at the worst parameters have been imposed.

**8.1. A normal form over a finite causal interface.** Fix a finite horizon and finite action and report alphabets. An action  $a_t$  is chosen before report  $y_t$ . A terminal output is included as one last action, followed by a dummy report. Illegal actions can be removed from each protocol type; equivalently, use a fixed padding of the finite protocol tree and impose its zero constraints. Define a *causal response array*  $C(\mathbf{a} \mid \mathbf{y})$  by nonnegativity, normalization in  $\mathbf{a}$  for every  $\mathbf{y}$ , and the requirement that its marginal on  $a_1, \dots, a_t$  depends only on  $y_1, \dots, y_{t-1}$ . The resulting set  $\mathcal{C}$  is a finite polytope. Conditioning successive marginals realizes every such array by a full-history randomized controller; arbitrary versions on zero marginals do not change the array.

For a fixed parameter  $\theta$ , the environment has a history-dependent likelihood  $L_\theta(\mathbf{a}, \mathbf{y})$ , obtained by marginalizing its hidden states. The bounded reward has the linear form

$$(19) \quad g_\theta(C) = \sum_{\mathbf{a}, \mathbf{y}} L_\theta(\mathbf{a}, \mathbf{y}) r_\theta(\mathbf{a}, \mathbf{y}) C(\mathbf{a} \mid \mathbf{y}).$$

Assume its coefficient vector is continuous on a compact metric parameter space. The parameter is fixed once, not selected after a report. Protocol-specific equalities, including a frozen validation choice, are represented by the corresponding finite protocol tree. A discarded protocol choice is not supplied again as a free input.

Here is an explicit positive realization of a response array. At cut  $t$  use  $k_t$  states, an initial distribution  $\alpha$ , and nonnegative matrices  $M_t^{a,y}$  of size  $k_{t-1}$  by  $k_t$  such that

$$(20) \quad M_t^{a,y} \mathbf{1} = p_t(a), \quad \sum_a p_t(a) = \mathbf{1}, \quad p_t(a) \text{ is independent of } y.$$

Then

$$(21) \quad C(\mathbf{a} \mid \mathbf{y}) = \alpha M_1^{a_1, y_1} \dots M_T^{a_T, y_T} \mathbf{1}.$$

The independence in (20) is essential: otherwise an action could use its not-yet-observed report. If an action or an input must survive an intermediate cut, split this formula at that cut and include its buffer in the state alphabet. Likewise, impose any declared shared-row constraints before optimizing. An externally fixed clock permits time-dependent matrices; an autonomous implementation has to store its phase or use the prescribed shared rows.

**Proposition 8.1** (Outer normal form and compatible continuations). *For the finite interface and declared cuts, the response arrays of all controllers with profile at most  $\mathbf{K}$  are exactly the arrays (21) with  $k_t \leq K_t$ , the normalization (20), and the declared interface constraints. This set, denoted  $\mathcal{C}_{\mathbf{K}}$ , is compact. The assertion is over all wirings of the allowed register, not one chosen transition graph.*

*Equivalently, there are at most  $K_t$  normalized continuation arrays  $B_{t,s}$  at each cut, with terminal continuation 1, and common nonnegative coefficients satisfying*

$$(22) \quad B_{t-1,s}(a\mathbf{a} \mid y\mathbf{y}) = \sum_{s'} M_t^{a,y}(s, s') B_{t,s'}(\mathbf{a} \mid \mathbf{y}), \quad C = \sum_s \alpha(s) B_{0,s}.$$

*Separate positive factorizations at the cuts are not sufficient without these common shift identities.*

*Proof.* In a controller, let  $p_t(a \mid s)$  be its action row and  $q_t(s' \mid s, a, y)$  its update row. Their product defines  $M_t^{a,y}$  and gives (20). Multiplication over a complete execution gives (21). Every

finite wiring embeds into the fully connected register by assigning zero to unused transitions; smaller alphabets are padded by unused states. Thus no further maximization over graph presentations is necessary.

Conversely choose action  $a$  with probability  $p_t(a \mid s)$ , and, after observing  $y$ , use the row  $M_t^{a,y}(s, s')/p_t(a \mid s)$  when the denominator is positive. At a zero denominator the entire corresponding nonnegative row vanishes; choose an arbitrary legal update there. This gives exactly the required runtime arguments. It does not expose a posterior, the parameter, or an offline occupation array to the machine. Apply the same construction at each declared buffer cut. A product of finitely many stochastic row simplices is compact; closed legality and sharing constraints preserve compactness. Its continuous image is  $\mathcal{C}_{\mathbf{K}}$ .

The future execution starting at a state  $s$  defines  $B_{t,s}$  and satisfies (22). Conversely, induction from the terminal continuation and these identities gives the product formula. Thus the continuation description has exactly the same realizations. In particular, independently selected factorizations at different cuts cannot be spliced unless the shift equations hold.  $\square$

This is a finite controlled positive-realization statement. The role of positivity and invariant generating cones in stochastic realization is classical [17, 18, 19]. Ordinary linear rank need not be a state count. Here the additional statistical question is which positive realizations meet an optimal saddle face. Proposition 8.1 provides a normal form, not an efficient factorization algorithm. It also does not compactify an unbounded number of observable operations.

## 8.2. The realization theorem. Let

$$U = \max_{C \in \mathcal{C}} \min_{\theta} g_{\theta}(C), \quad V_{\mathbf{K}} = \max_{C \in \mathcal{C}_{\mathbf{K}}} \min_{\theta} g_{\theta}(C).$$

By compact convex minimax there is a least-favorable prior  $\mu_*$  with  $U = \max_{C \in \mathcal{C}} \int g_{\theta}(C) d\mu_*$ . Put

$$\begin{aligned} \ell_*(C) &= \int g_{\theta}(C) d\mu_*, \\ F_* &= \{C \in \mathcal{C} : \ell_*(C) = U\}, \\ \mathcal{S}_* &= F_* \cap \bigcap_{\theta} \{C : g_{\theta}(C) \geq U\}. \end{aligned} \tag{23}$$

The set  $F_*$  is an exposed face. The second intersection is important: a Bayes best response to a least-favorable prior need not be minimax.

Here  $\mathcal{C}$  is the full-history convex reference for the finite protocol. A nonconvex restriction, such as reuse of one stochastic table at several visits, is imposed on  $\mathcal{C}_{\mathbf{K}}$ , not inserted into  $\mathcal{C}$  before invoking convex minimax. In that case  $U$  is a reference upper value unless exactness for the unrestricted physical class is separately known. In the reset applications below that exactness is supplied by Theorems 5.1 and 5.2.

**Proposition 8.2** (Bayes loss and worst-case loss). *Under the preceding assumptions,*

$$U - V_{\mathbf{K}} = \min_{C \in \mathcal{C}_{\mathbf{K}}} \left\{ U - \ell_*(C) + \ell_*(C) - \min_{\theta} g_{\theta}(C) \right\}. \tag{24}$$

*Both summands are nonnegative and the minimum is attained.*

*Proof.* The prior average is at most  $U$  and at least the minimum over fixed parameters. The sum in braces equals  $U - \min_{\theta} g_{\theta}(C)$ . Minimizing on the compact realization set proves the assertion.  $\square$

**Theorem 8.3** (Saddle-face contact and compatible realization). *Under the preceding assumptions,  $V_{\mathbf{K}} = U$  if and only if some array in  $\mathcal{S}_*$  has compatible positive continuation generators of profile at most  $\mathbf{K}$ . If no such generators exist,  $V_{\mathbf{K}} < U$  strictly.*

*For  $C \in \mathcal{S}_*$  one has  $g_\theta(C) = U$  on  $\text{supp } \mu_*$ . At an interior supporting parameter at which the payoff is differentiable,  $\nabla_\theta g_\theta(C) = 0$ . These equalities and stationarity conditions hold also in directions whose Bayes coefficient vanishes.*

*At any reset continuation cut, let  $R_h$  denote the conditional channel of future outputs under each externally specified future input word. It factors as*

$$(25) \quad R_h = \sum_{s=1}^{K_t} E(s \mid h) B_s, \quad E(\cdot \mid h) \in \Delta_{K_t},$$

*with one common family of continuation channels  $B_s$ . Any obstruction to this positive factorization for every member of  $\mathcal{S}_*$  is therefore a memory obstruction for every admissible architecture, regardless of its training wiring.*

*Proof.* By Proposition 8.2, the two nonnegative losses vanish exactly when  $C$  belongs to  $\mathcal{S}_*$ . Proposition 8.1 then proves the realization criterion. Compactness makes nonintersection a strictly positive value loss, not merely failure of one optimizer.

For an optimal array,  $g_\theta(C) - U$  is continuous, nonnegative, and has zero  $\mu_*$  integral. It is zero on the support of that measure. Every interior zero is a local minimum, so its gradient vanishes. No strict-sign hypothesis on individual coordinates is needed. Finally condition on the actual retained state at a reset cut. Given that state, the future program receives the same specified inputs and has the same output law, irrespective of the discarded past. Averaging gives (25). All persistent random variables are part of that state. The assertion can equivalently be checked on controller input tapes, using the generators in (22); it does not assume that a hidden physical state resets at a cut where the interface has not reset it.  $\square$

The identity (24) is an exact loss decomposition, not a new interchange of a minimum and maximum over nonconvex machines. Its use is that an unrestricted certificate identifies a finite face, while contact at its supporting parameters can determine the remaining coordinates. The resulting channels are then tested for causal realizability. This is stronger than choosing an arbitrary Bayes tie rule and counting the states of that one rule.

**Corollary 8.4** (Explicit coefficient form for frozen validation). *In the reset experiment of (7), write*

$$C_{z\omega}^* = \int P_\theta^{\otimes N}(z)(Q(\omega) - P_\theta(\omega)) d\mu_*(\theta).$$

*The first summand of (24) is exactly*

$$(26) \quad \sum_{C_{z\omega}^* > 0} C_{z\omega}^* (1 - h_z(\omega)) + \sum_{C_{z\omega}^* < 0} |C_{z\omega}^*| h_z(\omega).$$

*Thus optimality fixes every strict-sign coordinate, while the support contact and stationarity equations must still be imposed at the zeros. For  $K$  labels at the post-training decision cut, an arbitrary upstream encoder gives the compact relaxation*

$$(27) \quad h_z(\omega) = \sum_{s=1}^K E(s \mid z) D_s(\omega), \quad E \in (\Delta_K)^{\Omega^N}, \quad D_s \in [0, 1]^\Omega.$$

*If this relaxation misses the saddle set, its strictly positive gap bounds every smaller architectural class.*

*Proof.* Maximizing each coefficient separately gives the sum of its positive part. Subtraction gives (26). Conditioning on the decision state gives (27); the post-cut randomization is independent of the discarded word. Conversely an arbitrary encoder and a response list realize this factorization when other memory is unrestricted. The parameter spaces in (27) are compact, so the final assertion follows from Theorem 8.3.  $\square$

**8.3. Faces as memory witnesses.** For a finite input set  $\mathcal{Y}$  and output alphabet  $\mathcal{D}$ , continuation channels form the polytope  $\mathcal{P} = \prod_{y \in \mathcal{Y}} \Delta(\mathcal{D})$ . Its vertices are deterministic output functions. The analogous polytope for scalar test responses is  $[0, 1]^{\mathcal{Y}}$ .

**Lemma 8.5** (Vertex and face packing). *Suppose channels to be factored through one common state alphabet include  $s$  distinct vertices  $v_1, \dots, v_s$  of a polytope  $\mathcal{P}$  and rows  $r_1, \dots, r_j$ . Suppose  $r_i \in F_i$ , the faces  $F_i$  are pairwise disjoint, and*

$$r_i \notin \text{conv}\{v_a : v_a \in F_i\}.$$

*Every factorization of these rows as stochastic mixtures of generators in  $\mathcal{P}$  needs at least  $s + j$  generators.*

*Proof.* A convex decomposition of a vertex uses that same vertex at every positive coefficient. Hence all  $s$  vertices must occur among the generators. If a convex combination belongs to a face, all generators with positive coefficients belong to that face. The stated exclusion therefore forces an additional generator in each  $F_i$ . Pairwise disjointness prevents any such generator from serving two faces.  $\square$

The lemma does not assert that a stochastic state must itself be a history residual. Its generator can be any channel in the ambient polytope. This is why the argument also excludes randomized encoders and randomized continuations. It is a positive-factorization argument, not ordinary matrix rank or a restriction to a deterministic compiler.

**Proposition 8.6** (Resource equivalence and stable obstructions). *A causal, cut-preserving recoding with a causal inverse, both using only one transducer state and preserving the payoff, preserves every  $V_{\mathbf{K}}$ ,  $U$ , and the set of profiles attaining  $U$ . More generally suppose simulations in both directions have defect at most  $\epsilon$  and require at most  $R_t$  states at cut  $t$ . For rewards in  $[-1, 1]$ ,*

$$V_{\epsilon}(\mathbf{RK}) \geq V_{\mathfrak{F}}(\mathbf{K}) - 2\epsilon, \quad V_{\mathfrak{F}}(\mathbf{RK}) \geq V_{\epsilon}(\mathbf{K}) - 2\epsilon.$$

*For a common controller class and training-validation kernels whose values differ by at most  $\eta$ , a gap  $U - V_{\mathbf{K}} = \delta$  remains at least  $\delta - 2\eta$  after the perturbation.*

*Proof.* Transport a controller through each simulator and retain the product of its state and the simulator state. Apply the uniform bounded-reward variation bound and optimize. With an exact one-state inverse the two inequalities are equalities at the same profile. In the last assertion both the unrestricted and the constrained optimum change by at most  $\eta$ ; subtract their two bounds. The state products must be applied at the actual buffer cuts, not only at the terminal decision.  $\square$

These statements place the saddle face, the future-test quotient, and resource-aware causal morphisms in one theorem chain. The channel factorizations are presentation-independent under the stated causal recodings. The memory obstruction in the next section is derived from the experimental coefficients themselves, not from a metric dimension or a covering exponent supplied as an additional hypothesis.

## 9. FACIAL CERTIFICATES FOR SCHEDULE-OPTIMIZED MEMORY

A schedule is part of the resource problem. The following criterion extracts a whole family of schedule converses from a saddle, rather than minimizing the states of one selected program. Its hypotheses are finite identities of continuation functions and faces. Its conclusion applies to arbitrary stochastic state encoders.

Consider finitely many validation tapes, with a fixed internal order on each tape and finitely many symbols per slot. A *declared-clock schedule* is a word specifying which tape supplies each successive slot; it is fixed before training and is independent of all reports. Let  $\mathcal{G}$  be the finite acyclic graph of consumed-prefix counts. Its directed paths from the initial vertex to the final vertex are the legal schedules. This includes all interleavings, not only serial ones. The lower bound below does not give an adaptive scheduler free storage: a report-dependent choice of the next tape belongs to a different controlled interface and requires its own charged rows.

At a vertex  $v$  of  $\mathcal{G}$ , a retained state supplies a conditional channel on the unread tape suffixes. Assume in this section that every prefix and suffix combination used in a witness has positive probability under a supporting experiment. One may instead restrict to a stated common suffix subalphabet with this property. The channels form a product of probability simplices, denoted by  $\mathcal{P}_v$ .

**Definition 9.1** (Contact-forced facial certificate). A certificate at  $v$  consists of distinct deterministic channels  $d_1, \dots, d_s$  and channels  $r_1, \dots, r_j$ , such that every minimax-optimal auditor has these rows among its conditional continuations, allowing parameter-independent averaging of specified past rows. Each  $r_i$  lies in a face  $F_i$  of  $\mathcal{P}_v$ , the faces are pairwise disjoint, and

$$r_i \notin \text{conv}\{d_a : d_a \in F_i\}.$$

Its certified capacity is  $s + j$ . Define  $c(v)$  to be the largest such capacity within a declared finite witness family. Conditional averaging must retain the same future-input coordinates and may not add the unknown parameter as an input. A channel of mean zero is not thereby a deterministic zero channel.

For an upper certificate choose a minimax-optimal finite randomization over frozen deterministic events, with the selected event retained at the decision cut. Let  $\mathcal{D}_v$  be its distinct future deterministic output functions after all possible supported prefixes at  $v$ . When the input support is a full product, equality of these functions is closed under every next-symbol restriction. Put  $r(v) = |\mathcal{D}_v|$ . More general supported experiments may use any explicitly supplied shift-compatible deterministic completion; merely minimizing separate partial-function covers at different cuts is insufficient.

**Theorem 9.2** (Facial capacity and schedule realization). *Suppose contact with the unrestricted saddle supplies the preceding certificates. For each declared-clock path  $\pi$  and every stochastic auditor on that path attaining the unrestricted value,*

$$(28) \quad W(\pi) \geq \max_{v \in \pi} c(v).$$

*A shift-compatible deterministic residual family realizes the selected optimal event rule simultaneously with widths  $r(v)$  along any such path. If its training and selection peak is  $W_0$ , then*

$$(29) \quad \min_{\pi} \max_{v \in \pi} c(v) \leq W_{\text{clk}}^{\min} \leq \min_{\pi} \max\{W_0, \max_{v \in \pi} r(v)\}.$$

*In particular, a certificate and a realizing path with the same peak identify the exact minimum over all declared-clock schedules and all stochastic architectures on those schedules. If  $c(v) = r(v)$  at every vertex and  $W_0$  does not exceed the path peak, the entire minimum-profile problem reduces*

to the intrinsic capacity field on  $\mathcal{G}$ . The peak optimum of that field is computed by

$$(30) \quad b(v_0) = c(v_0), \quad b(v) = \max\{c(v), \min_{u \rightarrow v} b(u)\}.$$

The result is invariant under bijective, causal, slot-preserving recodings of the tape alphabets.

*Proof.* Condition on a charged retained state at  $v$ . Every past row is a stochastic mixture of the same at most  $W(\pi)$  future channels. Parameter-independent averaging preserves this factorization. The face-packing lemma therefore gives at least  $s + j$  states for each certificate, proving (28). This step ranges over all state wirings and all stochastic encoders, not a specified graph.

For the upper bound retain the current residual output function. If two residuals agree on the future input product, their restrictions after each legal next symbol agree as well. Therefore the next retained label is determined by the old label and that symbol. At the last cut it is the output itself. This constructs all cuts compatibly in one machine. The initially sampled event and its training selector are charged in  $W_0$ . Optimizing the two bounds over the finite path set proves (29). The recursion follows by classifying paths according to their last edge and taking the maximum with the cost of the final vertex. Induction proves it on the acyclic graph. Finally, a bijective recoding induces an affine isomorphism of every channel polytope, preserving vertices, faces, conditional averages and restriction maps. It preserves both certificates and realizing paths.  $\square$

The general positive-realization normal form and residual quotient have classical antecedents [17, 18, 19]. The minimization of partially specified machines likewise requires compatible coverings, not unrelated cutwise minima [20]. The contribution used here is different: the witness rows are forced by *every member of the uniform saddle*, through contact on its Bayes-indifferent coordinates. This makes the lower field independent of a chosen optimal program. The criterion is a certificate theorem for this class of experiments, not an assertion that arbitrary nonnegative-rank problems have become easy or that facial packing is always exact.

## 10. EXACT MINIMAX LAWS FOR A MARKED PRODUCT FAMILY

The posterior-predictive dual can be solved explicitly for a continuous family containing the collision target. Throughout this section, the training and candidate validation law is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

In the order 000, 001, 110, 111, let  $Q_\gamma$  have masses

$$((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4),$$

and zero mass elsewhere. Write  $U_1(\gamma) = U_1(b, Q_\gamma)$ , with exactly the training-validation convention of (7). Set

$$(31) \quad \gamma_* = 1 - 1/\sqrt{2}, \quad s_\gamma = \sqrt{\gamma^2 - 2\gamma + 5}, \quad u_\gamma = \gamma - 2 + s_\gamma, \quad \tau_\gamma = \frac{2u_\gamma}{u_\gamma + 2 - \gamma}.$$

**Theorem 10.1** (Exact marked minimax family). *For every  $0 \leq \gamma \leq \gamma_*$ ,*

$$(32) \quad U_1(\gamma) = \frac{3 + u_\gamma^2}{8}.$$

*An optimal response depends on the training word only through the report count  $K = X_1 + X_2$ . On the four target atoms its rows are*

$$(33) \quad h_0 = (\tau_\gamma, 0, 1, 1), \quad h_1 = (1, 1, 1, 1), \quad h_2 = (1, 1, 0, \tau_\gamma),$$

and all responses are zero off these atoms. A least-favorable prior is

$$(34) \quad \mu_\gamma = \frac{1}{2}\delta_{(t_\gamma, t_\gamma)} + \frac{1}{2}\delta_{(1-t_\gamma, 1-t_\gamma)}, \quad t_\gamma = \frac{1 - \sqrt{u_\gamma}}{2}.$$

The assertion optimizes over all stochastic responses to the full marked training word, not merely over count-based or symmetric responses.

*Proof.* First,  $u_\gamma$  is the positive root of

$$(35) \quad u^2 + (4 - 2\gamma)u - (1 + 2\gamma) = 0.$$

On the asserted interval,  $0 < u_\gamma < 1$  and  $0 < \tau_\gamma < 1$ . Indeed the polynomial is negative at zero and positive at one; also  $u_\gamma < 2 - \gamma$  because  $\gamma < 1/2$ . Substitution of  $1 - 2\gamma$  into the polynomial gives  $8(\gamma^2 - 2\gamma + 1/2)$ , which is nonnegative precisely on the present interval. Monotonicity on  $[0, \infty)$  therefore gives

$$(36) \quad u_\gamma \leq 1 - 2\gamma.$$

Put  $a = (1 - p)(1 - q)$ ,  $c = pq$ , and  $z = 1 - a - c$ . The probabilities of the three training counts are  $a, z, c$ . The independent training mark may be discarded by the displayed construction. Let  $G_\gamma(p, q)$  denote its score. With  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ , direct expansion gives

$$(37) \quad G_\gamma(p, q) - \frac{3 + u_\gamma^2}{8} = \frac{2 - \tau_\gamma}{16} \{(u - v - u_\gamma)^2 + 4v\}.$$

For clarity, this identity follows by substituting the three rows of (33) into

$$a(Q_\gamma - b)h_0 + z(Q_\gamma - b)h_1 + c(Q_\gamma - b)h_2,$$

using  $a + c = (1 + u - v)/2$ ,  $a - c = -(p + q - 1)$ , and then eliminating  $u_\gamma^2$  by (35). The coefficient of the resulting square is  $(2 - \tau_\gamma)/16$  and that of  $v$  is four times this coefficient. Both are nonnegative. Equality holds at both points of (34), since there  $v = 0$  and  $u = u_\gamma$ . This proves the lower bound and identifies its equality set.

It remains to bound every response, including nonsymmetric ones. Use (34) in Theorem 5.1. At  $t = t_\gamma$  put  $a = (1 - t)^2$ ,  $c = t^2$ , and  $T = a + c = (1 + u_\gamma)/2$ . For the training report pair 00, the four dual coefficients, apart from a common positive factor, are

$$(38) \quad \left( Q_H T - \frac{a^2 + c^2}{2}, \quad Q_L T - \frac{a^2 + c^2}{2}, \quad Q_L T - ac, \quad Q_H T - ac \right),$$

where  $Q_H = (1 + \gamma)/4$  and  $Q_L = (1 - \gamma)/4$ . The first coordinate is zero by (35); the second is  $-\gamma T/2 \leq 0$ . The last two are positive:  $T \geq 1/2$ ,  $ac \leq 1/16$ , and  $\gamma < 1/2$  imply  $Q_L T > 1/16 \geq ac$ . Thus  $(\tau_\gamma, 0, 1, 1)$  maximizes this linear functional. For the training pair 11, reversing all report bits and the mark reverses the four coordinates and gives the row  $h_2$ .

For either training pair 01 or 10, the two prior support points have the same likelihood  $t(1 - t)$ . The posterior is still equally weighted, and the candidate predictive mass at each target atom is  $T/4$ . Every one of the four coefficients is therefore nonnegative by  $Q_L - T/4 = (1 - 2\gamma - u_\gamma)/8 \geq 0$ . The response  $h_1$  is optimal. At off-diagonal validation atoms the target mass vanishes and the coefficient is nonpositive. Finally, conditioning on either training mark multiplies all these coefficients by  $1/2$ ; it creates no further optimizing choice. We have therefore optimized every coordinate of the full marked-word response space.

The prior average of the displayed response equals its value at either support point, namely  $(3 + u_\gamma^2)/8$ , by (37). Every other response has prior average at most this number and hence has minimum over fixed  $(p, q)$  at most this number. Together with the lower bound this proves (32), optimality of the response, and least favorability of the prior.  $\square$

**Corollary 10.2** (The exact one-preparation collision value). *For  $Q_* = Q_{1/4}$ ,*

$$(39) \quad U_1(b, Q_*) = u_{\text{ex}} := \frac{85 - 7\sqrt{73}}{64}, \quad u_{1/4} = \frac{\sqrt{73} - 7}{4}, \quad \tau_{1/4} = 2 - \frac{14}{\sqrt{73}}.$$

*If only the target changes to  $Q$ , then  $|U_1(b, Q) - u_{\text{ex}}| \leq \text{TV}(Q, Q_*)$ .*

*Proof.* Substitute  $\gamma = 1/4$  in Theorem 10.1. For a fixed trained response the target perturbation is at most total variation, uniformly in  $(p, q)$ . Taking first the minimum and then the maximum preserves this bound in both directions.  $\square$

**10.1. Complementary slackness and the event alphabet.** The tie in the first coordinate of (38) explains the randomization. Any value of that response coordinate is Bayes-optimal for the two-point prior. The minimax choice makes the uniform payoff stationary at its two support points; solving this condition gives  $\tau_\gamma$  and the square identity (37). This derives the prior and response together, rather than postulating that a numerically effective prior is optimal.

Operationally, for  $K = 0$  one draws once between the events with indicator vectors  $(0, 0, 1, 1)$  and  $(1, 0, 1, 1)$ , with probabilities  $1 - \tau_\gamma$  and  $\tau_\gamma$ . For  $K = 2$  one draws between  $(1, 1, 0, 0)$  and  $(1, 1, 0, 1)$ . For  $K = 1$  the event is  $(1, 1, 1, 1)$ . The resulting event identity is retained and used for both fresh validations. These are exactly the five events in the two-preparation construction below. The one-preparation theorem supplies their complementary-slackness interpretation; it does not prove that the two-preparation selector is optimal. The four-point rational prior retained below is a useful rational certificate, not a least-favorable prior.

The exact response uses an atomic stochastic row. It does not receive free persistent randomness. Replacing  $\tau_\gamma$  by a dyadic number within  $2^{-b}$  changes each conditional response, and hence the score, by at most  $2^{-b}$ . A sequential fair-bit implementation must retain its bit prefix and event identity. None of these implementation costs is needed by the deterministic two-preparation physical audit.

**Proposition 10.3** (The zero-preparation endpoint). *For  $0 \leq \gamma \leq 1$ ,  $U_0(b, Q_\gamma) = \gamma/2$ .*

*Proof.* The fixed event  $\{000, 111\}$  has score  $(1 + \gamma)/2 - (a + c)/2 \geq \gamma/2$  because  $a + c \leq 1$ . Conversely, the equally weighted prior on  $b(0, 0)$  and  $b(1, 1)$  has predictive validation law uniform on the four target atoms. Its total variation from  $Q_\gamma$  is  $\gamma/2$ . Theorem 5.1 with  $N = 0$  gives the matching upper bound.  $\square$

## 11. A SELF-CONTAINED COLLISION INTERFACE

We give the preparation, mechanical estimate, observation law and private simulator class needed for the physical specialization. The following argument does not appeal to an unpublished physical lemma. It retains the same positive-volume preparation and positive sensor noise as the earlier collision construction.

**Definition 11.1** (The reset row–event architecture). A preparation supplies two sequential report slots and, afterwards, an actual mark. The source reports in the two slots are constant. A private width-one simulator has no retained information between those slots and no persistent hidden seed. It may use fresh independent coins. Its first emission is  $X_1 \sim \text{Ber}(p)$ ; after receiving the current gate  $A \in \{0, 1\}$ , its second emission has a fixed Bernoulli kernel with parameter  $q_A$ . The parameters  $(p, q_0, q_1)$  are fixed throughout the audit. The simulator does not observe the actual mark. All its coins are independent of that mark. Different preparations reset all unretained variables and are independent conditional on the parameters.

The auditor observes the first report, chooses a gate using its retained state and that report, observes the second report, and then observes the mark. During training it may choose rows and

stop adaptively, using at most the declared number of candidate preparations. It next freezes one gate policy and one event, with any retained random choice included in its register. It uses that same row–event continuation on one fresh candidate preparation and one independent target preparation and returns the difference of their event indicators, target minus candidate. It may not reselect the event after either validation. Independent target-only calibration is allowed but all retained calibration and randomness are charged. Peak width counts every bit, mark, event and validation-accumulator cut. Clocked schedules are declared externally; an autonomous implementation must retain its phase. An unretained transcript, seed or stopping-time value is not available to a continuation.

In the all-on row the complete private law is  $b(p, q_1)$ , with an independent fair actual mark. For lower bounds it suffices to restrict the adversary to  $q_0 = 0$ ,  $q_1 = q$ . In this subfamily every deterministic gate policy is the pushforward

$$T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$$

of  $b(p, q)$ . The gate, when included in the transcript, is another function of these same coordinates. Randomized gate policies are covered by averaging their independent random tables. This proves both the all-on product characterization for the upper construction and the common-garbling subfamily used for the outer converse. The width-one constraint is a simulator constraint; it is not an uncharged restriction on the auditor's register.

**11.1. Preparation and elastic scattering.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$ , with no walls and contact distance  $d$ . Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ ,  $V = (v_1 + v_2)/2$ , and let the center of mass position range over any fixed rational box of positive volume. Prepare  $(B, W) \in \{0, 1\}^2$  with probability  $5/16$  at  $B = W$  and  $3/16$  at  $B \neq W$ . Conditional on  $(B, W)$ , use the uniform product preparation on the following boxes:

$$(40) \quad \begin{aligned} r &= (-a_0, (2B - 1)b_0, c_0), & a_0 &\in [29/10, 31/10], & b_0 &\in [9/20, 11/20], \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & & & |V_z - (2W - 1)| &\leq 1/100. \end{aligned}$$

Thus the actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ , preserved by momentum conservation. Set

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector, identically zero on the incoming transverse-velocity range.

**Lemma 11.2** (Uniform collision signal). *For every preparation in (40) and every  $9/10 \leq d \leq 11/10$ , exactly one collision occurs and its time lies in  $(4/5, 3/2)$ . Afterwards*

$$(2B - 1)v_{1,y} > 1/2, \quad (2B - 1)h(v_{1,y}) > 1/4.$$

*For  $0 < d \leq 2/5$  no collision occurs on  $[0, 3]$  and the detector is zero throughout that interval.*

*Proof.* Before contact,  $r(t) = r + tg$ . At  $t \leq 4/5$  its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At  $t = 3/2$  its absolute coordinate bounds are  $1/4$ ,  $113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . The first contact therefore occurs in the claimed interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$ . Hence the entry contact has  $n_x < 0$ , where  $n = r(t_c)/d$ . Its remaining coordinates give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B - 1)n_y \geq 87/220.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The elastic rule gives

$$v_1^+ = V + g/2 - (g \cdot n)n, \quad g^+ = g - 2(g \cdot n)n.$$

Consequently

$$(2B - 1)v_{1,y}^+ > -3/200 + (1443/1000)(87/220) > 1/2.$$

The definition of  $h$  implies the signal bound. Since  $r(t_c) \cdot g^+ > 0$ , squared separation increases strictly afterwards; there is no second collision. Finally, for  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . There is no contact, and the incoming  $|v_{1,y}| \leq 3/200$  makes  $h$  zero.  $\square$

**11.2. Positive noise and the actual mark.** Let  $\mathcal{B}_t$  be Brownian motion independent of the preparation and set

$$Y_t = \int_0^t h(v_{1,y}(s)) ds + \sigma \mathcal{B}_t, \quad 0 < \sigma \leq 1/24.$$

The two potential all-on reports are

$$Z_1 = \mathbf{1}_{\{2(Y_2 - Y_{3/2}) > 0\}}, \quad Z_2 = \mathbf{1}_{\{2(Y_3 - Y_{5/2}) > 0\}}.$$

The actual second report is  $AZ_2$ . The gate changes acquisition, not the mechanical path. The continuous path is implemented by the target sensor; it is not made available to the private simulator or supplied as an uncharged auditor buffer. Denote the law of  $(Z_1, Z_2, W)$  by  $Q_{d,\sigma}$ .

**Theorem 11.3** (Uniform physical presentation). *For  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ ,*

$$(41) \quad \text{TV}(Q_{d,\sigma}, Q_*) < 1/300.$$

*The same estimate holds after every declared feedback gate, including its observable gate value. The all-on private product family and the common-garbling subfamily in Definition 11.1 apply to this very experiment.*

*Proof.* Every collision occurs before  $3/2$ . Conditional on the preparation, the two normalized sensor windows are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . Lemma 11.2 makes their means have sign  $2B - 1$  and magnitude greater than  $1/4$ . Each potential report therefore differs from  $B$  with probability less than  $\Phi(-3)$ . The Gaussian tail estimate

$$\Phi(-x) \leq \frac{e^{-x^2/2}}{x\sqrt{2\pi}}$$

gives  $\Phi(-3) < 1/600$ :  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$  suffice. Couple the ideal and noisy reports using the same preparation, actual mark and gate random table. Except on a set of probability less than  $2\Phi(-3) < 1/300$ , both potential reports equal  $B$  and the entire gated transcript agrees. The ideal marked law is precisely  $Q_*$ , by the prepared  $(B, W)$  table. This proves (41) and the feedback-uniform version. Finally, the source is blind, its actual mark is unobserved by the simulator, and the gate is its only current input at the second emission. The product and subfamily assertions follow from the two independent private-emission kernels specified above.  $\square$

For  $d \leq 2/5$ , the two windows instead contain only independent centered Gaussian noise. Their signs are independent fair bits, independent of  $W$ , and a private width-one simulator reproduces every gated row exactly. Thus the informative regime and its no-collision control use the same detector, preparation convention and actual mark.

## 12. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1 - p)(1 - q)$  and  $c = pq$ . On the ordered atoms

$$(42) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(43) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \longrightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (43). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in Definition 11.1 and Theorem 11.3, explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem 12.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (1). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(44) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

*from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.*

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

### 12.1. An exact rational certificate against one preparation.

**Lemma 12.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem 5.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (8) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (42), the signed coefficients in (8), after grouping by  $K$ , are the entries of

$$(45) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1-p_i)^{2-k} \left( Q_{*,j} - \frac{(1-p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (45) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (45) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ . A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**12.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (42) and with indicator zero at every off-diagonal atom:

$$(46) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma 12.3** (Exact uniform score of the selector). *Against the ideal target, the selector (46) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (46) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(47) \quad G(p, q) = H(u, v) = -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}.$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u - v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

### 12.3. Causal compilation and the full register profile.

**Lemma 12.4.** *The selector and its two validations admit the deterministic profile (44). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event–function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2 w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (46). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem 12.1.* Lemma 12.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas 12.3 and 12.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary 12.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the local microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem 12.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in Theorem 11.3; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark 12.6* (The part of the frontier determined here). The deterministic theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . Theorem 13.1 and Corollary 13.2 below additionally determine the ideal maximum score with two preparations on this width range. The least peak width over all validation orders and the full boundary for  $3 \leq W \leq 11$  remain separate questions. Theorem 15.3 below determines the peak for forward serial validation, and Theorem 15.1 determines the order-independent decision cut. The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by (2, 12) in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

**Corollary 12.7** (The enlarged physical preparation segment). *With the full architecture of Definition 11.1,*

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

*Here  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$  is the exact one-preparation all-on value, rather than the older rational upper bound.*

*Proof.* Restrict the adversary to the common-garbling subfamily in Definition 11.1. Theorem 5.2 and Corollary 10.2 bound every at-most-one-preparation auditor, even with unlimited memory, by  $u_{\text{ex}} + \beta$ . The same deterministic two-preparation machine in Lemmas 12.3 and 12.4 has score at least  $m_2 - \beta$  against the full private candidate family. These inequalities prove the assertion. The four-preparation total, peak twelve and positive-noise specialization are unchanged.  $\square$

### 13. THE EXACT TWO-PREPARATION MARKED SADDLE

The one-preparation saddle has an exact successor. A new zero coefficient of the least-favorable predictive measure makes it necessary to randomize at the two extreme training counts. This randomization changes the value, but does not enlarge the alphabet of frozen validation events.

Let  $b(p, q)$  and  $Q_*$  be as in Section 12. Let  $r$  be the unique root in  $(1/3, 7/20)$  of

$$(48) \quad 2r^3 + 25r^2 - 3 = 0,$$

and define

$$(49) \quad \tau = \frac{6(-r^2 + 4r - 1)}{r(3r + 25)}, \quad v_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad p_{\pm} = \frac{1 \pm \sqrt{r}}{2}.$$

The polynomial in (48) is strictly increasing on the positive half-line and has opposite signs at the indicated endpoints. These observations prove the asserted existence, uniqueness and isolating interval. That interval also gives  $0 < \tau < 1$ .

**Theorem 13.1** (Exact two-preparation value). *For the full marked-word response class of (7),*

$$U_2(b, Q_*) = v_2.$$

*A least-favorable prior gives mass  $1/2$  to each of  $(p_-, p_-)$  and  $(p_+, p_+)$ . An optimal response discards the two training marks, retains the total number  $S$  of ones in the four training report bits, and uses*

$$(50) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & \tau & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & \tau \end{array}$$

*with zero response at off-diagonal validation atoms. Numerically,  $r = 0.3417694155\dots$ ,  $\tau = 0.1688236447\dots$  and  $v_2 = 0.4261127787\dots$ . The exact value is determined by (48)–(49), not by these decimals.*

*Proof.* Write  $a = (1 - p)(1 - q)$ ,  $c = pq$ ,  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ . Both  $u$  and  $v$  belong to  $[0, 1]$ . The score of the deterministic five-event selector is the polynomial  $H(u, v)$  in (47). Only counts zero and four are changed by (50). Their probabilities are  $a^2$  and  $c^2$ . Consequently the new score is

$$G(u, v) = H(u, v) + \tau J(u, v), \quad J = a^2(5/16 - a/2) + c^2(5/16 - c/2).$$

Expansion gives the polynomial identity

$$(51) \quad \begin{aligned} J(u, v) = & -\frac{u^3}{64} + \frac{3u^2v}{64} - \frac{25u^2}{128} - \frac{3uv^2}{64} + \frac{13uv}{64} \\ & + \frac{v^3}{64} - \frac{v^2}{128} - \frac{v}{32} + \frac{3}{128}. \end{aligned}$$

Thus

$$H(u, 0) = \frac{-u^3 + 6u^2 - 3u + 14}{32}, \quad J(u, 0) = \frac{3 - 25u^2 - 2u^3}{128}.$$

Equation (48) says  $J(r, 0) = 0$ , and the choice of  $\tau$  says  $\partial_u G(r, 0) = 0$ . Direct factorization, using these two identities, yields

$$(52) \quad G(u, 0) - v_2 = \frac{(u - r)^2 \{75 + 12r + 6u - 37r^2 - 74ru\}}{64r(3r + 25)}.$$

The expression in braces is strictly positive for  $0 \leq u \leq 1$ : it is at least  $75 - 37(7/20)^2 - 74(7/20) > 0$ . Moreover,

$$\partial_v H = \frac{3(u - v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}, \quad \partial_v J = \frac{3(u - v)^2 + 13u - v - 2}{64} \geq -\frac{3}{64}.$$

Because  $0 < \tau < 1$ ,  $\partial_v G \geq 11/64$  on the unit square. It follows that  $G(u, v) \geq G(u, 0) \geq v_2$ , with equality precisely when  $v = 0$  and  $u = r$ . Both equality points are feasible and are the two parameters in the asserted prior. This proves the global lower bound.

It remains to prove an upper bound against every response, not only those depending on  $S$ . Under the asserted prior the four training report bits are independent Bernoulli variables with common parameter  $p_-$  or  $p_+$ . Conditional on  $S = s$ , their arrangements and the two

independent training marks have parameter-independent distributions. The signed predictive coefficients can therefore be grouped by  $S$  without restricting any response coordinate. For the four displayed validation atoms put

$$C_{s,j} = \frac{1}{2} \sum_{p \in \{p_-, p_+\}} \binom{4}{s} p^s (1-p)^{4-s} \{Q_{*,j} - b_j(p, p)\}.$$

The first three rows of  $256C$  are

$$\begin{aligned} s = 0 : & \quad (-(2r^3 + 25r^2 - 3), -(2r^3 + 27r^2 + 12r - 1), \\ & \quad -(2r^3 - 5r^2 - 20r - 1), -(2r^3 - 7r^2 - 32r - 3)), \\ s = 1 : & \quad 4(r-1)(2r^2 + 7r - 3, 2r^2 + 9r - 1, \\ & \quad 2r^2 - 7r - 1, 2r^2 - 9r - 3), \\ s = 2 : & \quad -6(r-1)^2(2r-3, 2r-1, 2r-1, 2r-3). \end{aligned}$$

Rows three and four are the reversals of rows one and zero, respectively. Their signs, using  $1/3 < r < 7/20$ , are

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Every off-diagonal validation coefficient is nonpositive because its target mass is zero. Hence (50) maximizes every signed coefficient: it is one at positive coefficients, zero at negative ones, and arbitrary at the two zeros. The lower-bound equality at both prior points shows that this Bayes maximum is exactly  $v_2$ . The posterior-predictive dual, Theorem 5.1, now gives the matching upper bound for the full response class.  $\square$

**Corollary 13.2** (Exact physical score on the peak-twelve segment). *Use the atomic stochastic-row convention and the original marked interface of Definition 11.1. At two candidate training preparations, every peak budget  $W \geq 12$  has exact ideal worst-case score  $v_2$ . For a target  $Q$  with  $\text{TV}(Q, Q_*) \leq \beta$ , the corresponding value lies in  $[v_2 - \beta, v_2 + \beta]$ . In particular, with  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$ ,*

$$(53) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad u_{\text{ex}} + \beta \leq c < v_2 - \beta.$$

*Proof.* Let  $h_0, \dots, h_4$  be the five deterministic events in (46). At count zero select  $h_1$  with probability  $\tau$  and  $h_0$  otherwise; at count four select  $h_3$  with probability  $\tau$  and  $h_4$  otherwise. At the other counts retain the indicated event. Discard the count and retain the selected event for both validations. This realizes (50); the event alphabet remains five. The full charged profile, now including the separate event-selection update, is

$$(1, 2, 3, 3, 4, 5, 5, 5, 10, 12, 10, 10, 7, 3).$$

The common residual-function compiler in Lemma 12.4 applies unchanged. In particular, no persistent random selector is outside the register. The all-on law for every private candidate is  $b(p, q)$ , so Theorem 13.1 proves the constructive lower bound. For the converse restrict to the admissible common-garbling product subfamily and apply Theorem 5.2 followed by Theorem 13.1. This bounds all architectures, including those using feedback, stopping and more memory. Target perturbation changes each frozen-event expectation by at most  $\beta$ . Finally the exact one-preparation theorem excludes a strict score above  $c$  at  $N \leq 1$ , whereas the displayed machine achieves it at  $N = 2$  under (53).  $\square$

The root  $r$  is larger than  $2 - \sqrt{3}$ . The old diagonal polynomial  $H(u, 0)$  is strictly increasing between these points, whence  $v_2 > m_2$ . The deterministic theorem, including its zero-random-bit implementation, remains valid; the new exact score uses an additional stochastic row.

**Proposition 13.3** (Finite precision for the new row). *Replacing  $\tau$  by a dyadic  $\tau_b = k/2^b \in [0, 1]$  with  $|\tau_b - \tau| \leq 2^{-b}$  loses at most  $(5/16)2^{-b}$  in uniform score. A clocked fair-bit implementation uses  $b$  extra random bits and at most  $\max\{12, 6(b+1) + 5\}$  persistent states, including their phase, in addition to the unchanged preparation count.*

*Proof.* At each affected training word the response changes at a single atom;  $|5/16 - a/2|$  and  $|5/16 - c/2|$  are at most  $5/16$ . The two affected word probabilities sum to at most one. This gives the score estimate. To implement the dyadic coin, compare  $b$  fresh fair bits lexicographically with the fixed  $b$ -bit integer  $k$ . Retain the origin (count zero or four), one of the three comparison flags, and a phase in  $\{0, \dots, b\}$ . Once the comparison ends retain its chosen one of five events. Unaffected counts can wait in their event states. These states total at most  $6(b+1) + 5$ ; the other cuts have peak twelve. The cases  $k = 0, 2^b$  are deterministic. Exact atomic randomization and a finite fair-bit implementation are therefore distinct resource claims.  $\square$

#### 14. A CONTINUOUS TWO-PREPARATION MARKED FAMILY

The preceding saddle persists on an explicit interval of target laws, with exact rather than perturbative values. Use the target  $Q_\gamma$  from Section 10 and write  $U_2(\gamma) = U_2(b, Q_\gamma)$ .

**Theorem 14.1** (A two-preparation saddle family). *For  $6/25 \leq \gamma \leq 13/50$ , let  $r_\gamma$  be the unique root in  $(1/3, 7/20)$  of*

$$(54) \quad f_\gamma(r) = r^3 + (13 - 2\gamma)r^2 + (3 - 12\gamma)r - (1 + 2\gamma) = 0.$$

*Set*

$$D_\gamma(r) = 3r^2 + (26 - 4\gamma)r + 3 - 12\gamma, \quad t_\gamma = -\frac{2\{3r_\gamma^2 + (8\gamma - 14)r_\gamma + 3\}}{D_\gamma(r_\gamma)}.$$

*Then  $0 < t_\gamma < 1$ , and*

$$(55) \quad U_2(\gamma) = \frac{-r_\gamma^3 + (7 - 4\gamma)r_\gamma^2 - 3r_\gamma + 13 + 4\gamma}{32}.$$

*The response (50), with  $\tau = t_\gamma$ , is optimal. A least-favorable prior gives equal masses to the two diagonal parameters  $p = q = (1 \pm \sqrt{r_\gamma})/2$ . The response has the same five-event, peak-twelve atomic realization. At  $\gamma = 1/4$  these formulas reduce to Theorem 13.1.*

*Proof.* For brevity write  $r = r_\gamma$ ,  $D = D_\gamma(r)$  and  $t = t_\gamma$ . The derivative  $D_\gamma$  is positive on the rectangle  $\gamma \in [6/25, 13/50]$ ,  $r \in [1/3, 7/20]$ . For example its lower bound is  $1/3 + (26 - 52/50)/3 - 3/25 > 8$ . The polynomial  $f_\gamma$  decreases with  $\gamma$  at a fixed positive argument. Direct rational evaluations give  $f_{6/25}(1/3) < 0$  and  $f_{13/50}(7/20) > 0$ . Monotonicity therefore gives the root and its uniqueness in this interval. The numerator of  $t$  is  $-16\gamma r - 6r^2 + 28r - 6$ . It is bounded below by  $28/3 - 6 - 16(13/50)(7/20) - 6(7/20)^2 > 0$ , and above by  $28(7/20) - 6 < 4 < D$ . Thus  $0 < t < 1$ .

Let  $H, J$  be the polynomials from (47) and (51). Changing the target masses linearly in  $\gamma$  gives

$$\begin{aligned} H_\gamma(u, v) &= H(u, v) + (\gamma - 1/4) \frac{1 - (u - v)^2}{8}, \\ J_\gamma(u, v) &= J(u, v) + (\gamma - 1/4) \frac{(u - v)^2 + 6u - 2v + 1}{32}. \end{aligned}$$

The response's full-parameter score is  $G_\gamma = H_\gamma + tJ_\gamma$ . One has  $J_\gamma(r, 0) = -f_\gamma(r)/64 = 0$  and  $\partial_u G_\gamma(r, 0) = 0$ . Algebraic division gives

$$(56) \quad G_\gamma(u, 0) - H_\gamma(r, 0) = \frac{(u - r)^2 A_\gamma(r, u)}{16D},$$

where

$$A_\gamma(r, u) = 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru \\ + 12\gamma r + 6\gamma u - 51\gamma + 30.$$

For  $0 \leq u \leq 1$  this is at least  $30 - 10(7/20)^2 - 20(7/20) - 51(13/50) > 0$ . The transverse derivatives satisfy

$$32\partial_v H_\gamma = 3(u - v)^2 + (8\gamma - 10)u + (6 - 8\gamma)v + 15 \geq 5, \\ 64\partial_v J_\gamma = 3(u - v)^2 + (14 - 4\gamma)u + (4\gamma - 2)v - 4\gamma - 1 \geq -3$$

on  $0 \leq u, v \leq 1$ . Consequently  $\partial_v G_\gamma \geq 7/64$ . Equation (56) proves a lower bound  $H_\gamma(r, 0)$ , with equality precisely at the proposed prior points. This quantity is the right side of (55).

For the upper bound group the full training words by  $S$ , as in the preceding theorem. Put  $L(r) = r^2 + 6r + 1$ . Using  $f_\gamma(r) = 0$ , the first three rows of  $256C$  are

$$\begin{aligned} 0: & (0, -8\gamma L(r), 32r(r+1) - 8\gamma L(r), 32r(r+1)), \\ 1: & 8(r-1)(r^2 + 4r - 1 - 2\gamma(r+1), \\ & r^2 + 4r - 1 + 2\gamma(r+1), \\ & r^2 - 4r - 1 + 2\gamma(r+1), r^2 - 4r - 1 - 2\gamma(r+1)), \\ 2: & -12(r-1)^2(r-1 - 2\gamma, r-1 + 2\gamma, r-1 + 2\gamma, r-1 - 2\gamma). \end{aligned}$$

The other rows are their reversals. The sign pattern is again

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Here are explicit interval checks for the potentially small margins. In row zero the third coordinate is bounded below by  $32(1/3)(4/3) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 0$ . The first parenthesis of row one is at most  $(7/20)^2 + 4(7/20) - 1 - 2(6/25)(4/3) < 0$ ; the third is at most  $(7/20)^2 - 4/3 - 1 + 2(13/50)(27/20) < 0$ . The second parenthesis is positive already from  $r > 1/3$  and  $\gamma > 0$ , and the fourth is negative. Finally  $r - 1 + 2\gamma \leq -13/100 < 0$ . All off-diagonal validation coefficients are nonpositive. Thus the stated response is a Bayes best response for this prior, including its two zero coefficients. Its score at both supporting parameters equals the lower bound. The full posterior-predictive dual proves (55).  $\square$

This interval is a uniform certificate region for the displayed saddle, not a claim that the same masks remain optimal for every mark bias. The theorem supplies a continuous family at genuinely growing training history  $N = 2$ ; it does not infer a recurrence for every  $N$  from the one-preparation formulas.

## 15. EXACT MEMORY FROM A MARKED SADDLE

The realization criterion is now applied to a saddle with genuine Bayes indifference. The zero coefficients in the two-preparation problem are not harmless: their values are fixed by contact with the parameter family. This supplies a converse for all optimal audits, rather than for a preselected response table.

Put  $I = [6/25, 13/50]$ . Throughout this section  $r = r_\gamma$ ,  $t = t_\gamma$ , and  $v = U_2(\gamma)$  are those of Theorem 14.1. Denote the five deterministic events in (46) by  $e_0, \dots, e_4$ . Responses displayed below are ordered on 000, 001, 110, 111 and vanish at the other four atoms.

**Theorem 15.1** (Contact rigidity and exact decision memory). *For every  $\gamma \in I$ , every minimax optimal full-word response with two training preparations has, after averaging the independent training marks at the two extreme report counts, the five rows*

$$(57) \quad (t, 0, 1, 1), \quad (1, 0, 1, 1), \quad (1, 1, 1, 1), \quad (1, 1, 0, 1), \quad (1, 1, 0, t).$$

*At the three interior counts the displayed response is forced at each individual training word, not merely after averaging.*

*In the original reset row–event interface, the least number of states at the post-training cut that permits the exact ideal score  $v$  is five. This converse allows arbitrary upstream finite memory, randomized encoding, adaptive training gates, stopping, independent target-only calibration, and all legal post-cut randomizations. Other cuts are unrestricted in this decision-memory assertion.*

*Proof.* First consider a response to the full two-preparation word. Under the least-favorable prior of Theorem 14.1, every training word has positive probability. The strict coefficient signs force  $e_1, e_2, e_3$  at report counts 1, 2, 3. At count zero only the 000 coordinate is free; at count four only the 111 coordinate is free. All off-diagonal validation coefficients are strictly negative: the prior parameters are interior, each word likelihood is positive, and the target assigns zero mass to those atoms. Thus those coordinates are zero for every optimal response.

Let  $a$  and  $b$  be the averages of the two free coordinates over the four equiprobable training mark words at their respective extreme counts. On the diagonal parameter  $(p, p)$  the score is

$$(58) \quad H_\gamma((2p-1)^2, 0) + aA_\gamma(p) + bB_\gamma(p),$$

where

$$A_\gamma(p) = (1-p)^4 \left( \frac{1+\gamma}{4} - \frac{(1-p)^2}{2} \right), \quad B_\gamma(p) = p^4 \left( \frac{1+\gamma}{4} - \frac{p^2}{2} \right).$$

Here  $H_\gamma$  is the deterministic five-event score in the proof of Theorem 14.1. At  $p_+ = (1 + \sqrt{\gamma})/2$ ,  $A_\gamma(p_+) + B_\gamma(p_+) = J_\gamma(r, 0) = 0$  and  $A_\gamma(p_+) > 0$ . The latter follows from  $p_+ > 1/2$  and  $(1 + \gamma)/4 > 1/4$ . Reflection exchanges  $A$  and  $B$  at  $p_- = 1 - p_+$ . Also  $H_\gamma(r, 0) = v$ . Optimality forces contact at both prior points, by Theorem 8.3. Subtracting  $v$  from (58) therefore gives  $(a - b)A_\gamma(p_+) = 0$ , hence  $a = b$ .

With this common value the diagonal score is  $H_\gamma(u, 0) + aJ_\gamma(u, 0)$ , where

$$H_\gamma(u, 0) = \frac{-u^3 + (7 - 4\gamma)u^2 - 3u + 13 + 4\gamma}{32}, \quad J_\gamma(u, 0) = -\frac{f_\gamma(u)}{64}.$$

The supporting value  $r$  lies in  $(0, 1)$ , so the derivative at  $r$  vanishes. Since  $f'_\gamma(r) = D_\gamma(r) > 8$ , the derivative equation has the unique solution

$$a = b = \frac{64 \partial_u H_\gamma(r, 0)}{D_\gamma(r)} = t_\gamma.$$

This proves (57). Individual extreme mark words may still use different tie values; no unnecessary uniqueness is asserted.

Now take an arbitrary audit with  $K$  states at the decision cut. Restrict the candidate to the common-garbling subfamily in Definition 11.1. Generate two all-on words and simulate the adaptive training and its stopping with independent coins. The retained state is a parameter-independent stochastic function of those two words. Conditional on that state, the frozen row–event continuation pulls back to a response  $D_s \in [0, 1]^8$  on the all-on alphabet. Any calibration is part of the same encoding and retained state. Thus (27) holds without increasing  $K$ . If the audit attains  $v$  against the full physical class, its pullback attains  $v$  against this subfamily, since the unrestricted upper bound is  $v$ . Averaging selected rows preserves their factorization.

The three interior rows in (57) are distinct vertices of  $[0, 1]^8$ , so the generators must include  $e_1, e_2, e_3$  themselves. The first row lies in the face

$$F_0 = \{d : d(001) = 0, d(110) = d(111) = 1, d = 0 \text{ off the diagonal}\}.$$

Of those three obligatory vertices only  $e_1$  lies in  $F_0$ ; since  $t < 1$ , this row is not  $e_1$ . It needs another generator in  $F_0$ . Similarly the last row needs another generator in

$$F_4 = \{d : d(000) = d(001) = 1, d(110) = 0, d = 0 \text{ off the diagonal}\}.$$

Only  $e_3$  among the obligatory vertices lies there. The two faces are disjoint. Lemma 8.5 gives  $K \geq 3 + 2 = 5$ . Conversely the optimal response mixes  $e_0, e_1$  at count zero and  $e_4, e_3$  at count four and otherwise selects the indicated event. Only its five-valued event label survives the cut. The inherited compiler realizes its subsequent validation with finite memory and attains  $v$ . This proves exactness of the decision count.  $\square$

The contact argument is essential. Setting both free coordinates equal to one gives a Bayes best response with only the three events  $e_1, e_2, e_3$ , but its derivative at  $r$  is nonzero because  $t < 1$ . It is not minimax. Counting the states of a Bayes best response alone would give an incorrect resource conclusion.

**Corollary 15.2** (A strict gap and its physical persistence). *There is  $\delta_* > 0$ , uniform for  $\gamma \in I$ , such that every two-preparation audit with at most four states at the decision cut has ideal worst-case score at most  $U_2(\gamma) - \delta_*$ . In particular, this bound holds for every original-interface audit of whole-schedule peak at most four. If only the target changes by total variation at most  $\beta < \delta_*/2$ , the five-state decision construction still strictly outperforms this class.*

*Proof.* Let  $W_4(\gamma)$  be the maximum worst-case score over the relaxed factorizations (27) with  $K = 4$  and two full training words. Their encoder and decoder spaces are compact and fixed, independently of  $\gamma$ . The score is jointly continuous in these variables, the target bias, and  $(p, q)$ . Consequently  $W_4$  is continuous. By Theorem 15.1 it is strictly less than  $U_2(\gamma)$  for each  $\gamma \in I$ . The minimum of this positive continuous gap on compact  $I$  is positive. This defines  $\delta_*$  without pretending to have evaluated it numerically. The domination argument in that theorem makes it an upper bound for every original-interface audit in question. Changing only the target changes any fixed audit's mean score by at most  $\beta$ . The difference between the two classes therefore decreases by at most  $2\beta$ .  $\square$

For the microscopic family at  $\gamma = 1/4$ , the signal is larger than  $1/4$  and the standard deviation of each normalized sensor noise is  $\sqrt{2}\sigma$ . The Gaussian tail bound used in Theorem 11.3 gives the sharper, vanishing estimate

$$(59) \quad \text{TV}(Q_{d,\sigma}, Q_*) \leq \frac{8\sigma}{\sqrt{\pi}} \exp\{-1/(64\sigma^2)\}, \quad 9/10 \leq d \leq 11/10.$$

Thus Corollary 15.2 holds uniformly in  $d$  for all sufficiently small positive  $\sigma$ . This is an existence statement with the displayed physical modulus. The present proof does not certify that every  $\sigma \leq 1/24$  lies below the unknown gap threshold.

**15.1. The sharp serial-validation peak.** A decision cut and the whole execution have different resource costs. We now determine the latter in a declared validation schedule. In the *forward serial class*, both training preparations finish before validation; the candidate validation's two report slots and mark are read before any target validation report is read. The same frozen row-event continuation is used on both preparations, as in Definition 11.1. Training gates, stochastic state updates and frozen gate policies are unrestricted within that interface. No intermediate output can be reread as external memory.

**Theorem 15.3** (Sharp forward serial peak). *For every  $\gamma \in I$ , the least whole-schedule peak width attaining  $U_2(\gamma)$  in the forward serial class is twelve. In particular, a peak of at most eleven in this class incurs a strictly positive loss, which can be chosen uniformly for  $\gamma \in I$ .*

*Proof.* Use the common-garbling subfamily and the two raw all-on training words as in Theorem 15.1. Any optimal audit must finish both training preparations almost surely under its least-favorable prior. Indeed a stopped branch after a first preparation would have a response independent of the unused second word. For each first report count 0, 1, 2, two choices of the unused word force two different interior vertices from  $e_1, e_2, e_3$ . Each has positive conditional probability. A positive stopped component cannot be a convex component of two distinct vertices. The same argument excludes stopping before the first draw. Null branches may be completed arbitrarily.

Consider the cut after the candidate's second report slot and before its mark. On a canonical raw input tape its continuation is a channel from  $(w, y) \in \{0, 1\} \times \{000, 001, 110, 111\}$  to  $\{-1, 0, 1\}$ , where  $w$  is the unread candidate mark and  $y$  the fresh target word. All these target words have positive probability. Each retained state supplies one such continuation channel, common to every past leading to it. Hence the rows indexed by selected pasts factor through at most the peak number of generators.

For the strict interior training counts, the following eight rows are forced deterministic channels:

$$(60) \quad e_1(y) - f(w), \quad f \in \{0, 1 - w, 1\}; \quad e_2(y) - f(w), \quad f \in \{0, 1\}; \quad e_3(y) - f(w), \quad f \in \{0, w, 1\}.$$

For example  $e_1$  has candidate residual 0 after an off-diagonal report pair,  $1 - w$  after 00, and 1 after 11. The other cases follow by restriction of their masks. Each listed past has positive probability under both supporting candidate parameters. The eight functions are distinct: subtracting two with the same mask compares their distinct  $w$  functions; for different masks their difference depends nontrivially on  $y$  and cannot equal a function of  $w$  alone. They are eight distinct vertices of the product of output simplices.

There are four additional required rows. Average the extreme training marks as in Theorem 15.1, and take the candidate raw report pair to be, respectively, off diagonal and 11 at count zero, and off diagonal and 00 at count four. Independence of a fresh raw candidate preparation from the frozen continuation preserves the averaged tie probability  $t$ . On the four target words these rows have means

$$(61) \quad (t, 0, 1, 1), \quad (t - 1, -1, 0, 0), \quad (1, 1, 0, t), \quad (0, 0, -1, t - 1),$$

for both values of  $w$ . More precisely, each integer coordinate here is a point mass at that integer, and the remaining coordinate is the Bernoulli mixture between the two neighboring integers. This stronger channel statement, not a statement about a zero mean alone, follows because the candidate indicator is fixed at 0 or 1 on the selected raw pair, while the target indicator is a bit. Fresh gate randomness is already part of this channel; it supplies no additional past-dependent argument to a retained state.

The four rows lie in four pairwise disjoint faces of the product of output simplices. These faces fix, for both  $w$ , respectively,

|           | 000 | 001 | 110 | 111 |
|-----------|-----|-----|-----|-----|
| $F_{0,+}$ | *   | 0   | 1   | 1   |
| $F_{0,-}$ | *   | -1  | 0   | 0   |
| $F_{4,+}$ | 1   | 1   | 0   | *   |
| $F_{4,-}$ | 0   | 0   | -1  | *   |

where a number specifies a point mass and  $*$  is unrestricted. Among the eight vertices (60), each face contains exactly one:  $e_1$ ,  $e_1 - 1$ ,  $e_3$ , and  $e_3 - 1$ , respectively. Since  $t < 1$ , none of the four required rows is that vertex. Face packing forces four more generators, for a total of twelve. This argument uses conditional future-output laws and not the continued storage of an event name after a residual has replaced it.

The optimal five-event selection followed by the inherited forward compiler has peak twelve, including its stochastic selection cut. It proves the matching upper bound. To see strictness below twelve, use the finite-protocol normal form of Proposition 8.1 with all logical cuts bounded by eleven, including selection and frozen-continuation buffers. Unobserved internal random computations can be collapsed to common transition kernels on the same register; an unretained random duration cannot be supplied as a later input. The normalized row spaces and closed frozen-interface restrictions are compact. If the constrained value equalled  $U_2$ , the preceding face obstruction would apply. Continuity and compactness in  $\gamma$  give a uniform strictly positive gap, just as in Corollary 15.2.  $\square$

Theorem 15.3 is a minimum-width theorem for a specified serial order, not a claim that an arbitrary validation order has the same minimum. The ideal target has support restrictions that can change future residuals when the target is read first. Reverse-order and interleaved validations require their own continuation analysis. The decision-memory converse in Theorem 15.1 does not make this serial-order assumption. Neither statement replaces the original physical interface by an uncharged atomic validation.

## 16. A FULL-SUPPORT MARKED SADDLE

The support restriction of the ideal target can be removed without replacing the private simulator or changing the training experiment. This section identifies an explicit region of positive targets on which both the statistical saddle and its decision-memory number are exact. The next section shows that the original Brownian sensor belongs to this region throughout its previously stated noise range.

Put

$$\mathcal{R} = [6/25, 13/50] \times [0, 1/1000].$$

For  $(\gamma, \kappa) \in \mathcal{R}$ , define  $Q_{\gamma, \kappa}$  on  $\{0, 1\}^3$  by the masses

$$(62) \quad \frac{\omega}{Q_{\gamma, \kappa}(\omega)} \left| \begin{array}{cccc|c} 000 & 001 & 110 & 111 & \text{each other atom} \\ a & b & b & a & \kappa \end{array} \right|, \quad a = \frac{1 + \gamma}{4} - \kappa, \quad b = \frac{1 - \gamma}{4} - \kappa.$$

These masses sum to one. For  $\kappa > 0$  every atom has positive mass. The candidate is still  $b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2)$ ; there is no additional candidate parameter.

**Theorem 16.1** (Full-support saddle and contact rigidity). *For every  $(\gamma, \kappa) \in \mathcal{R}$ , there is a unique  $r = r_{\gamma, \kappa}$  in  $(33/100, 7/20)$  satisfying*

$$(63) \quad f(r) = r^3 + (13 - 2\gamma + 8\kappa)r^2 + (3 - 12\gamma + 48\kappa)r - 1 - 2\gamma + 8\kappa = 0.$$

Set  $D = f'(r)$  and

$$(64) \quad t = \frac{2\{-3r^2 + (14 - 8\gamma - 16\kappa)r - 3 + 48\kappa\}}{D},$$

$$(65) \quad v = \frac{-r^3 + (7 - 4\gamma - 8\kappa)r^2 + (-3 + 48\kappa)r + 13 + 4\gamma - 104\kappa}{32}.$$

Then  $8 < D < 10$ ,  $1/10 < t < 1/4$ , and

$$U_2(b, Q_{\gamma, \kappa}) = v.$$

The optimal five response rows are (57), with this value of  $t$ , and zero at all off-diagonal atoms. The equal prior on  $p = q = (1 \pm \sqrt{r})/2$  is least favorable. The same averaged rows are forced for every full-word minimax response. At the three interior counts the entire deterministic event is forced word by word.

The least post-training decision width attaining  $v$  is exactly five, including in the original gate interface with arbitrary stochastic training, stopping and independently acquired calibration.

*Proof.* On the indicated rectangle in  $(\gamma, \kappa, r)$ , direct monotonicity gives  $8 < f'(r) < 10$ . The polynomial decreases with  $\gamma$  and increases with  $\kappa$ . Its two endpoint evaluations are bounded by

$$f_{6/25,1/1000}(33/100) = -81619/5000000 < 0, \quad f_{13/50,0}(7/20) = 387/40000 > 0.$$

This proves existence and uniqueness in the stated interval. The numerator of  $t$  is  $-16\gamma r - 32\kappa r + 96\kappa - 6r^2 + 28r - 6$ . Bounding its negative and positive terms separately gives a lower bound  $10378/10000 > 1$  and an upper bound  $19754/10000 < 2$ . Together with  $8 < D < 10$  these prove the asserted interval for  $t$ .

Let  $u = (p + q - 1)^2$ ,  $z = (p - q)^2$ , and retain the polynomials  $H_\gamma, J_\gamma$  from Theorem 14.1. The probabilities of the five training counts give

$$E(u, z) = \frac{(u - z)^2 - 6u + 2z + 13}{4},$$

$$L(u, z) = \frac{(u - z)^2 + 6u - 2z + 1}{8}.$$

Here  $E$  is the expected cardinality of the deterministic selected four-atom event, and  $L$  is the probability of an extreme training count. The score of the proposed response is therefore

$$G = H_{\gamma,\kappa} + tJ_{\gamma,\kappa}, \quad H_{\gamma,\kappa} = H_\gamma - \kappa E, \quad J_{\gamma,\kappa} = J_\gamma - \kappa L.$$

This is an identity in the actual training probabilities, not an estimate. On the diagonal,  $J_{\gamma,\kappa}(u, 0) = -f(u)/64$  and  $H_{\gamma,\kappa}(r, 0) = v$ . Polynomial division, using  $f(r) = 0$ , gives

$$(66) \quad G(u, 0) - v = \frac{(u - r)^2 A(\gamma, \kappa, r, u)}{16D},$$

where

$$A = 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru + 12\gamma r + 6\gamma u - 51\gamma + 30$$

$$- 384\kappa^2 - 96\kappa r - 48\kappa u - 144\kappa.$$

For  $0 \leq u \leq 1$  the negative terms alone give  $A > 8$  throughout  $\mathcal{R}$ . Moreover, on  $0 \leq u, z \leq 1$  the bounds in the preceding family theorem yield

$$\partial_z H_{\gamma,\kappa} \geq 5/32 - \kappa, \quad \partial_z J_{\gamma,\kappa} \geq -3/64.$$

Indeed the additional derivatives are respectively  $\kappa(u - z - 1)/2$  and  $\kappa(u - z + 1)/4$ . Since  $t < 1/4$ , one has  $\partial_z G > 1/8$ . Thus (66) is a global lower certificate on the parameter square, with equality at exactly the two proposed prior points.

For the Bayes upper bound, group the four report bits by their total  $S$ ; the independent training marks and arrangements conditional on  $S$  are parameter independent under this prior. Put  $L_r = r^2 + 6r + 1$ . The first three rows of 256 times the signed coefficient table on

000, 001, 110, 111 are

$$\begin{aligned}
S = 0 : & \quad (0, -8\gamma L_r, 32r(r+1) - 8\gamma L_r, 32r(r+1)), \\
S = 1 : & \quad 8(r-1)(r^2 + 4r - 1 - 2\gamma(r+1) + 8\kappa(r+1), \\
& \quad r^2 + 4r - 1 + 2\gamma(r+1) + 8\kappa(r+1), \\
& \quad r^2 - 4r - 1 + 2\gamma(r+1) + 8\kappa(r+1), \\
& \quad r^2 - 4r - 1 - 2\gamma(r+1) + 8\kappa(r+1)), \\
S = 2 : & \quad -12(r-1)^2(r-1-2\gamma+8\kappa, r-1+2\gamma+8\kappa, \\
& \quad r-1+2\gamma+8\kappa, r-1-2\gamma+8\kappa).
\end{aligned}$$

The other rows are their reversals. For example the potentially small first parenthesis in row one is at most

$$(7/20)^2 + 4(7/20) - 1 - 2(6/25)(133/100) + 8(1/1000)(27/20) < -1/10.$$

The third parenthesis is negative by the same endpoint bounds; the second is positive and the fourth negative. In row two,  $r-1+2\gamma+8\kappa \leq -61/500 < 0$ . Row zero's third entry is positive since  $32(33/100)(133/100) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 7$ . Consequently the signs are exactly those of the previous two-preparation saddle. At each off-diagonal atom the candidate mass on both prior points equals  $(1-r)/8 > 13/160$ , whereas  $\kappa \leq 1/1000$ . Every off-diagonal coefficient is strictly negative. Coordinatewise Bayes maximization therefore selects the proposed response, including its two indifferent coordinates. Its equal score at the prior support closes the minimax match against the full response class.

For completeness the contact argument persists, not just the sign pattern. If  $a_0, b_0$  are the averaged extreme response coordinates, their extra diagonal contributions are

$$a_0(1-p)^4\{a - (1-p)^2/2\} + b_0p^4\{a - p^2/2\}.$$

At either support point their sum with  $a_0 = b_0 = 1$  is zero by (63); the first term is positive at  $p_+$ . Contact at both supports gives  $a_0 = b_0$ . Interior stationarity gives  $a_0 = b_0 = 64\partial_u H_{\gamma,\kappa}(r, 0)/D = t$ . All strict coordinates are forced individually. Thus the three vertices and two disjoint faces used in Theorem 15.1 are unchanged. That theorem's positive-factorization argument gives five states for every admissible stochastic encoder, while the same five-event selection attains it. The common-garbling reduction is unchanged because the candidate interface is unchanged.  $\square$

The rectangle  $\mathcal{R}$  is an explicit stability region for the *saddle and its exact decision-memory number*. It is not a claim that arbitrary nonsymmetric total-variation perturbations have the same optimizer. At  $\kappa = 0$  every formula reduces to the retained ideal theorem. Positive off-diagonal target masses do not destroy the strict negative Bayes coefficients at those atoms: their magnitude relative to the candidate, rather than their being zero, is what is needed.

## 17. EXACT STATISTICAL FORM OF THE BROWNIAN COLLISION SENSOR

The full-support theorem applies to the original microscopic target, not only to an independently constructed contamination model. The preparation symmetries supply the required form exactly.

**Theorem 17.1** (Physical symmetry and a quantitative noise region). *Use exactly the preparation boxes, elastic collision, detector and Brownian windows of Section 11. Conditional on the preparation put*

$$Z = |h(v_{1,y}^+)|, \quad e = \Phi\left(-\frac{Z}{\sqrt{2}\sigma}\right), \quad \mu_1 = \mathbb{E}e, \quad \mu_2 = \mathbb{E}e^2.$$

For every  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$  the exact all-on target law is

$$(67) \quad Q_{d,\sigma} = Q_{\gamma_{d,\sigma}, \kappa_{d,\sigma}}, \quad \gamma_{d,\sigma} = \frac{1}{4} - \frac{\mu_1}{2}, \quad \kappa_{d,\sigma} = \frac{\mu_1 - \mu_2}{2}.$$

In particular

$$\frac{1}{4} - \frac{1}{1200} < \gamma_{d,\sigma} < \frac{1}{4}, \quad 0 < \kappa_{d,\sigma} < \frac{1}{1200},$$

so the entire physical range lies inside  $\mathcal{R}$ , and every target atom has strictly positive probability. The physical two-preparation value in the unrestricted-memory original gate interface equals (65) at these parameters. Its exact decision-memory number is five.

*Proof.* The collision estimate gives  $Z > 1/4$  for every prepared point. The conditional two window noises are independent, of equal variance, and the deterministic signal is constant after the collision. Thus, given  $(B, W, Z)$ , the two report bits are independent copies of  $B$  flipped with probability  $e$ .

We justify the distribution of  $Z$  rather than assume a noise symmetry. Reflection in the spatial  $y$  coordinate sends  $(r_y, g_y, V_y)$  to their negatives, interchanges the two  $B$  boxes, and preserves their uniform product laws and the elastic equations. It negates  $v_{1,y}^+$  and leaves  $Z$  unchanged. The only box that depends on  $W$  is the one for  $V_z$ ; changing this center-of-mass velocity cannot change the relative collision or the outgoing  $y$  velocity. All other box coordinates are independent of  $W$ . Consequently  $Z$ , and hence  $e$ , has the same conditional law for all four  $(B, W)$  labels. The Brownian increments are independent of these labels and of the preparation.

The prepared masses of  $(B, W)$  are  $5/16$  for equality and  $3/16$  otherwise. Direct averaging therefore gives

$$\begin{aligned} Q(000) &= Q(111) = 5/16 - 5\mu_1/8 + \mu_2/2, \\ Q(001) &= Q(110) = 3/16 - 3\mu_1/8 + \mu_2/2, \\ Q(010) &= Q(011) = Q(100) = Q(101) = (\mu_1 - \mu_2)/2. \end{aligned}$$

These are precisely (62) with (67). This calculation uses both the common signal and the actual mark; replacing the common signal by independent unconditional report errors would in general replace  $\mu_2$  incorrectly by  $\mu_1^2$ .

The Gaussian bound already proved in the physical bridge yields  $0 < e < 1/600$  uniformly in this physical range. Thus  $0 < \mu_2 < \mu_1 < 1/600$ , proving the parameter bounds. Positivity follows also directly from  $0 < e < 1$  and positive prepared label masses. The all-on construction works against every private candidate in Definition 11.1; its score is the product-family score. Conversely the common-garbling private subfamily gives the architecture-uniform upper bound. Theorem 16.1 therefore supplies both exact value and exact decision count for the original interface, not for an auxiliary sensor.  $\square$

*Remark 17.2* (Known target and acquired calibration). The exact value and exact atomic stochastic realization are statements for a specified target law. Their event-selection probability depends on that target, not on the unknown candidate. When  $d, \sigma$  and the preparation are known, the expectations in (67) are defined integrals of that known physical law. They are not free information about the private parameter. An auditor that must acquire the target instead uses finite calibration and a precision allowance. The following explicit bound makes this separation operational.

**Proposition 17.3** (Acquisition and finite row precision). *Let the fixed physical target be in the preceding theorem. From  $n$  independent all-on target calibration words define*

$$\hat{\kappa} = \frac{1}{4n} \sum_{i=1}^n \mathbf{1}_{\{X_{1i} \neq X_{2i}\}}, \quad \hat{\gamma} = \frac{1}{n} \sum_{i=1}^n (\mathbf{1}_{\{000,111\}} - \mathbf{1}_{\{001,110\}})(X_i).$$

*Clip these separately to the two intervals of  $\mathcal{R}$ . With probability at least  $1 - 4\exp(-na^2/2)$ , both coordinate errors are at most  $a$ . Choose the optimal response for this clipped target and replace its tie probability by a dyadic number with error at most  $2^{-b}$ . Conditional on that calibration event, its worst-case score against the true target is at least*

$$(68) \quad U_2(b, Q_{d,\sigma}) - 9a - 2^{-b}.$$

*The calibration can be acquired with at most  $(n+1)^3$  counter states and at most  $4(n+1)^3$  states including the current report buffer; retaining the calibration output during the audit gives the conservative product bound  $12(n+1)^3$  at logical report cuts. A sequential fair-bit realization of the tie coin, with its origin and bit phase retained, has a finite explicit bound  $12(n+1)^3 + 8(b+2)(n+1)^3$ .*

*Proof.* The off-diagonal indicator has mean  $4\kappa$  and range one. The signed diagonal indicator has mean  $2a - 2b = \gamma$  and range two. Hoeffding's inequality and a union bound give the displayed failure probability; clipping to an interval containing the truth cannot increase coordinate error. The two target laws have total variation at most  $|\Delta\gamma|/2 + 4|\Delta\kappa| \leq 9a/2$ . Every fixed trained response changes score by at most this amount when only the target changes, and so does the unrestricted optimal value. Using an optimizer for the estimated target therefore loses at most  $9a$  against the true one. Only the two extreme-count event choices are rounded. Their score contribution changes by at most the coin error, because their total probability is at most one and the change in a single indicator expectation has magnitude at most one. This proves (68).

Three nonnegative category counts, each bounded by  $n$ , compute the two statistics; they also fix the clipped estimates and the subsequent program choice. Keeping this count triple with the twelve-state audit costs at most the stated product. At an extreme count, sample the dyadic coin using  $b$  fair bits and comparison with its binary threshold, retaining the two-valued origin, the comparison flag and the phase. At most  $8(b+2)$  additional states suffice per calibration choice. All other counts select deterministic events. The bound includes the coin workspace instead of identifying an algebraic row with a finite random-bit primitive. The  $n$  target calibrations and the four audit preparations are all charged.  $\square$

## 18. OPTIMAL VALIDATION ORDERS AND A POSITIVE-NOISE MEMORY JUMP

We now optimize the order in the original two-tape, bit-level validation interface. Each tape has slots  $1, 2, w$  in that order. Write  $X$  for the candidate tape and  $Y$  for the target tape. There are twenty declared-clock interleavings. A fixed clock is common to all executions; its phase is not a report-dependent side channel. Gate choices, state updates, training and frozen-event selection remain stochastic and otherwise unrestricted as before.

Let  $e_0, \dots, e_4$  be the five events (46). A full raw validation word has output  $e_i(Y) - e_i(X)$ . For the strict training counts, contact forces  $i = 1, 2, 3$  respectively. At either extreme only one raw-event coordinate is indifferent; Theorem 16.1 fixes its mark-averaged probability to  $t \in (1/10, 1/4)$ .

One precaution is needed. A freshly randomized gate need not couple its two validation coins as one stored event mask would. When both raw validation words equal the indifferent atom, their difference may be random with mean zero. None of the lower certificates below uses that coordinate as a forced deterministic zero. For every additional mixed witness, the known

prefix excludes at least one validation word from the indifferent atom, so at least one of the two event indicators is already deterministic. Its future output law is then fixed by the remaining indicator's marginal. This covers both stored-mask and fresh gate implementations.

**Theorem 18.1** (The minimum over all declared-clock validation orders). *For every  $(\gamma, \kappa) \in \mathcal{R}$  with  $\kappa > 0$ , the least whole-schedule peak attaining  $U_2(b, Q_{\gamma, \kappa})$ , minimized over all twenty declared-clock interleavings, is twelve. The only minimizing orders are the two serial orders*

$$XXXYYY, \quad YYYXXX.$$

*Every nonserial declared order requires peak at least fourteen. The lower bounds permit the full stochastic gate and event interface, not merely an all-on deterministic compiler. These conclusions apply to  $Q_{d, \sigma}$  for every  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ .*

*Proof.* Every raw validation prefix has positive probability at either supporting candidate and at the target. Thus all cut witnesses may be compared on a common full future alphabet. Generate all-on words to simulate training gates as in Theorem 15.1. The post-training response is an unrestricted optimizer on the supporting subfamily, hence has the contact-forced rows of Theorem 16.1. Stopping before the two training preparations cannot occur with positive supporting probability: for each retained first-word branch, two possible unused second words force different strict vertices. A positive stopped component cannot belong to both vertices. The witnesses below therefore concern actual post-training validation cuts.

At a cut with two slots consumed from one tape and none from the other, the eight deterministic vertices and four disjoint additional faces from Theorem 15.3 give twelve. That argument required only the four positive target diagonal words. It is still valid with full target support. Exchanging the two raw tapes negates the output and gives exactly the same channel-polytope certificate at the reversed cut. Thus either serial order needs twelve.

We give explicit certificates at the two possible nonserial entrance cuts. After one slot of each tape, write  $x = X_1$ ,  $y = Y_1$ , and use suffix coordinates  $(u, w, v, z) = (X_2, X_w, Y_2, Y_w)$ . Define

| $i$ | $g_i^0(u, w)$    | $g_i^1(u, w)$ |
|-----|------------------|---------------|
| 1   | $(1 - u)(1 - w)$ | $u$           |
| 2   | $1 - u$          | $u$           |
| 3   | $1 - u$          | $uw$          |

and let  $d_i^{xy} = g_i^y(v, z) - g_i^x(u, w)$ . The twelve expressions with  $i = 1, 2, 3$  and  $x, y \in \{0, 1\}$  give ten distinct deterministic vertices. The only repetitions are  $d_2^{11} = d_1^{11}$  and  $d_3^{00} = d_2^{00}$ , as is seen by substituting  $u, w, v, z \in \{0, 1\}$  in the displayed functions.

There are four more required channels. Use count zero at prefixes  $(x, y) = (0, 1), (1, 0)$  and count four at these same two prefixes. Their endpoints are respectively the continuations of  $(e_0, e_1)$  and  $(e_4, e_3)$ , with nontrivial weights  $1 - t, t$ . Each excludes simultaneous occurrence of the indifferent atom. The minimal face of each such channel consists of distributions supported, at each suffix, on the two endpoint output values. Among the ten mandatory vertices it contains only  $d_1^{01}, d_1^{10}, d_3^{01}, d_3^{10}$ , respectively. These four faces are pairwise disjoint. In their listed order, suffixes separating their six pairs are

| pair           | 12   | 13   | 14   | 23   | 24   | 34   |
|----------------|------|------|------|------|------|------|
| $(u, w, v, z)$ | 0110 | 0010 | 0000 | 0000 | 0001 | 0000 |

At each listed suffix the two sets of permitted output integers are disjoint; this follows directly from the displayed  $g_i^x$  and the masks  $e_0, e_4$ . None of the required mixed rows is the sole mandatory vertex in its face, because  $0 < t < 1$ . Face packing gives  $10 + 4 = 14$ .

Suppose instead two slots of  $X$  and one of  $Y$  have been consumed. A deterministic continuation is indexed by  $(i, X_1X_2, Y_1)$ . The following twelve choices are distinct and include every strict-count continuation:

| $i$ | $(X_1X_2, Y_1)$                                        |
|-----|--------------------------------------------------------|
| 1   | $(00, 0), (00, 1), (01, 0), (01, 1), (11, 0), (11, 1)$ |
| 2   | $(00, 0), (01, 0)$                                     |
| 3   | $(00, 1), (01, 1), (11, 0), (11, 1)$                   |

They are verified by the formula  $e_i(Y_1, Y_2, Y_w) - e_i(X_1, X_2, X_w)$  on the eight suffixes  $(X_w, Y_2, Y_w)$ . At training count zero take additionally prefixes  $(01, 0)$  and  $(11, 0)$ . The corresponding two faces have endpoints  $(0, (1 - Y_2)(1 - Y_w))$  and  $(-1, -1 + (1 - Y_2)(1 - Y_w))$ , respectively. Each contains just its listed  $i = 1$  vertex, and they are disjoint at any suffix with  $Y_2 = 1$ . Both mixtures are nontrivial. Thus this cut also requires fourteen. Swapping  $X, Y$  proves the same result at the cut with one and two slots consumed.

Any nonserial interleaving either reads one slot from each tape first, or starts with two slots of one tape and then switches before its mark. It therefore passes one of the preceding cuts and needs fourteen. Every serial order has an upper realization of peak twelve: select the same five-valued frozen event and use its future residual functions. For full-support raw words the validation widths in either serial order are

$$(5, 10, 12, 10, 10, 7, 3).$$

These counts follow by restriction of the five masks, exactly as in Lemma 12.4; for the reverse order negate all output residuals and exchange the tapes. Training and the charged stochastic selection cut have width at most five. Therefore both serial orders attain twelve, proving all assertions by Theorem 9.2. The physical specialization follows from Theorem 17.1.  $\square$

This theorem optimizes the externally declared schedule; it does not optimize a report-dependent scheduler that changes which tape is read next. Such a scheduler has a different action interface, and its protocol state cannot be supplied for free. The phrase “all orders” in Theorem 18.1 refers to all twenty declared interleavings, with this quantifier fixed explicitly.

**Theorem 18.2** (A singular support transition in reverse serial memory). *For every  $\gamma \in [6/25, 13/50]$ , the exact minimum peak in the reverse serial order  $YYYXXX$  for the ideal target  $Q_{\gamma,0}$  is ten. For every  $0 < \kappa \leq 1/1000$  it is twelve. In particular the reverse-serial exact memory of the physical collision experiment jumps from ten at its zero-noise target to twelve at every positive  $\sigma \leq 1/24$ , although its target laws converge in total variation as  $\sigma \downarrow 0$ .*

*Proof.* For the upper bound at the ideal target, ignore its first report bit; its second bit equals the first almost surely, so this does not remove any needed information. After its second bit and mark, retain the residual  $c - e_i(X)$ , where  $c = e_i(Y)$ . Event  $e_2$  has  $c = 1$  surely; each other event permits two values of  $c$ . The compatible reverse validation profile is

$$(5, 5, 9, 9, 10, 7, 3).$$

After the second target bit the nine functions are, with the unread mark denoted by  $z$ ,

$$-e_0, 1 - e_0, 1 - z - e_1, 1 - e_1, 1 - e_2, 1 - e_3, z - e_3, 1 - e_4, -e_4.$$

Restricting after the target mark gives nine functions  $c - e_i$ . After the first candidate bit they give ten distinct functions of  $(X_2, X_w)$ ; after its second bit they give the seven scalar mark functions in Lemma 12.4. Equality of residual functions is preserved by restriction, so these counts describe one compatible machine, not independent cutwise colorings. Training remains of peak five and the terminal score is correct almost surely for every candidate. On target words of zero probability, choose arbitrary legal transitions.

For the converse examine the cut after all three target slots and the first candidate bit. Write suffixes  $(X_2, X_w)$  in the order 00, 01, 10, 11. The three strict training events force the following eight distinct deterministic output channels:

$$\begin{aligned} (0, 1, 1, 1), \quad (-1, 0, 0, 0), \quad (1, 1, 0, 0), \quad (0, 0, -1, -1), \\ (0, 0, 1, 1), \quad (-1, -1, 0, 0), \quad (1, 1, 1, 0), \quad (0, 0, 0, -1). \end{aligned}$$

At training count zero take  $X_1 = 0$  and target words 001 and 110. They force the channels with output means

$$(-t, 0, 0, 0), \quad (1 - t, 1, 1, 1).$$

Every integer coordinate is a point mass, and the remaining coordinate is the indicated mixture of neighboring output integers, because the target event indicator is fixed on these words. Their faces each contain exactly one of the eight mandatory vertices. They are disjoint at suffix 01, which requires output zero in the first and one in the second. Thus two additional generators are required, giving ten. All these prefixes have positive supporting probability. The full-support value twelve follows from the preceding theorem. Formula (67) gives the physical assertion and  $\mu_1, \mu_2 \rightarrow 0$  by the uniform Gaussian bound.  $\square$

The discontinuity concerns exact attainment. It neither contradicts continuity of the optimal score nor prevents a lower-memory device from approximating that score. It also explains why a support-zero compiler cannot be transferred to the noisy physical target by simply keeping its state count unchanged.

## 19. PREPARATION LIMITS AND LOCALIZATION OF LEAST-FAVORABLE PRIORS

The contact structure has a second consequence, now for an arbitrary number of training preparations. We separate a general localization principle from the special geometry of the marked product family. An exact finite- $N$  two-point prior is not assumed.

**Theorem 19.1** (Nearest-experiment limit and prior localization). *Let  $P_\theta$  be a continuous family on a finite alphabet of size  $d$ , with compact metric parameter space, and let  $Q$  be fixed. Put*

$$d_Q(\theta) = \text{TV}(Q, P_\theta), \quad d_* = \min_\theta d_Q(\theta), \quad C_* = \{\theta : d_Q(\theta) = d_*\}.$$

*For  $N \geq 1$ , the unrestricted frozen-validation values satisfy*

$$(69) \quad d_* - \sqrt{(d-1)/N} \leq U_N(P, Q) \leq d_*, \quad U_N \uparrow d_*.$$

*Every least-favorable prior  $\mu_N$  in Theorem 5.1 satisfies*

$$(70) \quad \int (d_Q - d_*) d\mu_N \leq \sqrt{(d-1)/N}.$$

*Consequently every weak limit of such priors is supported on  $C_*$ . For every  $a > 0$  their mass on  $\{d_Q - d_* \geq a\}$  is at most  $\sqrt{(d-1)/N}/a$ . More generally, an upper bound  $b_N$  on twice the expected total-variation error of a common empirical reconstruction replaces  $\sqrt{(d-1)/N}$  in both conclusions.*

*Proof.* Let  $\hat{P}$  be the empirical law of the  $N$  reports, and choose the indicator  $h_{\hat{P}}$  maximizing  $(Q - \hat{P})h$ . If  $h_\theta$  maximizes  $(Q - P_\theta)h$ , the two event inequalities give

$$(Q - P_\theta)h_{\hat{P}} \geq d_Q(\theta) - 2\text{TV}(\hat{P}, P_\theta).$$

This inequality holds for the same parameter-independent response rule at every parameter. For any law  $P$  on  $d$  atoms,

$$\mathbb{E} \text{TV}(\hat{P}, P)^2 \leq \frac{d}{4N} \left( 1 - \sum_x P(x)^2 \right) \leq \frac{d-1}{4N}.$$

Thus its expected score is at least  $d_Q(\theta) - \sqrt{(d-1)/N}$ . Every response has score at most  $d_Q(\theta)$  at that parameter, which proves the upper bound at a minimizing parameter. Ignoring the last observation proves monotonicity and hence the limit.

Against a minimizing prior, the Bayes optimum is  $U_N$ . It is at least the prior average of the same empirical rule. Therefore

$$U_N \geq \int d_Q d\mu_N - \sqrt{(d-1)/N}.$$

Combine this with  $U_N \leq d_*$  to get (70). Markov's inequality proves the mass estimate. The function  $d_Q - d_*$  is nonnegative and continuous on the compact parameter space, so its integral under any weak limit is zero. Such a limit is supported on its zero set. The proof uses only the common reconstruction bound, which proves the last assertion.  $\square$

The empirical estimate in (69) is the same finite-alphabet mechanism underlying the retained decision-spectrum classification. Its role here is different: it controls every least-favorable prior, not merely a constructive selector. In particular, finite-preparation saddle supports cannot remain far from the closest candidate experiments as the preparation number grows.

**Theorem 19.2** (Intrinsic marked contact geometry). *For every  $\gamma \in I$ , set  $s_\gamma = \sqrt{(1+\gamma)/2}$  and*

$$d_\gamma = 2s_\gamma - 1 - \gamma/2, \quad C_\gamma = \{(s_\gamma, s_\gamma), (1-s_\gamma, 1-s_\gamma)\}.$$

*Then*

$$(71) \quad \min_{p,q} \text{TV}(Q_\gamma, b(p, q)) = d_\gamma, \quad \operatorname{argmin}_{p,q} \text{TV}(Q_\gamma, b(p, q)) = C_\gamma.$$

*Moreover, for Euclidean distance in  $[0, 1]^2$ ,*

$$(72) \quad \text{TV}(Q_\gamma, b(p, q)) - d_\gamma \geq \frac{7}{2300} \operatorname{dist}((p, q), C_\gamma)^2.$$

*The constant is uniform on  $I$  and is derived from the experiment's atom probabilities, not from a metric-entropy or small-ball assumption.*

*Proof.* Put  $a = (1-p)(1-q)$ ,  $c = pq$ ,  $l = (1-\gamma)/2$  and  $h = (1+\gamma)/2$ . The common mass of target and candidate is  $\psi(a) + \psi(c)$ , where

$$\psi(z) = \begin{cases} z, & 0 \leq z \leq l, \\ z/2 + (1-\gamma)/4, & l \leq z \leq h, \\ 1/2, & h \leq z \leq 1. \end{cases}$$

This follows by summing the smaller mass on each of the two marked atoms corresponding to the report pair. Reflection  $(p, q) \mapsto (1-p, 1-q)$  exchanges  $a, c$ ; assume  $c \geq a$ . If  $c < 1/4$ , both terms are in the first segment of  $\psi$ , and their sum is at most  $1/2$ .

For  $c \geq 1/4$ , put  $x = \sqrt{c} \geq 1/2$ . By the arithmetic-geometric mean inequality,

$$a \leq (1-x)^2 \leq 1/4 < l.$$

Consequently the common mass is at most  $F(x) = (1-x)^2 + \psi(x^2)$ , with equality only when  $p = q = x$ . On the three consecutive intervals with endpoints  $1/2, \sqrt{l}, \sqrt{h}, 1$ , this function is respectively

$$(1-x)^2 + x^2, \quad (1-x)^2 + x^2/2 + (1-\gamma)/4, \quad (1-x)^2 + 1/2.$$

The first two are strictly convex and the last strictly decreases. The first increases away from  $1/2$ . Thus a maximum must occur at  $\sqrt{l}$  or  $\sqrt{h}$ . Their difference is

$$(73) \quad F(\sqrt{h}) - F(\sqrt{l}) = \gamma \left( \frac{3}{2} - \frac{2}{\sqrt{h} + \sqrt{l}} \right) > \frac{7}{575}.$$

Indeed  $\sqrt{h} > 39/50$ ,  $\sqrt{l} > 3/5$ , and  $\gamma \geq 6/25$ , so the right side is greater than  $(6/25)(3/2 - 100/69) = 7/575$ . The unique maximizing diagonal point on this side is  $x = \sqrt{h}$ . Its common mass is  $(1 - \sqrt{h})^2 + 1/2 > 1/2$ , also excluding  $c < 1/4$ . Subtracting it from one gives  $d_\gamma$ . Reflection proves (71) and the assertion about all minimizers.

We record a uniform quantitative form. Write  $s = \sqrt{h}$  and  $\Delta = 7/575$ . For  $1/2 \leq x \leq \sqrt{l}$ , the common mass is at most  $F(\sqrt{l})$ , so its deficit from  $F(s)$  is at least  $\Delta$ . For  $\sqrt{l} \leq x \leq s$ , convexity puts  $F$  below the chord between its endpoint values. Since this interval has length at most one, its deficit is at least  $\Delta(s-x)$ . For  $s \leq x \leq 1$  the deficit is

$$(1-s)^2 - (1-x)^2 = (x-s)(2-s-x) \geq (1-s)(x-s).$$

Since  $s < 4/5$ , this too is at least  $\Delta|x-s|$ . Together the three intervals give  $F(s) - F(x) \geq \Delta|x-s|$ .

Let  $z = (p-q)^2$ . At fixed  $c = x^2$  the additional loss from the nondiagonal candidate is exactly

$$(1-x)^2 - a = p + q - 2x = \frac{z}{p+q+2x} \geq z/4.$$

The geometric mean  $x$  lies between  $p$  and  $q$ , and hence

$$(p-s)^2 + (q-s)^2 \leq 4z + 4(x-s)^2 \leq 4z + 4|x-s|.$$

It follows that the total deficit is at least  $(\Delta/4)((p-s)^2 + (q-s)^2)$ , proving (72) in this case. If  $c < 1/4$ , the total variation is at least  $1/2$ , whereas  $d_\gamma < 12/25$  from  $s < 4/5$  and  $\gamma \geq 6/25$ . The excess is therefore greater than  $1/50$ ; Euclidean squared distance in the square is at most two, and  $1/50 > 2(7/2300)$ . This proves the remaining case. Reflection completes the proof.  $\square$

**Corollary 19.3** (An all-preparation law and a limiting two-point prior). *For all  $N \geq 1$  and  $\gamma \in I$ ,*

$$(74) \quad d_\gamma - \sqrt{3/N} \leq U_N(b, Q_\gamma) \leq d_\gamma, \quad U_N(b, Q_\gamma) \uparrow d_\gamma.$$

*Every least-favorable prior  $\mu_{N,\gamma}$  satisfies*

$$(75) \quad \int \text{dist}(\theta, C_\gamma)^2 d\mu_{N,\gamma}(\theta) \leq \frac{2300}{7} \sqrt{3/N}.$$

*A least-favorable prior can be chosen invariant under simultaneous complementation of the two parameters. Every such symmetric choice satisfies, for the Euclidean quadratic transport distance,*

$$(76) \quad W_2 \left( \mu_{N,\gamma}, \frac{1}{2} \delta_{(s_\gamma, s_\gamma)} + \frac{1}{2} \delta_{(1-s_\gamma, 1-s_\gamma)} \right) \leq \sqrt{2300/7} (3/N)^{1/4}.$$

*In particular, the limiting symmetric least-favorable law is unique.*

*Proof.* Estimate the four-atom report-pair law from training and tensor it with the known fair mark. Tensoring with a common probability preserves total variation. The proof of Theorem 19.1 therefore uses  $d = 4$  rather than eight, proving (74) and an excess bound  $\sqrt{3/N}$ . Combining the latter with (72) gives (75).

Simultaneously complement both report bits and the mark in every training and validation word. This leaves  $Q_\gamma$  invariant and sends  $b(p, q)$  to  $b(1 - p, 1 - q)$ . The Bayes objective in (8) is invariant under this transformation and convex in the prior. Averaging a minimizing prior with its reflected image is therefore again minimizing and is symmetric.

Map each parameter to a closest point of  $C_\gamma$ , choosing the two points with equal probabilities at a tie. This is a Borel kernel, equivariant under reflection. A symmetric prior is pushed forward to the equal two-point law in (76); the induced coupling has squared transport cost exactly the left side of (75). Taking square roots proves the assertion.  $\square$

These conclusions identify the endpoint and limiting contact geometry for every preparation number. They do not assert that the exact prior has two atoms at every finite  $N$ , or that the displayed convergence rates and constants are sharp. The finite- $N = 1, 2$  saddles are preserved as exact results. The new theorem explains their relationship to an intrinsically determined limiting contact set without extrapolating their particular event tables to unproved values of  $N$ .

## 20. AN EXACT PREPARATION–DECISION-MEMORY LAW

A second solvable family separates a genuine joint resource law from an implementation bound. Here the memory coordinate is the number of states at the training–validation cut. It is not identified with the bit-level peak width of the collision audit.

Fix  $m = 2^d$ ,  $0 < \alpha < 1$ , and an unknown parameter  $\theta \in \{1, \dots, m\}$ . A fresh training preparation reports  $\theta$  with probability  $\alpha$  and an erasure  $\perp$  otherwise. Conditional on  $\theta$ , the preparations are independent. Candidate validation has law  $\delta_\theta$  and target validation is uniform on  $\{1, \dots, m\}$ . At the decision cut the auditor retains at most  $K = 2^k$  states,  $0 \leq k \leq d$ . Its subsequent response may depend only on that state, current validation observations and fresh independent randomness. In particular, a calibration table, remembered seed or stopping time outside the retained state is not available. Upstream and downstream memory are otherwise unrestricted for the converse. Let  $V_N^{\text{er}}(K)$  be the best worst-case expected signed validation score with at most  $N$  training preparations.

**Theorem 20.1** (Exact joint law). *For every  $N \geq 0$  and  $K = 2^k \leq m$ ,*

$$(77) \quad V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N) \left(1 - \frac{1}{K}\right).$$

*The converse covers stochastic encoders and arbitrary legal stopping. The value is attained by a clocked machine with  $K$  training states. With atomic preparation and validation outcomes, the complete audit has peak at most  $\max\{2K, 3\}$  and uses at most  $N + 2$  preparations.*

*Proof.* Write  $q = (1 - \alpha)^N$  and pre-generate  $N$  potential training reports. A stopped auditor ignores the unused reports; this does not disclose extra information to it. On the event that all  $N$  reports are erasures, its retained-state law  $r = (r_j)_{j=1}^K$  is independent of  $\theta$ . After padding any smaller register with unused states, its channel to the decision register has the form

$$(78) \quad C(j \mid \theta) = qr_j + (1 - q)S(j \mid \theta)$$

for a stochastic channel  $S$ . This identity remains valid with randomized stopping and randomized state updates.

Use the uniform prior on parameters as an upper certificate. The part  $qr_j$  has zero expected score for every response: averaging  $\delta_\theta$  under this prior gives the target itself. For the other

part, optimizing over all responses gives a convex function of  $S$ , a sum of positive parts of linear functions. Every stochastic channel is a convex combination of deterministic channels  $j = g(\theta)$ ; therefore its value is at most the largest deterministic-channel value. This convexification is used only to bound a channel. It does not presuppose that a mixture of width- $K$  machines is realizable at width  $K$ .

If the fibers of  $g$  have sizes  $n_1, \dots, n_K$ , a nonempty fiber has posterior uniform on that fiber, so its total variation from the uniform target is  $1 - n_j/m$ . The prior-averaged optimal score is

$$\sum_j \frac{n_j}{m} \left(1 - \frac{n_j}{m}\right) = 1 - \sum_j (n_j/m)^2 \leq 1 - 1/K.$$

Empty fibers contribute zero. Cauchy–Schwarz proves the inequality. This is an upper bound on the average score and hence on its minimum over fixed parameters. Multiplying by  $1 - q$  proves the upper bound in (77).

For attainment, partition the parameter alphabet into  $K$  equal groups and let  $g(\theta)$  denote its group. Initialize the register uniformly on the  $K$  group labels. On an erasure leave it unchanged; on a revealed parameter overwrite it by  $g(\theta)$ . No extra “revelation occurred” flag is needed. At the decision cut its law is  $q \text{Unif}[K] + (1 - q)\delta_{g(\theta)}$ . For register  $j$ , freeze the event which is the complement of group  $j$ . On a revelation its score is  $1 - 1/K$ . Under a uniformly random initial label, the mean score is zero for each fixed  $\theta$ : one of the  $K$  labels has score  $1 - 1/K$  and the others have score  $-1/K$ . This proves the exact worst-case value.

The  $k$  initialization bits can be accumulated in the  $K$ -state register; all earlier prefix counts are at most  $K$ . Thus no persistent seed lies outside it. Candidate validation retains the group label and its event indicator, using at most  $2K$  states. Target validation produces one of the three values  $-1, 0, 1$ . This proves the atomic-outcome peak bound. The controller uses a declared external schedule; an autonomous stopping implementation must additionally retain its phase. A phase-tagged implementation is finite, but its cost is not included in  $K$ .  $\square$

**Corollary 20.2** (Thresholds and matching resource scales). *For  $K \geq 2$  and  $0 \leq c < 1 - 1/K$ , the least integer number of training preparations giving a score strictly greater than  $c$  is*

$$(79) \quad N_c^{\text{er}}(K) = \left\lfloor \frac{\log(1 - c/(1 - 1/K))}{\log(1 - \alpha)} \right\rfloor + 1.$$

*If  $c \geq 1 - 1/K$ , no finite  $N$  suffices. For  $0 < \varepsilon < 1$ , achieving  $V_N^{\text{er}}(K) \geq 1 - \varepsilon$  requires*

$$K \geq \varepsilon^{-1}, \quad N \geq \frac{\log(1/\varepsilon)}{-\log(1 - \alpha)}.$$

*Conversely, whenever an allowed  $K \leq m$  satisfies  $K \geq 2/\varepsilon$ , the choice  $N \geq \log(2/\varepsilon)/[-\log(1 - \alpha)]$  suffices.*

*Proof.* The strict threshold is equivalent to  $(1 - \alpha)^N < 1 - c/(1 - 1/K)$ . Since the denominator logarithm is negative, the least integer satisfying this strict inequality is (79), including equality cases of the real quotient. Also

$$1 - V_N^{\text{er}}(K) = q + (1 - q)/K.$$

This is at least  $q$  and at least  $1/K$ , and is at most  $q + 1/K$ . These three inequalities prove the necessary and sufficient bounds.  $\square$

The exact law concerns an entire  $(N, K, \alpha, m)$  family, not a single finite diagnostic. Its mechanism is a parameter-independent erasure component followed by the convex geometry of the decision channel. It demonstrates how a preparation obstruction and a memory obstruction can be matched in one theorem. It does not identify the least physical peak width at two collision

preparations. Encoding the  $m$ -symbol reports bit by bit also introduces cuts not present in this atomic model; the physical bit-level accounting is given separately.

## 21. INTEGER MEMORY AND THE FAILURE OF A NAIVE PARTITION FORMULA

The divisibility assumptions in Theorem 20.1 can be removed, but a balanced-partition Bayes bound must not be mistaken for a minimax equality when a persistent random partition is not free. This distinction leads to another exact finite-resource transition.

Keep the revelation interface, but allow any integers  $m \geq 2$  and  $1 \leq K \leq m$ . Put  $\rho = 1 - (1 - \alpha)^N$ , and denote the genuine  $K$ -label minimax value by  $V_{N,m}^{\text{er}}(K)$ . Write  $m = Kq + s$ ,  $0 \leq s < K$ , and set

$$(80) \quad B_{m,K} = 1 - \frac{(K-s)q^2 + s(q+1)^2}{m^2}.$$

Here and below all-erasure initialization randomness is a state initialization, not an unrecorded seed used again at validation.

**Proposition 21.1** (Arbitrary integer alphabet bounds and low-reveal equality). *The optimal uniform-prior Bayes score is  $\rho B_{m,K}$ . The minimax value satisfies*

$$(81) \quad V_{N,m}^{\text{er}}(K) \leq \min \left\{ \rho B_{m,K}, 1 - \frac{\lceil m/K \rceil}{m} \right\}.$$

If  $\rho \leq m/(m+s)$ , equality with the first term holds. At perfect revelation  $\rho = 1$  the exact value is the second term. In particular, when  $s > 0$  the uniform-prior Bayes optimum at perfect revelation is strictly larger than the minimax value.

*Proof.* The all-erasure decomposition (78) holds without any divisibility condition. Its parameter-independent part has zero uniform-prior score. Optimizing the other part over responses gives a convex function of its stochastic channel. A deterministic channel with fiber sizes  $n_j$  has Bayes score  $1 - \sum_j (n_j/m)^2$ . If two nonempty fiber sizes differ by at least two, moving one index from the larger to the smaller strictly decreases the sum of squares. Allowing empty fibers and repeating gives sizes  $q$  and  $q+1$ , proving the Bayes bound. It is attained by this partition and its complementary events, with any parameter-independent initialization. This proves the first upper bound as well as the asserted Bayes optimum.

For perfect revelation, fix any  $K$  response vectors. For each known parameter choose a response maximizing its score; this deterministic assignment cannot decrease any parameter's payoff, even when the original encoder was randomized. Some assigned fiber has size at least  $\lceil m/K \rceil$ . Averaging its parameters, the score of their common response is at most the total variation between the uniform target and the uniform law on that fiber, namely  $1 - |\text{fiber}|/m$ . The minimum is no larger. Balanced fibers with their complementary events attain the resulting upper bound. A perfectly informed encoder can simulate any less informative encoder, so this is an upper bound at every  $\rho$ .

For the low-reveal equality let balanced fibers have weights  $w_j = n_j/m$ . When  $\rho < 1$ , initialize their label register with probabilities

$$(82) \quad r_j = \frac{\rho w_j + (1 - 2\rho)/K}{1 - \rho}.$$

These sum to one, and are nonnegative precisely throughout the stated range: the smallest numerator is  $\rho q/m + (1 - 2\rho)/K$ . On a revealed parameter overwrite the label by its fiber; on

erasure do nothing. No revelation flag is retained. For a parameter in fiber  $i$ , the complementary-event score is

$$\begin{aligned} g_i &= \rho(1 - w_i) + (1 - \rho) \left( r_i - \sum_j r_j w_j \right) \\ &= \rho \left( 1 - \sum_j w_j^2 \right) = \rho B_{m,K}. \end{aligned}$$

This matches the upper bound uniformly in the fixed parameter. If  $\rho = 1$  and  $s = 0$ , the deterministic revealed label already attains that value, so the singular denominator in (82) is not used. Finally, with unequal balanced fibers the weighted average of their sizes is strictly smaller than the largest size; equivalently  $B_{m,K} > 1 - \lceil m/K \rceil / m$ . This proves the last assertion.  $\square$

**Theorem 21.2** (The complete two-label revelation law). *For every  $m \geq 2$ , every  $N \geq 0$ , and  $0 < \alpha < 1$ , set  $w = \lfloor m/2 \rfloor / m$  and  $b = \lceil m/2 \rceil / m$ . Then*

$$(83) \quad V_{N,m}^{\text{er}}(2) = \min\{2wb\rho, w\}, \quad \rho = 1 - (1 - \alpha)^N.$$

*The same formula holds at the limiting endpoints  $\rho = 0, 1$ . For odd  $m$  it changes regime at  $\rho = m/(m+1)$ ; for even  $m$  it reduces to  $\rho/2$ . The attaining machine uses two training labels, a frozen two-event alphabet, and atomic peak at most four.*

*Proof.* Proposition 21.1 gives the upper bound and its attainment for  $\rho \leq 1/(2b)$ . Above this threshold, partition into fibers of weights  $w, b$  and initialize deterministically in the larger fiber's label. Continue to overwrite on a reveal and leave the state unchanged on an erasure. A parameter in the larger fiber has score  $w$ ; a parameter in the smaller fiber has score  $(2\rho - 1)b$ . The latter is at least  $w$  exactly when  $\rho \geq 1/(2b)$ . This attains the second upper bound. For even  $m$  the threshold is one, so the low-reveal construction suffices. The endpoint  $\rho = 0$  may instead freeze a constant event. Candidate validation retains the selected label and its indicator, with at most four states; target validation produces the difference. Initialization is atomic randomization when its probabilities are not dyadic.  $\square$

For example,  $m = 3, K = 2$  gives  $V_{N,3}^{\text{er}}(2) = \min\{4\rho/9, 1/3\}$ , rather than  $4\rho/9$  for all  $\rho$ . The balanced-integer expression is therefore not the unqualified replacement of the divisible minimax formula. For  $K \geq 3$  outside the low-reveal range, (81) remains a bound rather than an asserted equality. The compatible dynamic formulation of Section 7 retains the exact optimization in that regime. These results strengthen the revelation example without identifying its decision-cut coordinate with the collision model's bit-level peak.

## 22. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows, and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r - 1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(84) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma 22.1** (Causal interpretation of the coefficients). *Every coefficient in (84) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (84) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem 22.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_\theta g_\theta(q^C), \quad u_C = \min_\theta \max_\alpha b_{\theta,C,\alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(85) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_\alpha (u_C - b_{\theta_C,C,\alpha}) B_\alpha(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .*

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (84) implies

$$\min_\theta g_\theta(q) \leq \min_\theta \max_\alpha b_{\theta,C,\alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma 22.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (85). Choose  $\theta_C$  attaining

the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

*Remark 22.3.* The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem 5.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

### 23. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [6]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma 23.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-} (L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem 23.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(86) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(87) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma 23.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ , and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (87).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_\pm^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ . Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_\pm^n(i, \cdot), \pi_\pm) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (87). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (86). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (87) is an observation time at which an external analyst reads the autonomous machine, not a free input clock used by its transitions. The adversarial model of [10] is not covered by the independent-report proof above.

## 24. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary 24.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\bar{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\bar{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\bar{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding's inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition 24.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (8); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem. This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

## 25. A SHARPENED PHYSICAL CONSUMER AND ITS SIMULATION BUDGET

The exact two-preparation theorem has a downstream use with explicit hypotheses, rather than a merely renamed dependency arrow. It sharpens the mean margin of a raw-interface confidence test, and the causal morphism theorem transfers that test, with its full memory and calibration costs, to another executable interface.

**Theorem 25.1** (Confidence and transported resource certificate). *Let  $Q$  be a physical marked target with  $\text{TV}(Q, Q_*) \leq \beta$ . Use the two-preparation event selector with a dyadic coin  $\tau_b$  satisfying  $|\tau_b - \tau| \leq 2^{-b}$ , and put*

$$a_b = v_2 - \beta - \frac{5}{16}2^{-b}, \quad W_b = \max\{12, 6(b+1) + 5\}.$$

*If  $0 < c < a_b$ ,  $R$  independent four-preparation blocks, followed by the test  $\overline{D}_R > c$ , have error bounds*

$$(88) \quad \sup_{\text{private}} \mathbb{P}(\overline{D}_R \leq c) \leq \exp\{-R(a_b - c)^2/2\},$$

$$(89) \quad \sup_{\text{equal}} \mathbb{P}(\overline{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*They use  $4R$  preparations, at most  $bR$  fresh random bits, and at most  $W_b(2R+1)$  persistent states under a clocked schedule. With an exact atomic coin, replace  $a_b, W_b$  by  $v_2 - \beta, 12$ .*

*Suppose a source interface simulates this entire repeated audit under Theorem 3.4, uniformly over the private and equal-law families, with path defect  $\Delta_R$ . Then the corresponding source error bounds are the right sides of (88)–(89) plus  $\Delta_R$ , capped at one. At aligned cuts its state bound is  $C_{\text{cal}}R_tM_tW_b(2R+1)$ , and its preparation count is  $N_{\text{cal}}$  plus all source calls required to supply the  $4R$  audit preparations. Calibration is acquired and retained, not supplied as a free real-valued table.*

*Proof.* Corollary 13.2 and Proposition 13.3 give mean block score at least  $a_b$  under every fixed private parameter. Independent fresh preparations and independent coins give independent block scores in  $[-1, 1]$ . Hoeffding’s inequality proves (88). Under the equal-law null, conditional on training and the frozen event, the two validation indicators have the same mean. Each block therefore has mean zero, proving (89) by the same inequality. Retain the integer sum in  $\{-R, \dots, R\}$  alongside the current block register. Updating the sum and resetting the block is a deterministic boundary operation. This proves the raw resource bounds.

Apply Theorem 3.4 to the whole repeated experiment, including its stopping and validation fields. Its defect bound applies to each of the two terminal error events, whose indicators have range one; each probability therefore changes by at most  $\Delta_R$ , not  $2\Delta_R$ . The same theorem gives the state product and preparation count. The source blocks need not be independent after a shared calibration stage: independence was used only for the reference audit, and path-law comparison transfers its final event probability.  $\square$

The first part uses the exact saddle, the original microscopic bridge and the compiled residual machine. The second additionally needs the uniform acquired causal simulation theorem. A source which does not satisfy that theorem’s stability and calibration hypotheses is not covered. Likewise this consumer supplies no reverse simulation and therefore does not transfer an optimal-width lower bound to an arbitrary source. It is an actual conditional theorem interface for subsequent models, not an assertion that the independent geometric A2 chain or the unbounded B4/C2 operator obligations have already been discharged.

## 26. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section 22 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The

physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section 23 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (45), polynomial identity (47), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: SADDLE GEOMETRY AND THE MEMORY OF CAUSAL EXPERIMENTS

QIAN QI

**ABSTRACT.** We study the memory required to attain a statistical saddle in a causal experiment. For finite interfaces, admissible registers give normalized positive realizations of the experiment's continuation channels. An unrestricted minimax saddle determines an exposed Bayes face; optimal finite-memory realizations must also satisfy contact and stationarity at the supporting parameters. These additional conditions can fix responses on Bayes ties and thereby force memory that a Bayes best response alone would not require. For a continuous family of marked product experiments we obtain exactly five states at the decision cut of an optimal two-preparation audit. For serial validation with the candidate read first, the minimum whole-schedule peak is exactly twelve. Both converses include stochastic encoders and continuations. They are proved by positive face packing, not by minimizing a chosen deterministic machine. We also identify the all-preparation limiting value and derive the closest-product geometry directly from the experimental probabilities. Every least-favorable prior localizes near two intrinsic contact points; symmetric priors converge to their equal mixture with an explicit quadratic-transport bound. Prepared predictive quotients, causal simulation, informative finite-memory control, exact one- and two-preparation saddles, and positive-noise physical realization are developed within the same resource framework.

## 1. INTRODUCTION

A statistical saddle determines the best expected decision, but need not determine a machine that can make that decision. A Bayes response can lose information that is immaterial under its prior yet necessary for uniform optimality over the parameter family. In a causal experiment, this distinction has a resource cost: discarded information cannot be recovered by an uncharged random selector or a terminal decoder. The central question of this paper is how to read that cost from the saddle itself.

The underlying experiment consists of a preparation, positive normalized kernels, a causal action interface, executable future tests, and charged register cuts. The unknown parameter is fixed throughout an execution. The preparation determines path laws and posterior continuations; no geometric reference measure is supplied independently of the experiment. The predictive quotient identifies histories that admit identical legal future tests. Its stochastic realizations, rather than ordinary linear rank alone, govern finite memory.

**1.1. Saddle geometry and its realizations.** For a finite causal interface, all controller wirings within a given profile are represented by common normalized positive matrix products. The generators at successive cuts must be compatible under every one-step continuation. Independently factoring each cut does not suffice. Let  $\mathcal{C}_{\mathbf{K}}$  be this compact, generally nonconvex response set,

and let  $U$  be the unrestricted minimax value. A least-favorable prior exposes the Bayes face  $F_*$ . The profiles attaining  $U$  are precisely those admitting compatible positive realizations of

$$\mathcal{S}_* = F_* \cap \{C : g_\theta(C) \geq U \text{ for all } \theta\}.$$

Theorem 8.2 gives the exact loss decomposition, attainment criterion, supporting-parameter contact equations, and the factorizations imposed at a retained-state cut. This is not a minimax interchange over nonconvex machines. Its operative distinction is between a Bayes exposed face and its uniformly optimal part.

This distinction is decisive when some Bayes coefficients vanish. Contact and stationarity at interior supporting parameters may determine these coordinates even though the Bayes objective does not. Once they are determined, a convex-face obstruction applies to every stochastic encoder and decoder. Lemma 8.4 gives a simple reusable form: obligatory vertices and additional rows in disjoint faces require separate positive generators. Exact causal recodings preserve the attainable profiles; approximate simulations transport the value with explicit state products and error allowances.

**1.2. Exact memory in a continuous marked experiment.** Our main application is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2,$$

where the last coordinate is the actual preparation mark. The target  $Q_\gamma$  has masses  $((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4)$  on 000, 001, 110, 111, and zero mass elsewhere. After candidate training, the auditor freezes a row and event and applies them to independent candidate and target validations. The score is target indicator minus candidate indicator. Write  $U_N(\gamma)$  for its unrestricted minimax value with  $N$  training preparations.

The exact two-preparation saddle of Theorem 13.1 has a two-point least-favorable prior for  $6/25 \leq \gamma \leq 13/50$ . Its two extreme-count response coordinates are Bayes ties. Theorem 14.1 proves that every minimax response, not only the displayed symmetric optimizer, must average these coordinates to the same explicitly determined number  $t_\gamma \in (0, 1)$ . Three other count rows are forced cube vertices. Two disjoint exposed faces then require two additional generators. Consequently

minimum decision width at the exact two-preparation value = 5.

The result applies to the original adaptive row–event interface: training, gates, stopping, retained randomness, and independent calibration are included. A common-garbling subfamily supplies the converse; the construction works against the original private candidate class.

Applying the same argument to future *output channels* at a validation cut, rather than only to event responses, yields a stronger scheduled result. If the candidate’s complete validation is read before any target validation report, eight deterministic continuation vertices and four additional disjoint faces force twelve generators. Theorem 14.3 therefore proves

minimum peak for exact forward serial validation = 12.

The matching implementation is the existing five-event residual machine. The lower bound does not assume that the event name remains stored after its residual is sufficient. This serial-order assertion is distinguished from the order-independent decision-width theorem. Reverse-order and interleaved validations are not assigned a peak optimum by this result.

For the collision bias  $\gamma = 1/4$ , the exact statistical values are

$$(1) \quad U_1 = \frac{85 - 7\sqrt{73}}{64}, \quad U_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad 2r^3 + 25r^2 - 3 = 0,$$

where  $1/3 < r < 7/20$ . Their full-parameter lower certificates and matching Bayes upper bounds are proved in the article. The new memory converses extract consequences from the entire optimal face of these calculations. They do not replace the exact values by a relaxation or a finite grid. Compactness also gives a strict four-state loss uniformly over the bias interval, and a strictly positive eleven-state loss for the forward serial class. The four-state loss survives sufficiently small positive sensor noise through an explicit vanishing Gaussian-tail modulus.

**1.3. A law for every preparation number.** The finite- $N$  saddles also determine a natural limiting question. Theorem 15.1 proves that unrestricted values increase to the distance from the target to the nearest candidate experiment. More significantly, every least-favorable prior concentrates on that closest-experiment set. This follows from the same common empirical response used as a competitor in the saddle game; the prior is not replaced by a parameter-dependent algorithm.

For the marked family the closest candidates and a uniform quadratic growth inequality are derived directly from its four diagonal masses. With  $s_\gamma = \sqrt{(1 + \gamma)}/2$ , the exact limiting value is

$$d_\gamma = 2s_\gamma - 1 - \gamma/2,$$

and its contact set consists exactly of  $(s_\gamma, s_\gamma)$  and  $(1 - s_\gamma, 1 - s_\gamma)$ . For every  $N \geq 1$ ,

$$d_\gamma - \sqrt{3/N} \leq U_N(\gamma) \leq d_\gamma.$$

Every symmetric least-favorable prior converges to the equal mixture of those points, with quadratic-transport distance at most  $\sqrt{2300/7}(3/N)^{1/4}$ . The intrinsic growth constant is derived, not assumed as a dimension or small-ball hypothesis. These are uniform bounds and a limiting classification, not a claim that a two-point prior is exact at every finite preparation number or that the rates are sharp.

**1.4. Prepared foundations and retained consequences.** The general foundations layer proves path construction, predictive quotient closure, checkpoint resolution, and acquired causal transport. The latter jointly charges calibration, preparation, quantization, numerical and model error, and the memory of a downstream controller. The informative routing family exhibits the exact values  $1/(2\lceil m/K \rceil)$  with a real routing cut and  $K/(2m)$  with a free persistent controller selector. The separate nonlinear occupation recursion retains all common-row constraints. These results distinguish an unrestricted saddle from its legal positive realizations.

The positive-noise collision construction realizes the marked experiment on the original report and actual-mark interface. The exact ideal score for  $N = 2$ ,  $W \geq 12$ , the finite-precision implementation, and the transported confidence theorem remain part of the paper. So do the integer revelation laws, compatible subdivision certificates, and the explicitly attributed autonomous finite-memory comparison. For reference, the deterministic precursor constants are

$$(2) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

Their earlier constructions and proofs are retained along with their later exact improvements.

**1.5. Relation to earlier work.** Positive stochastic realization and invariant cone methods have classical antecedents in Heller [17]; Vidyasagar [18] surveys the complete hidden-Markov realization problem. Nonnegative rank differs from ordinary linear rank, and its geometric interpretation is developed by Gillis and Glineur [19]. Our matrix normalization adds the specified causal action order and charged cuts. We do not claim the positive-realization mechanism itself as new. The additional argument links its generators to the uniformly optimal portion of a statistical saddle, including contact equations on Bayes-indifferent coordinates.

Blackwell comparison and convex minimax provide the statistical mechanisms [2, 3]. Belief-state dynamic programming is classical [1]. Controlled information acquisition and adaptive sensing have an established history [13, 14, 15]; neither causal action selection nor an adaptive advantage by itself is a priority claim here. Finite-memory testing and randomization are likewise classical [6, 7, 8, 9]. The autonomous stationary formula below is attributed to Hellman and Cover. Recent work on memory-constrained adversarial testing [10] and imperfect-recall optimization [16] concerns adjacent constraints with different adversarial or objective conventions. Polynomial policy optimization and positivity methods also have substantial antecedents [4, 5]. We retain the explicit distinctions in the literature crosswalk accompanying the source.

The empirical estimation bound used in the preparation limit is the same elementary finite-alphabet estimate appearing in the retained decision-spectrum theorem. The new use is localization of every least-favorable prior, followed by an explicit intrinsic contact calculation. Norberg's filtered-experiment comparison [11] remains an adjacent general theory; no proof-level non-overlap claim is made without a complete comparison of the original work.

**1.6. Organization.** The prepared foundations and finite interface are followed by statistical and controlled duality. Section 8 gives the central realization criterion. The exact marked saddles and physical bridge supply its hypotheses, and Section 14 extracts the decision and serial-peak converses. Section 15 gives the all-preparation law. The remaining resource and physical consumers follow. Complete predecessor volumes retain the development of the predictive, geometric, and operator interfaces. The independent historical A2 chain and the B4/C2 aggregate obligations are not turned into consequences of a finite-state theorem by a change of terminology.

## 2. CAUSAL EXPERIMENTS AND THEIR PREDICTIVE QUOTIENTS

We begin with the object and morphism structure. Its elementary probability statements fix the meaning of later resource theorems; classical kernel construction, conditional expectation and quantization are not assigned a new priority. The substantive comparisons below retain their preparation, memory and approximation coordinates simultaneously.

**2.1. The experimental object.** An experiment has a fixed unknown parameter  $\theta \in \Theta$ , hidden states  $X_t$ , visible actions  $A_t$ , reports  $Y_{t+1}$ , and preparation laws  $\mu_\theta$ . We impose the following six conventions.

**A0 (types and visibility).** These spaces are standard Borel. Visible histories include actions, reports and publicly recorded resource increments. A legal-action set and its remaining budget are part of the visible protocol type. Two histories with different legal continuations are not identified.

**A1 (positive kernels).** There are jointly measurable normalized nonnegative kernels  $K_t^\theta(dx', dy, dc \mid x, a)$ , with  $c$  a nonnegative resource increment. An absorbing symbol represents termination or failure. Dirac kernels are allowed. Positivity here does not require every outcome to have strictly positive probability. A hidden state can contain the necessary physical past; this notation does not assume a finite-dimensional physical closure.

**A2 (causality).** A policy is a kernel  $\alpha_t(da \mid h_t)$  depending only on visible past data and allowed independent randomization. It cannot read the unknown parameter. Stopping is with respect to the visible filtration.

**A3 (executable tests).** The specified bounded future tests include constants, required report events and their legal one-step continuations. For discrete reports the one-step instrument is

$$(\mathbb{T}_{t,a,y}f)(\theta, x) = \int f(\theta, x') K_t^\theta(dx', \{y\}, dc \mid x, a).$$

The test spaces are closed under the required instruments, finite linear combinations and the bounded monotone limits needed to recover the stated event laws. For general reports one uses event instruments and regular conditional distributions, not division by the probability of a continuous singleton.

**A4 (actual preparation).** Average risks and acquired state laws refer to the specified preparation and exploration protocol. Failed trials, calibration, resets and conditioning events retain their probabilities and implementation costs. A convenient measure on a reachable set does not replace its acquired law.

**A5 (executable resources).** Persistent labels, temporary buffers, program constants, calibration precision, preparations and clocks are distinguished. A retained selector is a state. A parameter-dependent table is not a known program constant. A simulator with  $R_t$  labels composed with a controller with  $K_t$  labels has the direct product bound  $R_t K_t$ , before any justified quotient is taken. Atomic stochastic rows and fair-bit implementations are separately specified.

**Proposition 2.1** (Prepared path laws). *For every fixed parameter and causal policy, the preparation and kernels uniquely determine their finite-dimensional path laws. On a finite horizon they are the iterated kernel product*

$$\mu_\theta(dx_0) \prod_{t < T} \alpha_t(da_t \mid h_t) K_t^\theta(dx_{t+1}, dy_{t+1}, dc_t \mid x_t, a_t).$$

*These laws are consistent under marginalization. For a countable horizon they determine the usual kernel extension. Deterministic dynamics give their original trajectory laws when represented by Dirac kernels.*

*Proof.* Successive integration constructs each finite law. Normalization of the last two kernels gives its preceding marginal, and induction proves consistency and uniqueness on cylinder events. The countable kernel extension gives the full law; equivalently one applies the standard extension theorem to these consistent iterated kernels. Integration against a Dirac transition is evaluation along that transition, which proves the last assertion.  $\square$

**2.2. Prepared predictive equivalence.** For Bayesian predictions additionally fix a prior on the parameter, and regard  $(\theta, X_t)$  as the hidden variable. A prepared posterior  $\pi$  at a given protocol type evaluates the future tests. Define  $\pi \sim_t \tilde{\pi}$  if their evaluations agree on every specified future test. This definition concerns one prepared experiment; it does not identify a prior-dependent posterior with a statistic sufficient simultaneously for all fixed parameters.

**Theorem 2.2** (Predictive quotient and causal closure). *For finite report alphabets, predictive equivalence is preserved by every legal positive-probability report update. Its class determines the laws of all specified future experiments. Every deterministic history statistic that determines those laws factors onto this quotient. For a measurable realization it is sufficient that a countable separating test family gives a measurable evaluation map with standard Borel image, and that the chosen statistic admits a measurable factor. In finite history spaces the latter conditions are automatic.*

*Proof.* For a legal action and report, Bayes' rule gives

$$\pi'(f) = \frac{\pi(\mathbb{T}_{t,a,y} f)}{\pi(\mathbb{T}_{t,a,y} 1)}.$$

Both numerator and denominator depend only on the old class by A3. Equivalent posteriors assign the same probability to the report, so updates agree on the next test space whenever that probability is positive. Null reports do not affect the prepared law and may be assigned a fixed

admissible version. Induction determines every finite future report word; the monotone-class extension gives the required future events. Conversely those event laws determine the tests. If two histories have the same sufficient statistic, they have the same future evaluations; the quotient is therefore constant on its fibers. This gives the factor set-theoretically. The stated measurable factor assumption supplies its measurable version; no claim that every abstract quotient of a standard Borel space is standard Borel is used.  $\square$

**Proposition 2.3** (Barycenters, entropy and normalized response). *In a fixed preparation, suppose a hidden target  $Z$ , observation  $Y$  and postprocessing  $W$  form a Markov chain  $Z \rightarrow Y \rightarrow W$ . For any bounded vector of tests  $f$ ,*

$$p_W = \mathbb{E}[p_Y | W], \quad p_Y = \mathbb{E}[f(Z) | Y], \quad \mathbb{E}\varphi(p_W) \leq \mathbb{E}\varphi(p_Y)$$

*for every convex  $\varphi$  for which these expectations exist. For a parameter-independent kernel  $G$ ,  $P \ll Q$ , and finite  $D(P\|Q)$ , regular conditional laws give*

$$\begin{aligned} D(P\|Q) &= D(PG\|QG) \\ &\quad + \int D(P(dx | w)\|Q(dx | w)) (PG)(dw). \end{aligned}$$

*Finally, if  $f, g$  are bounded and  $\pi_u(dx) = e^{ug(x)}\pi(dx)/\pi(e^{ug})$ , then*

$$\left. \frac{d}{du} \pi_u(f) \right|_{u=0} = \text{Cov}_\pi(f, g).$$

*Proof.* The Markov property and the tower rule give the conditional barycenter; conditional Jensen gives convex order. The joint laws  $P(dx)G(dw | x)$  and  $Q(dx)G(dw | x)$  have relative entropy  $D(P\|Q)$ . Disintegrating by  $w$  and applying the entropy chain rule gives the identity, and hence data processing. The last equality follows by quotient differentiation; boundedness justifies differentiation under the integral.  $\square$

The barycenter statement concerns a law of predictions, not a pointwise map between reachable sets. Likewise the covariance in the last formula is a normalized response, not an independently postulated Fisher matrix or a global sufficiency theorem.

### 3. ATTAINABLE RESOLUTION AND RESOURCE-AWARE SIMULATION

**3.1. Checkpoint and online prediction.** Fix an actual exploration protocol and its history law. Let  $p(h)$  be a bounded  $d$ -dimensional conditional prediction vector, with law  $\nu$ . For instance, a future test is sampled independently after encoding, and the coordinates include its sampling weights. Squared excess prediction loss is then  $\mathbb{E}\|p(h) - \hat{p}\|^2$ .

**Proposition 3.1** (Checkpoint resolution). *For at most  $M$  retained labels the least checkpoint excess loss is*

$$(3) \quad \inf_{c_1, \dots, c_M} \int \min_{1 \leq j \leq M} \|p - c_j\|^2 \nu(dp).$$

*Independent randomized encoders or decoders cannot improve it. This formula concerns the stated preparation and does not provide a common codebook by separately optimizing at each unknown true parameter.*

*Proof.* Conditional squared loss decomposes into its Bayes loss and squared distance from the conditional mean. For each retained label replace a random decoder by its mean. Random assignment to the resulting centers cannot do better than a nearest center. Conversely a nearest-center assignment attains the infimum over codebooks arbitrarily closely. Conditioning on an independent shared random seed, if such a seed is allowed, gives a codebook for each seed,

each with risk at least (3). Averaging cannot improve the bound. The formula does not charge the computation of a checkpoint assignment as an online algorithm; online compatibility is a separate condition.  $\square$

**Theorem 3.2** (A matched online resolution law). *Suppose a fixed prepared experiment has a predictive state  $s_t$  in a compact metric space  $S$ , a known initial state, and updates  $s_{t+1} = F_{t,a,y}(s_t)$ . Assume every permitted update is  $\rho$ -Lipschitz for one  $0 \leq \rho < 1$ , and the prediction map  $p : S \rightarrow \mathbb{R}^d$  is  $L$ -Lipschitz. Suppose  $S$  has a  $\delta$ -net of at most  $C\delta^{-d}$  points for all sufficiently small  $\delta$ . At a checkpoint  $T$ , assume the actual law  $\nu$  of  $p(s_T)$  satisfies the small-ball bound  $\nu(B(z,a)) \leq Aa^d$  for every center  $z$  and all sufficiently small  $a > 0$ . Then for all sufficiently large  $M$ , the minimum online excess prediction loss with  $M$  retained predictive labels satisfies*

$$(4) \quad c_0 M^{-2/d} \leq R_M^{\text{on}} \leq C_0 M^{-2/d}.$$

Here one may take

$$c_0 = \frac{1}{2}(2A)^{-2/d}, \quad C_0 = \frac{L^2 C^{2/d}}{(1-\rho)^2},$$

Any separate exploration controller, report buffer or clock is charged in addition to these  $M$  labels. The exploration protocol and the preparation are fixed before optimizing the encoder.

*Proof.* Any online  $M$ -label state is also a checkpoint encoder, so Proposition 3.1 applies. For any  $M$  centers, the union of balls of radius  $a = (2AM)^{-1/d}$  has  $\nu$ -mass at most one half. On its complement squared distance is at least  $a^2$ . Integration gives  $c_0 M^{-2/d}$ . This argument also permits randomized online encoders.

For the upper bound take a  $\delta$ -net with  $\delta = (C/M)^{1/d}$ , and a fixed measurable nearest-net assignment (with a fixed tie rule). Quantize the known initial state and, after each legal update, quantize again. The state error obeys  $e_{t+1} \leq \rho e_t + \delta$ ,  $e_0 \leq \delta$ , and hence  $e_t \leq \delta/(1-\rho)$ . The prediction error is at most  $L e_t$ . Squaring proves the upper bound, uniformly in time. Each update uses only the current net label and the current permitted input, so the construction is online. It does not grant the encoder free access to the original discarded history. If the exploration policy needs another register, that register is combined by a product construction.  $\square$

For example, a Lebesgue density bounded above by  $B$  gives the small-ball hypothesis with  $A = Bv_d$ , where  $v_d$  is unit-ball volume. The lower hypothesis is a condition on the *acquired prediction law*. A reachable set of dimension  $d$  without a mass condition does not imply the lower bound. Similarly, the contraction assumption is additional dynamics, not a consequence of kernel positivity.

**3.2. Causal morphisms and simultaneous error budgets.** A causal simulator  $\Gamma : \mathfrak{E} \rightarrow \mathfrak{F}$  is a parameter-independent executable transducer that uses source preparations to supply the target interface under every allowed target policy. Its defect  $\varepsilon$  is a uniform total-variation bound on the resulting path laws, including the fields required by the task. Its resource map  $\rho_\Gamma$  bounds the source resources of the transducer composed with a target controller.

**Proposition 3.3** (Composition and risk transfer). *Causal simulators compose. Their uniform defects add, capped at one, and their resource maps compose in the order  $\rho_{\Gamma_1} \circ \rho_{\Gamma_2}$ . For a terminal loss in  $[0, L]$  and a common target task,*

$$\mathcal{R}_{\mathfrak{E}}(\rho_\Gamma(B)) \leq \mathcal{R}_{\mathfrak{F}}(B) + L\varepsilon.$$

For reward in  $[-1, 1]$ , the corresponding maximum worst-case rewards satisfy the reverse inequality with an error  $2\varepsilon$ .

*Proof.* Interleave the two transducers; their pair of internal states is a causal implementation. Total variation contracts under a kernel and obeys the triangle inequality, proving the defect sum. If their state counts are  $R_t$  and  $M_t$ , the pair has at most  $R_t M_t$  states. Other declared resource bounds compose by execution of the two protocols. A bounded loss changes expectation by at most its range times total variation. Apply this bound to every fixed parameter and target controller and take the appropriate infimum or supremum. Uniformity in the controller is essential to this step.  $\square$

**Theorem 3.4** (Acquisition, quantization and model-error transport). *Suppose an exact source transducer has predictive state  $s_t \in S_t$  and additional charged buffers of size  $R_t$ , supplies  $T$  target operations, and has uniform model defect at most  $\varepsilon_{\text{mod}}$ . Its initialization and update depend on a calibration quantity  $\xi$ . From  $N_{\text{cal}}$  source preparations acquire an estimate  $\hat{\xi}$  with at most  $C_{\text{cal}}$  retained labels, such that*

$$\sup_{\theta} \mathbb{P}_{\theta}(d(\hat{\xi}, \xi) > a) \leq \eta.$$

*Subsequent preparation noises are independent of calibration conditional on the fixed parameter. Let finite nets of sizes  $M_t$  have radii  $\delta_t$ . Assume, on matching input/output histories and on the good calibration event, that the quantized transducer's state error satisfies*

$$(5) \quad e_0 \leq d_0 + a_0 a + \delta_0, \quad e_{t+1} \leq \rho_t e_t + d_{t+1} + a_{t+1} a + \delta_{t+1}.$$

*Assume its next output kernel and the exact transducer's output kernel differ in total variation by at most  $\epsilon_t + L_t e_t + b_t a$ , uniformly in the fixed parameter and legal policy. All constants and nets are declared independently of that unknown parameter. Then the quantized acquired transducer has defect at most*

$$(6) \quad \Delta = \min \left\{ 1, \varepsilon_{\text{mod}} + \eta + \sum_{t < T} (\epsilon_t + L_t e_t + b_t a) \right\}.$$

*Composing it with any target controller of cut widths  $K_t$  requires at most  $C_{\text{cal}} R_t M_t K_t$  labels at aligned execution cuts and transfers its bounded reward with loss at most  $2\Delta$ . Its preparations are  $N_{\text{cal}}$  plus all source preparations specified by the transducer; no successful-trial conditioning removes the failures.*

*Proof.* On the good calibration event, iterate (5). More explicitly, with  $D_0 = d_0 + a_0 a + \delta_0$  and  $D_j = d_j + a_j a + \delta_j$ ,

$$e_t \leq \sum_{j=0}^t D_j \prod_{k=j}^{t-1} \rho_k.$$

Couple each pair of output kernels maximally while their external histories agree. On agreement the target controller sees the same inputs, so it uses the same legal action and may use the same independent randomization. Its discontinuous action choices require no Lipschitz assumption: before a disagreement their arguments are identical. The chance of a first discrepancy is bounded by the sum in (6). Add the probability of bad calibration and the exact transducer's model defect. This proves the path bound, including stopping after padding by absorbing states.

The executable approximate transducer stores its calibration label, additional buffer, and net index. Combine these with the actual target register, not its full history or an uncharged belief. The resulting product gives the state count. If an operation contains further buffer cuts, apply the same product at each such cut;  $R_t$  was assumed to include them. Preparation costs add by execution. Finally apply Proposition 3.3.  $\square$

**Corollary 3.5** (A finite acquisition register). *Suppose  $r_0$  calibration rows have at most  $d$  outcomes, and take  $n$  independent preparations from each row on a fixed schedule. Their empirical rows satisfy, with probability at least  $1 - \eta$  uniformly in the row probabilities,*

$$\max \text{TV}(\hat{P}, P) \leq \frac{dz}{2}, \quad \eta = \min\{1, 2r_0d \exp(-2nz^2)\}.$$

*Their counts can be retained in at most  $(n+1)^{r_0(d-1)}$  labels. Thus Theorem 3.4 can use  $N_{\text{cal}} = r_0n$ ,  $a = dz/2$  and this finite calibration register when its calibration metric is the maximum row total variation.*

*Proof.* For each outcome the empirical frequency is the mean of independent Bernoulli indicators. Hoeffding's bound and a union bound over at most  $r_0d$  coordinates give the event stated. The total-variation estimate is half the sum of coordinate errors. Retain  $d - 1$  counts per row; the last is reconstructed from the known number of draws at that stage of the clocked schedule. Each retained count takes at most  $n + 1$  values. An autonomous implementation must additionally charge its schedule.  $\square$

These results separate exact predictive equivalence, average checkpoint resolution, online realizability, and uniform simulation risk. In particular, neither an optimal checkpoint codebook nor the proof-state bundle of Section 7 is automatically an executable finite register.

#### 4. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition 4.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{s_r}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller's random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(7) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition 4.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (7) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row. Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section 18 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

## 5. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(8) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z) (Q - P_\theta) h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem 5.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(9) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_\theta^{\otimes N}(z) \{Q(\omega) - P_\theta(\omega)\} d\mu(\theta) \right]_+$$

$$(10) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_\mu(z) \text{TV}(Q, \bar{P}_\mu(\cdot | z)).$$

Here  $m_\mu(z) = \int P_\theta^{\otimes N}(z) d\mu(\theta)$  and, when  $m_\mu(z) > 0$ ,

$$\bar{P}_\mu(\omega | z) = \frac{\int P_\theta^{\otimes N}(z) P_\theta(\omega) d\mu(\theta)}{m_\mu(z)}.$$

A zero-mass term in (10) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (8) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [3] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (9). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_\mu(z)$  it equals  $m_\mu(z)(Q - \bar{P}_\mu(\cdot | z))$ , proving (10). If  $m_\mu(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem 5.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_\theta$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^\Omega$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (8). This proves the upper bound for the union of all architectures. Conversely, retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (8).  $\square$

*Remark 5.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_\theta^{\otimes N} d\mu(\theta)$ , not  $(\int P_\theta d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (10) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary 5.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (9) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (9) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory’s theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

## 6. CONTROLLED EXPERIMENTS WITHOUT A DOMINATING ACTION

The reduction to one dominating row is not needed for a statistical dual, provided causal action choice is retained in the dual recursion. We give the finite-action theorem with a compact parameter space and an explicit protocol state. Its equality is an unrestricted-memory statement; its upper certificates apply to every smaller-memory class.

Let  $\Theta$  be compact metric and  $E$  a finite set of protocol states. At  $e \in E$  let  $\mathcal{A}_e$  be a finite set of training actions. Action  $a$  produces  $x$  in a finite alphabet  $X_a$  with law  $P_\theta^a$  and changes the protocol state to  $T(e, a, x)$ . The functions  $\theta \mapsto P_\theta^a(x)$  are continuous. An unknown  $\theta$  is fixed throughout the experiment. Conditional on it, each requested preparation uses a fresh independent draw from the selected row. Legal validation designs form a nonempty finite set  $\mathcal{B}_e$ . Design  $b$  has a finite outcome alphabet  $Y_b$ , target law  $Q^b$  and continuous candidate law  $V_\theta^b$ . A policy may stop after at most  $N$  training actions. It then freezes  $b \in \mathcal{B}_e$  and an event on  $Y_b$ , before one candidate and one target validation. Randomization is independent of  $\theta$ . No training action is assumed to dominate another.

For a finite nonnegative measure  $\nu$  on  $\Theta$  write  $\nu_{a,x}(d\theta) = P_\theta^a(x)\nu(d\theta)$  and set

$$(11) \quad \Phi_e(\nu) = \max_{b \in \mathcal{B}_e} \sum_{y \in Y_b} \left[ Q^b(y)\nu(\Theta) - \int V_\theta^b(y) d\nu \right]_+,$$

$$F_0(e, \nu) = \Phi_e(\nu),$$

$$(12) \quad F_n(e, \nu) = \max \left\{ \Phi_e(\nu), \max_{a \in \mathcal{A}_e} \sum_{x \in X_a} F_{n-1}(T(e, a, x), \nu_{a,x}) \right\}.$$

If no training action is legal, only the stopping term is retained. All the functions vanish at the zero measure, so no posterior division is required on null histories. For positive mass, (11) is the mass times the largest posterior-predictive total variation.

**Theorem 6.1** (Controlled posterior-predictive dual). *Let  $\mathcal{U}_N(e_0)$  be the maximum worst-case expected validation score over all randomized causal policies in the declared protocol, with at most  $N$  training preparations and no memory cap. Then*

$$(13) \quad \mathcal{U}_N(e_0) = \min_{\mu \in \mathcal{P}(\Theta)} F_N(e_0, \mu).$$

*Both extrema are attained. Each  $F_n(e, \cdot)$  is the maximum of finitely many continuous linear functionals on the cone of measures; in particular it is convex, continuous and positively homogeneous. For every prior  $\mu$ ,  $F_N(e_0, \mu)$  bounds the worst-case score of every finite-memory architecture implementing this protocol.*

*Proof.* There are finitely many histories of length at most  $N$  and finitely many event masks at each stopping history. Consequently there are finitely many deterministic policy trees, denoted by  $\Pi_N(e_0)$ . For  $\pi \in \Pi_N(e_0)$  its payoff  $g_\pi(\theta)$  is a finite sum of finite products of continuous primitive probabilities and is continuous in  $\theta$ .

A randomized causal policy induces the same outcome laws as a probability distribution on these trees: sample its finite random decision table in advance and condition on it. Conversely, with no memory cap, a sampled tree can be retained and followed. Thus the unrestricted payoff vectors are exactly the convex hull of the  $g_\pi$ . This step is not an assertion that mixing machines preserves a specified register width.

The simplex on  $\Pi_N(e_0)$  and  $\mathcal{P}(\Theta)$  are compact and convex. The expected payoff is continuous and bilinear. Minimax therefore gives

$$\max_{\lambda \in \Delta(\Pi_N)} \min_{\theta} \sum_{\pi} \lambda_{\pi} g_{\pi}(\theta) = \min_{\mu} \max_{\pi \in \Pi_N} \int g_{\pi} d\mu.$$

For a fixed measure, the terminal maximum is (11), because an event includes precisely the positive coordinates of its signed predictive measure. At a training node one selects an action and, after its observed outcome, selects a continuation tree separately on that branch. The unnormalized branch measure is exactly  $\nu_{a,x}$ . Backward induction proves (12) and identifies the right side with (13). It also proves the finite-linear-functional representation. Compactness gives an optimizing prior and an optimizing mixed tree. Finally, the minimum over fixed parameters of any policy is at most its average under  $\mu$ , which is at most  $F_N(e_0, \mu)$ . This remains true after restricting its memory or architecture.  $\square$

The minimization in (13) occurs once, outside the recursion. It cannot be replaced by fresh adversarial choices after observations. The posterior carries dependence on one fixed unknown parameter. Also, a Bayes-optimal tree for a minimizing prior need not by itself be a minimax policy; the saddle-point mixture is supplied by the finite game in the proof.

**Corollary 6.2** (Bellman upper certificates). *Suppose functions  $\Psi_n(e, \nu)$  satisfy  $\Psi_0 \geq \Phi$  and, for  $n \geq 1$ , satisfy*

$$\Psi_n(e, \nu) \geq \Phi_e(\nu), \quad \Psi_n(e, \nu) \geq \sum_x \Psi_{n-1}(T(e, a, x), \nu_{a,x}) \quad (a \in \mathcal{A}_e).$$

*Then  $\Psi_N(e_0, \mu)$  is an upper certificate for every admissible architecture and every prior  $\mu$ . The family  $F_n$  is the least such family. An optimal prior can be chosen with at most  $d + 1$  support points, where  $d$  is the affine dimension of  $\{(g_{\pi}(\theta))_{\pi \in \Pi_N} : \theta \in \Theta\}$ .*

*Proof.* Induction in (12) gives  $F_n \leq \Psi_n$ . The equality case is the recursion itself. The objective depends on a prior only through its vector of integrals of the finitely many  $g_{\pi}$ . An optimal such vector belongs to the convex hull of their compact evaluation image. Carathéodory's theorem gives the stated support bound while preserving every pure-tree payoff.  $\square$

**Proposition 6.3** (Causal stability). *Consider two models with the same protocol, alphabets and policy class. Suppose their training rows differ uniformly in total variation by at most  $\epsilon$ , their candidate validation rows by at most  $\eta$ , and their target validation rows by at most  $\beta$ . Their unrestricted values, or their values in any common specified memory class, differ by at most  $2N\epsilon + \eta + \beta$ .*

*Proof.* Use the same policy randomization and couple corresponding training rows while the histories agree. The probability of a first discrepancy is at most  $N\epsilon$ , even with feedback and stopping. Conditional expected validation rewards lie in  $[-1, 1]$ , so differing training histories contribute at most  $2N\epsilon$ . On agreeing histories the same frozen design and event are used, and their conditional mean rewards differ by at most  $\eta + \beta$ . The bound is uniform in the fixed parameter and in the policy. Taking minima and suprema preserves it, with the reverse inequality obtained by interchanging the models.  $\square$

**6.1. An informative action choice.** The following calculation distinguishes the controlled theorem from a common-row reduction. Let  $\Theta = \{(i, j) : i, j \in \{0, 1\}\}$ . Action  $R$  reports  $i$ . Action  $L$  reports  $j$  when  $i = 0$  and otherwise reports an independent fair bit. Action  $H$  reports  $j$  when  $i = 1$  and otherwise reports an independent fair bit. The candidate validation is  $\delta_{(i,j)}$  and the target is uniform on  $\Theta$ .

**Proposition 6.4** (Strict adaptive advantage). *With two training preparations, the unrestricted adaptive value is  $3/4$  and the best nonadaptive value is  $5/8$ . Nonadaptive policies here include mixtures of schedules, with their random schedule retained. No available single training action dominates all the others.*

*Proof.* Take  $R$  first, and then  $L$  or  $H$  according to the observed  $i$ . The parameter is recovered exactly. The complement of its validation atom has score  $3/4$ . No policy can exceed  $\text{TV}(Q, \delta_\theta) = 3/4$  even with full information.

For the converse for fixed schedules, use the uniform prior. For a pair of actions  $a, b$  its Bayes value is explicitly

$$(14) \quad \sum_{x,y,\theta} \left[ \frac{1}{16} \sum_{\vartheta} P_{\vartheta}^a(x) P_{\vartheta}^b(y) - \frac{1}{4} P_{\theta}^a(x) P_{\theta}^b(y) \right]_+.$$

Substitution of the three displayed kernels gives

|     | $R$   | $L$    | $H$    |
|-----|-------|--------|--------|
| $R$ | $1/2$ | $5/8$  | $5/8$  |
| $L$ | $5/8$ | $7/16$ | $1/2$  |
| $H$ | $5/8$ | $1/2$  | $7/16$ |

This is an exact finite sum, not a parameter-grid estimate. It bounds any mixture of fixed schedules by  $5/8$ ; an early stop can be padded with an ignored observation. To attain the bound uniformly in  $\theta$ , choose with equal probabilities the schedules  $(R, L)$  and  $(R, H)$ . When the chosen branch-specific action matches  $i$ , the parameter is known and the score is  $3/4$ . Otherwise only  $i$  is known, and the complement of its two-atom fiber gives score  $1/2$ . Each fixed parameter therefore has mean score  $5/8$ .

Action  $R$  cannot distinguish parameters differing only in  $j$ . Action  $L$  cannot distinguish  $(1, 0)$  and  $(1, 1)$ , and  $H$  cannot distinguish  $(0, 0)$  and  $(0, 1)$ . An experiment which fails to distinguish such a pair cannot garble to one that distinguishes it. Hence no action is a common dominating row.  $\square$

If every binary report is additionally passed through an independent binary symmetric channel of crossover  $\epsilon$ , the primitive training rows change by at most  $\epsilon$  and have full support for  $0 < \epsilon < 1/2$ . Proposition 6.3, applied to both policy classes, leaves an adaptive advantage at least  $1/8 - 8\epsilon$ , which is positive for  $0 < \epsilon < 1/64$ . Thus the distinction is not confined to disjoint observation supports. The finite-horizon belief recursion and its piecewise-linear structure are classical [1]. The contribution here is their explicit integration with the frozen validation score, one fixed adversarial parameter, outer certificates, and the resource conventions; no priority for Bellman recursion itself is claimed.

## 7. CONTROLLED EXPERIMENTS AT A PRESCRIBED MEMORY PROFILE

An unrestricted posterior is a useful information state for a proof, but it is not a free runtime state. We first give a resource-exact dynamic formulation and then solve a controlled family in which replacing that formulation by a policy-tree mixture changes the value strictly.

**7.1. A parameterwise occupation state.** Fix a finite horizon  $T$ , a compact metric parameter space  $\Theta$ , finite hidden execution spaces  $H_t$ , and register alphabets  $S_t$  of sizes at most  $K_t$ . The visible inputs to each stochastic row and all legal actions are specified. Any input that must survive a cut belongs to  $S_t$ : this includes a chosen action, an unread report buffer, a stop flag, a selected validation event and a validation accumulator. One may subdivide an operation into several cuts to expose these costs. The scheduled time is available only in the clocked convention.

For now rows at different scheduled times are independently prescribed. Let  $\mathcal{Q}_t$  be the finite product of legal row simplices at stage  $t$ . A prescription  $q \in \mathcal{Q}_t$  is a table, chosen at design time, whose runtime arguments are exactly the declared visible inputs. After summing the fixed environmental kernels its one-stage transition is a stochastic matrix  $M_{t,\theta}^q$  on the hidden-state/register pairs. We assume this matrix is jointly continuous in  $(q, \theta)$ . Both action selection and state updating occur in this matrix, in their specified causal order; it is not an arbitrary matrix chosen separately for each hidden state or each parameter.

For a continuous bundle of probability vectors  $x = (x_\theta(h, s))_{\theta \in \Theta}$  define

$$(\mathcal{T}_{t,q}x)_\theta(h', s') = \sum_{h,s} x_\theta(h, s) M_{t,\theta}^q((h, s), (h', s')).$$

The initial bundle  $x_0$  is fixed by preparation. Terminal rewards  $r_\theta(h, s) \in [-1, 1]$  are continuous in  $\theta$ . Absorbing stopped states and frozen validation phases are included in this execution, not added afterwards without charge. Put

$$(15) \quad B_T(x) = \min_{\theta \in \Theta} \sum_{h,s} x_\theta(h, s) r_\theta(h, s),$$

$$(16) \quad B_t(x) = \max_{q \in \mathcal{Q}_t} B_{t+1}(\mathcal{T}_{t,q}x), \quad 0 \leq t < T.$$

The argument  $x$  is an *offline occupation bundle*, not the realized history, not an observed parameter, and not an additional register made available to the machine.

**Theorem 7.1** (Resource-exact dynamic value and supersolutions). *For the specified clocked profile and observable-row interface,  $B_0(x_0)$  is the exact maximum worst-case reward over all stochastic controllers. The maximum is attained by a sequence of legal common prescriptions. With the norm  $\|x - x'\| = \sup_\theta \sum_{h,s} |x_\theta(h, s) - x'_\theta(h, s)|$ , each  $B_t$  is 1-Lipschitz. Moreover,*

$$(17) \quad B_0(x_0) = \inf_H H_0(x_0),$$

where the infimum ranges over families of functions on occupation bundles satisfying

$$H_T \geq B_T, \quad H_t(x) \geq H_{t+1}(\mathcal{T}_{t,q}x) \quad (q \in \mathcal{Q}_t).$$

The infimum is attained by  $H = B$ . No convexification over retained controllers and no new adversarial choice after a report occurs in these identities.

*Proof.* For a fixed sequence  $q_0, \dots, q_{T-1}$ , iteration of the displayed transition gives its actual terminal law for every fixed  $\theta$ . The terminal minimum is therefore exactly its worst-case reward. A runtime randomized controller in this interface is precisely such a sequence of common conditional rows; independence of fresh randomization and the declared register specify all its conditional choices. Persistent random correlations are allowed only through that register.

The occupation bundle at the next stage is determined by the current bundle and the prescription, without drawing a realized history in the design problem. Hence optimizing over the remaining prescription sequence gives (16) by ordinary backward induction. This does not select a different continuation for each unrecorded history. Each maximizing  $q$  is still a single legal table common to all hidden histories and parameters. At  $x_0$  one follows the maximizing sequence of design prescriptions, computing their occupation bundles offline; the runtime controller only reads its allowed inputs.

Stochastic matrices contract the  $\ell^1$  norm. The terminal minimum is 1-Lipschitz in the displayed norm. Induction, using the same  $q$  when comparing two bundles and then taking the two maxima, proves the Lipschitz assertion. Joint continuity and compactness of  $\mathcal{Q}_t$  give attainment at each stage, and compactness of  $\Theta$  gives the terminal minimum. Any family  $H$

in (17) bounds the terminal reward along every prescription sequence. Backward induction therefore gives  $H_t \geq B_t$ . Equality is admissible, proving (17) and its attainment.  $\square$

This is a nonlinear supersolution dual, not a least-favorable-prior saddle theorem at fixed width. Its optimization can be large and nonconvex. The principle of dynamic programming is classical; the point of this formulation is that the common-row and memory constraints remain in the maximizations. If rows are shared across scheduled times, as for an autonomous controller, choose the shared rows once and hold them fixed in all subsequent transitions; equivalently augment the *design* problem by that immutable prescription. Maximizing a shared row anew at each time would solve a different problem. A finite union of allowed interfaces can be handled by taking their maximum, or by a fully wired interface with the prescribed profile and its legal observable inputs. Neither operation enlarges a runtime register invisibly.

**7.2. An exact informative-control bottleneck.** Fix integers  $m \geq 2$  and  $1 \leq K \leq m$ . The fixed parameter is  $\theta = (i, j) \in [m] \times \{0, 1\}$ . The first training experiment  $R$  reports  $i$ . Across the next cut the controller retains at most  $K$  labels, with an arbitrary stochastic encoder  $E(s | i)$ . It then chooses one of the  $m$  sensing actions with probabilities  $D(a | s)$ . The selected action is kept in a charged  $m$ -state action buffer and the old label is discarded. Action  $a$  reports  $j$  when  $a = i$  and reports  $\perp$  otherwise. The first report is no longer available.

The candidate validation law on  $\{0, 1\}$  is  $\delta_j$ ; the target is uniform. An event is frozen before one fresh candidate and one fresh target validation. Stopping before either training action is permitted. No independent persistent selector is given to the controller. The observation symbols are atomic; a bitwise input implementation would have additional cuts. Denote the maximum worst-case score by  $V_{m,K}$ .

**Theorem 7.2** (Exact finite-memory control and its convexification gap). *In this protocol,*

$$(18) \quad V_{m,K} = \frac{1}{2 \lceil m/K \rceil}.$$

*The value obtained by allowing an uncharged ex ante mixture of complete  $K$ -label controllers is instead*

$$(19) \quad \bar{V}_{m,K} = \frac{K}{2m}.$$

*The inequality is strict whenever  $K$  does not divide  $m$ . The matching controller for (18) has charged cut profile bounded by  $(1, K, m, 3, 6, 3)$ . The  $K$ -label cut controls both retention of the routing observation and the subsequent informative action choice.*

*Proof.* For a fixed  $i$ , let

$$p_i = \sum_s E(s | i) D(i | s).$$

This is the probability of taking the informative action. On its complement, all retained information is independent of  $j$ . Averaging over the two values of  $j$  makes the expected validation score zero there, for any frozen event or randomized response. On the informative part the score is at most  $\text{TV}(\text{Ber}(1/2), \delta_j) = 1/2$ . Thus the minimum over  $j$  at a given  $i$  is at most  $p_i/2$ . A stop before sensing is also uninformative about  $j$  and obeys the same bound; it can be padded by an ignored sensing operation.

Set  $L = \lceil m/K \rceil$ . Since  $p_i \leq \max_s D(i | s)$ , a value  $\min_i p_i > 1/L$  would require every  $i$  to have some row  $s$  with  $D(i | s) > 1/L$ . Each stochastic row has at most  $L - 1$  such indices. But  $K(L - 1) < m$ . This contradiction proves the upper bound. Partition  $[m]$  into at most  $K$  fibers of size at most  $L$ , retain the fiber label after  $R$ , and choose uniformly inside that fiber. On a successful report freeze  $\{1\}$  when  $j = 0$  and  $\{0\}$  when  $j = 1$ ; on  $\perp$  freeze the empty event. The

score for every  $j$  is  $1/(2|\text{fiber}(i)|)$ , proving equality. The event alphabet has three labels. Storing the event and its candidate indicator requires at most six labels, and the final difference has three. The chosen sensing action was separately charged, proving the displayed profile.

For the convexified upper bound use the uniform prior on  $(i, j)$ . For any one controller,

$$\frac{1}{m} \sum_i p_i = \frac{1}{m} \sum_{i,s} E(s | i) D(i | s) \leq \frac{1}{m} \sum_{i,s} D(i | s) = \frac{K}{m}.$$

The same upper bound holds for mixtures. For the matching mixture, choose uniformly one of the  $m$  cyclic intervals of  $K$  indices. For that interval hardcode a deterministic  $K$ -label encoder which routes each included index to its own sensing action, and assigns other indices arbitrarily. Each  $i$  belongs to exactly  $K$  intervals. A successful action is followed by the complementary singleton event and failure by the empty event, as above. Every fixed  $(i, j)$  has mean score  $K/(2m)$ . This proves (19).  $\square$

For example,  $V_{3,2} = 1/4$  whereas  $\bar{V}_{3,2} = 1/3$ . The mixture just constructed can be implemented with a retained interval selector and a local label, using at most  $mK$  labels at the bottleneck. It cannot be declared a  $K$ -label realization: when the displayed gap is positive, (18) proves that no such realization exists. The action buffer of size  $m$  is not part of the  $K$  coordinate and has not been omitted from the profile. The theorem is a multicut resource law, not an assertion that its uniform peak equals  $K$ .

The actions are statistically incomparable.  $R$  cannot distinguish the two values of  $j$  at any fixed  $i$ , while action  $a$  does distinguish them at  $i = a$ . For  $a \neq b$ , action  $a$  does not distinguish the pair with  $i = b$ , while  $b$  does. A parameter-independent garbling cannot create a distinction absent from its input experiment.

**Corollary 7.3** (A strict gap with positive report probabilities). *Replace each of the two training kernels by a mixture with weight  $\epsilon > 0$  of the uniform law on its report alphabet. Let  $\Delta_{m,K} = K/(2m) - 1/(2\lceil m/K \rceil) > 0$ . For  $\epsilon < \Delta_{m,K}/8$  the resulting full-support model still has a strict gap between the genuine profile-constrained value and its free-selector convexification.*

*Proof.* Each training row changes by at most  $\epsilon$  in total variation. Couple corresponding rows until the first disagreement. For any fixed controller or mixed controller the probability of such a disagreement is at most  $2\epsilon$ , and its conditional reward lies in  $[-1, 1]$ . Each of the two optimal values changes by at most  $4\epsilon$ . Their difference is therefore at least  $\Delta_{m,K} - 8\epsilon > 0$ . All row arguments and register alphabets are unchanged.  $\square$

The distinction between mixed and behavioral strategies without perfect recall is classical; it is not first asserted here. Contemporary polynomial formulations over behavioral simplices include [16]. Theorem 7.2 evaluates the discrepancy in this specific frozen-validation experiment for every  $m, K$ , with a matching actual register and a noisy persistence statement. In particular, a single prior followed by an unrestricted policy-tree best response cannot be substituted for (16).

## 8. SADDLE FACES AND CAUSAL REALIZATION

The statistical saddle and its implementation are different objects. The former is convex; the latter need not be. The purpose of this section is to retain that distinction while extracting memory obstructions from an unrestricted saddle. In particular, a zero Bayes coefficient must not be discarded before the contact conditions at the worst parameters have been imposed.

**8.1. A normal form over a finite causal interface.** Fix a finite horizon and finite action and report alphabets. An action  $a_t$  is chosen before report  $y_t$ . A terminal output is included as one last action, followed by a dummy report. Illegal actions can be removed from each protocol type; equivalently, use a fixed padding of the finite protocol tree and impose its zero constraints. Define a *causal response array*  $C(\mathbf{a} \mid \mathbf{y})$  by nonnegativity, normalization in  $\mathbf{a}$  for every  $\mathbf{y}$ , and the requirement that its marginal on  $a_1, \dots, a_t$  depends only on  $y_1, \dots, y_{t-1}$ . The resulting set  $\mathcal{C}$  is a finite polytope. Conditioning successive marginals realizes every such array by a full-history randomized controller; arbitrary versions on zero marginals do not change the array.

For a fixed parameter  $\theta$ , the environment has a history-dependent likelihood  $L_\theta(\mathbf{a}, \mathbf{y})$ , obtained by marginalizing its hidden states. The bounded reward has the linear form

$$(20) \quad g_\theta(C) = \sum_{\mathbf{a}, \mathbf{y}} L_\theta(\mathbf{a}, \mathbf{y}) r_\theta(\mathbf{a}, \mathbf{y}) C(\mathbf{a} \mid \mathbf{y}).$$

Assume its coefficient vector is continuous on a compact metric parameter space. The parameter is fixed once, not selected after a report. Protocol-specific equalities, including a frozen validation choice, are represented by the corresponding finite protocol tree. A discarded protocol choice is not supplied again as a free input.

Here is an explicit positive realization of a response array. At cut  $t$  use  $k_t$  states, an initial distribution  $\alpha$ , and nonnegative matrices  $M_t^{a,y}$  of size  $k_{t-1}$  by  $k_t$  such that

$$(21) \quad M_t^{a,y} \mathbf{1} = p_t(a), \quad \sum_a p_t(a) = \mathbf{1}, \quad p_t(a) \text{ is independent of } y.$$

Then

$$(22) \quad C(\mathbf{a} \mid \mathbf{y}) = \alpha M_1^{a_1, y_1} \dots M_T^{a_T, y_T} \mathbf{1}.$$

The independence in (21) is essential: otherwise an action could use its not-yet-observed report. If an action or an input must survive an intermediate cut, split this formula at that cut and include its buffer in the state alphabet. Likewise, impose any declared shared-row constraints before optimizing. An externally fixed clock permits time-dependent matrices; an autonomous implementation has to store its phase or use the prescribed shared rows.

**Proposition 8.1** (Outer normal form and compatible continuations). *For the finite interface and declared cuts, the response arrays of all controllers with profile at most  $\mathbf{K}$  are exactly the arrays (22) with  $k_t \leq K_t$ , the normalization (21), and the declared interface constraints. This set, denoted  $\mathcal{C}_{\mathbf{K}}$ , is compact. The assertion is over all wirings of the allowed register, not one chosen transition graph.*

*Equivalently, there are at most  $K_t$  normalized continuation arrays  $B_{t,s}$  at each cut, with terminal continuation 1, and common nonnegative coefficients satisfying*

$$(23) \quad B_{t-1,s}(a\mathbf{a} \mid y\mathbf{y}) = \sum_{s'} M_t^{a,y}(s, s') B_{t,s'}(\mathbf{a} \mid \mathbf{y}), \quad C = \sum_s \alpha(s) B_{0,s}.$$

*Separate positive factorizations at the cuts are not sufficient without these common shift identities.*

*Proof.* In a controller, let  $p_t(a \mid s)$  be its action row and  $q_t(s' \mid s, a, y)$  its update row. Their product defines  $M_t^{a,y}$  and gives (21). Multiplication over a complete execution gives (22). Every finite wiring embeds into the fully connected register by assigning zero to unused transitions; smaller alphabets are padded by unused states. Thus no further maximization over graph presentations is necessary.

Conversely choose action  $a$  with probability  $p_t(a \mid s)$ , and, after observing  $y$ , use the row  $M_t^{a,y}(s, s')/p_t(a \mid s)$  when the denominator is positive. At a zero denominator the entire corresponding nonnegative row vanishes; choose an arbitrary legal update there. This gives

exactly the required runtime arguments. It does not expose a posterior, the parameter, or an offline occupation array to the machine. Apply the same construction at each declared buffer cut. A product of finitely many stochastic row simplices is compact; closed legality and sharing constraints preserve compactness. Its continuous image is  $\mathcal{C}_{\mathbf{K}}$ .

The future execution starting at a state  $s$  defines  $B_{t,s}$  and satisfies (23). Conversely, induction from the terminal continuation and these identities gives the product formula. Thus the continuation description has exactly the same realizations. In particular, independently selected factorizations at different cuts cannot be spliced unless the shift equations hold.  $\square$

This is a finite controlled positive-realization statement. The role of positivity and invariant generating cones in stochastic realization is classical [17, 18, 19]. Ordinary linear rank need not be a state count. Here the additional statistical question is which positive realizations meet an optimal saddle face. Proposition 8.1 provides a normal form, not an efficient factorization algorithm. It also does not compactify an unbounded number of observable operations.

**8.2. The realization theorem.** Let

$$U = \max_{C \in \mathcal{C}} \min_{\theta} g_{\theta}(C), \quad V_{\mathbf{K}} = \max_{C \in \mathcal{C}_{\mathbf{K}}} \min_{\theta} g_{\theta}(C).$$

By compact convex minimax there is a least-favorable prior  $\mu_*$  with  $U = \max_{C \in \mathcal{C}} \int g_{\theta}(C) d\mu_*$ . Put

$$\begin{aligned} \ell_*(C) &= \int g_{\theta}(C) d\mu_*, \\ F_* &= \{C \in \mathcal{C} : \ell_*(C) = U\}, \\ \mathcal{S}_* &= F_* \cap \bigcap_{\theta} \{C : g_{\theta}(C) \geq U\}. \end{aligned} \tag{24}$$

The set  $F_*$  is an exposed face. The second intersection is important: a Bayes best response to a least-favorable prior need not be minimax.

Here  $\mathcal{C}$  is the full-history convex reference for the finite protocol. A nonconvex restriction, such as reuse of one stochastic table at several visits, is imposed on  $\mathcal{C}_{\mathbf{K}}$ , not inserted into  $\mathcal{C}$  before invoking convex minimax. In that case  $U$  is a reference upper value unless exactness for the unrestricted physical class is separately known. In the reset applications below that exactness is supplied by Theorems 5.1 and 5.2.

**Theorem 8.2** (Saddle-face realization and exact resource loss). *Under the preceding assumptions, the constrained outer value satisfies*

$$U - V_{\mathbf{K}} = \min_{C \in \mathcal{C}_{\mathbf{K}}} \left\{ U - \ell_*(C) + \ell_*(C) - \min_{\theta} g_{\theta}(C) \right\}. \tag{25}$$

*Both summands are nonnegative. Consequently  $V_{\mathbf{K}} = U$  if and only if some array in  $\mathcal{S}_*$  has compatible positive continuation generators of profile at most  $\mathbf{K}$ . If no such generators exist,  $V_{\mathbf{K}} < U$  strictly.*

*For  $C \in \mathcal{S}_*$  one has  $g_{\theta}(C) = U$  on  $\text{supp } \mu_*$ . At an interior supporting parameter at which the payoff is differentiable,  $\nabla_{\theta} g_{\theta}(C) = 0$ . These equalities and stationarity conditions hold also in directions whose Bayes coefficient vanishes.*

*At any reset continuation cut, let  $R_h$  denote the conditional channel of future outputs under each externally specified future input word. It factors as*

$$R_h = \sum_{s=1}^{K_t} E(s \mid h) B_s, \quad E(\cdot \mid h) \in \Delta_{K_t}, \tag{26}$$

with one common family of continuation channels  $B_s$ . Any obstruction to this positive factorization for every member of  $\mathcal{S}_*$  is therefore a memory obstruction for every admissible architecture, regardless of its training wiring.

*Proof.* For every  $C$ , its prior average is at most  $U$  and at least its minimum over fixed parameters. The expression in braces in (25) is identically  $U - \min_{\theta} g_{\theta}(C)$ . Taking its minimum over the compact set  $\mathcal{C}_{\mathbf{K}}$  proves the identity and attainment. Its two nonnegative summands vanish exactly when  $C$  belongs to  $\mathcal{S}_*$ . Proposition 8.1 then proves the realization criterion. Compactness makes nonintersection a strictly positive value loss, not merely failure of one optimizer.

For an optimal array,  $g_{\theta}(C) - U$  is continuous, nonnegative, and has zero  $\mu_*$  integral. It is zero on the support of that measure. Every interior zero is a local minimum, so its gradient vanishes. No strict-sign hypothesis on individual coordinates is needed. Finally condition on the actual retained state at a reset cut. Given that state, the future program receives the same specified inputs and has the same output law, irrespective of the discarded past. Averaging gives (26). All persistent random variables are part of that state. The assertion can equivalently be checked on controller input tapes, using the generators in (23); it does not assume that a hidden physical state resets at a cut where the interface has not reset it.  $\square$

The identity (25) is an exact loss decomposition, not a new interchange of a minimum and maximum over nonconvex machines. Its use is that an unrestricted certificate identifies a finite face, while contact at its supporting parameters can determine the remaining coordinates. The resulting channels are then tested for causal realizability. This is stronger than choosing an arbitrary Bayes tie rule and counting the states of that one rule.

**Corollary 8.3** (Explicit coefficient form for frozen validation). *In the reset experiment of (8), write*

$$C_{z\omega}^* = \int P_{\theta}^{\otimes N}(z)(Q(\omega) - P_{\theta}(\omega)) d\mu_*(\theta).$$

The first summand of (25) is exactly

$$(27) \quad \sum_{C_{z\omega}^* > 0} C_{z\omega}^* (1 - h_z(\omega)) + \sum_{C_{z\omega}^* < 0} |C_{z\omega}^*| h_z(\omega).$$

Thus optimality fixes every strict-sign coordinate, while the support contact and stationarity equations must still be imposed at the zeros. For  $K$  labels at the post-training decision cut, an arbitrary upstream encoder gives the compact relaxation

$$(28) \quad h_z(\omega) = \sum_{s=1}^K E(s | z) D_s(\omega), \quad E \in (\Delta_K)^{\Omega^N}, \quad D_s \in [0, 1]^{\Omega}.$$

If this relaxation misses the saddle set, its strictly positive gap bounds every smaller architectural class.

*Proof.* Maximizing each coefficient separately gives the sum of its positive part. Subtraction gives (27). Conditioning on the decision state gives (28); the post-cut randomization is independent of the discarded word. Conversely an arbitrary encoder and a response list realize this factorization when other memory is unrestricted. The parameter spaces in (28) are compact, so the final assertion follows from Theorem 8.2.  $\square$

**8.3. Faces as memory witnesses.** For a finite input set  $\mathcal{Y}$  and output alphabet  $\mathcal{D}$ , continuation channels form the polytope  $\mathcal{P} = \prod_{y \in \mathcal{Y}} \Delta(\mathcal{D})$ . Its vertices are deterministic output functions. The analogous polytope for scalar test responses is  $[0, 1]^{\mathcal{Y}}$ .

**Lemma 8.4** (Vertex and face packing). *Suppose channels to be factored through one common state alphabet include  $s$  distinct vertices  $v_1, \dots, v_s$  of a polytope  $\mathcal{P}$  and rows  $r_1, \dots, r_j$ . Suppose  $r_i \in F_i$ , the faces  $F_i$  are pairwise disjoint, and*

$$r_i \notin \text{conv}\{v_a : v_a \in F_i\}.$$

*Every factorization of these rows as stochastic mixtures of generators in  $\mathcal{P}$  needs at least  $s + j$  generators.*

*Proof.* A convex decomposition of a vertex uses that same vertex at every positive coefficient. Hence all  $s$  vertices must occur among the generators. If a convex combination belongs to a face, all generators with positive coefficients belong to that face. The stated exclusion therefore forces an additional generator in each  $F_i$ . Pairwise disjointness prevents any such generator from serving two faces.  $\square$

The lemma does not assert that a stochastic state must itself be a history residual. Its generator can be any channel in the ambient polytope. This is why the argument also excludes randomized encoders and randomized continuations. It is a positive-factorization argument, not ordinary matrix rank or a restriction to a deterministic compiler.

**Proposition 8.5** (Resource equivalence and stable obstructions). *A causal, cut-preserving recoding with a causal inverse, both using only one transducer state and preserving the payoff, preserves every  $V_{\mathbf{K}}$ ,  $U$ , and the set of profiles attaining  $U$ . More generally suppose simulations in both directions have defect at most  $\epsilon$  and require at most  $R_t$  states at cut  $t$ . For rewards in  $[-1, 1]$ ,*

$$V_{\epsilon}(\mathbf{RK}) \geq V_{\mathfrak{F}}(\mathbf{K}) - 2\epsilon, \quad V_{\mathfrak{F}}(\mathbf{RK}) \geq V_{\epsilon}(\mathbf{K}) - 2\epsilon.$$

*For a common controller class and training-validation kernels whose values differ by at most  $\eta$ , a gap  $U - V_{\mathbf{K}} = \delta$  remains at least  $\delta - 2\eta$  after the perturbation.*

*Proof.* Transport a controller through each simulator and retain the product of its state and the simulator state. Apply the uniform bounded-reward variation bound and optimize. With an exact one-state inverse the two inequalities are equalities at the same profile. In the last assertion both the unrestricted and the constrained optimum change by at most  $\eta$ ; subtract their two bounds. The state products must be applied at the actual buffer cuts, not only at the terminal decision.  $\square$

These statements place the saddle face, the future-test quotient, and resource-aware causal morphisms in one theorem chain. The channel factorizations are presentation-independent under the stated causal recodings. The memory obstruction in the next section is derived from the experimental coefficients themselves, not from a metric dimension or a covering exponent supplied as an additional hypothesis.

## 9. EXACT MINIMAX LAWS FOR A MARKED PRODUCT FAMILY

The posterior-predictive dual can be solved explicitly for a continuous family containing the collision target. Throughout this section, the training and candidate validation law is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

In the order 000, 001, 110, 111, let  $Q_{\gamma}$  have masses

$$((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4),$$

and zero mass elsewhere. Write  $U_1(\gamma) = U_1(b, Q_\gamma)$ , with exactly the training-validation convention of (8). Set

$$(29) \quad \gamma_* = 1 - 1/\sqrt{2}, \quad s_\gamma = \sqrt{\gamma^2 - 2\gamma + 5}, \quad u_\gamma = \gamma - 2 + s_\gamma, \quad \tau_\gamma = \frac{2u_\gamma}{u_\gamma + 2 - \gamma}.$$

**Theorem 9.1** (Exact marked minimax family). *For every  $0 \leq \gamma \leq \gamma_*$ ,*

$$(30) \quad U_1(\gamma) = \frac{3 + u_\gamma^2}{8}.$$

*An optimal response depends on the training word only through the report count  $K = X_1 + X_2$ . On the four target atoms its rows are*

$$(31) \quad h_0 = (\tau_\gamma, 0, 1, 1), \quad h_1 = (1, 1, 1, 1), \quad h_2 = (1, 1, 0, \tau_\gamma),$$

*and all responses are zero off these atoms. A least-favorable prior is*

$$(32) \quad \mu_\gamma = \frac{1}{2}\delta_{(t_\gamma, t_\gamma)} + \frac{1}{2}\delta_{(1-t_\gamma, 1-t_\gamma)}, \quad t_\gamma = \frac{1 - \sqrt{u_\gamma}}{2}.$$

*The assertion optimizes over all stochastic responses to the full marked training word, not merely over count-based or symmetric responses.*

*Proof.* First,  $u_\gamma$  is the positive root of

$$(33) \quad u^2 + (4 - 2\gamma)u - (1 + 2\gamma) = 0.$$

On the asserted interval,  $0 < u_\gamma < 1$  and  $0 < \tau_\gamma < 1$ . Indeed the polynomial is negative at zero and positive at one; also  $u_\gamma < 2 - \gamma$  because  $\gamma < 1/2$ . Substitution of  $1 - 2\gamma$  into the polynomial gives  $8(\gamma^2 - 2\gamma + 1/2)$ , which is nonnegative precisely on the present interval. Monotonicity on  $[0, \infty)$  therefore gives

$$(34) \quad u_\gamma \leq 1 - 2\gamma.$$

Put  $a = (1 - p)(1 - q)$ ,  $c = pq$ , and  $z = 1 - a - c$ . The probabilities of the three training counts are  $a, z, c$ . The independent training mark may be discarded by the displayed construction. Let  $G_\gamma(p, q)$  denote its score. With  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ , direct expansion gives

$$(35) \quad G_\gamma(p, q) - \frac{3 + u_\gamma^2}{8} = \frac{2 - \tau_\gamma}{16} \{(u - v - u_\gamma)^2 + 4v\}.$$

For clarity, this identity follows by substituting the three rows of (31) into

$$a(Q_\gamma - b)h_0 + z(Q_\gamma - b)h_1 + c(Q_\gamma - b)h_2,$$

using  $a + c = (1 + u - v)/2$ ,  $a - c = -(p + q - 1)$ , and then eliminating  $u_\gamma^2$  by (33). The coefficient of the resulting square is  $(2 - \tau_\gamma)/16$  and that of  $v$  is four times this coefficient. Both are nonnegative. Equality holds at both points of (32), since there  $v = 0$  and  $u = u_\gamma$ . This proves the lower bound and identifies its equality set.

It remains to bound every response, including nonsymmetric ones. Use (32) in Theorem 5.1. At  $t = t_\gamma$  put  $a = (1 - t)^2$ ,  $c = t^2$ , and  $T = a + c = (1 + u_\gamma)/2$ . For the training report pair 00, the four dual coefficients, apart from a common positive factor, are

$$(36) \quad \left( Q_H T - \frac{a^2 + c^2}{2}, \quad Q_L T - \frac{a^2 + c^2}{2}, \quad Q_L T - ac, \quad Q_H T - ac \right),$$

where  $Q_H = (1 + \gamma)/4$  and  $Q_L = (1 - \gamma)/4$ . The first coordinate is zero by (33); the second is  $-\gamma T/2 \leq 0$ . The last two are positive:  $T \geq 1/2$ ,  $ac \leq 1/16$ , and  $\gamma < 1/2$  imply  $Q_L T > 1/16 \geq ac$ . Thus  $(\tau_\gamma, 0, 1, 1)$  maximizes this linear functional. For the training pair 11, reversing all report bits and the mark reverses the four coordinates and gives the row  $h_2$ .

For either training pair 01 or 10, the two prior support points have the same likelihood  $t(1-t)$ . The posterior is still equally weighted, and the candidate predictive mass at each target atom is  $T/4$ . Every one of the four coefficients is therefore nonnegative by  $Q_L - T/4 = (1 - 2\gamma - u_\gamma)/8 \geq 0$ . The response  $h_1$  is optimal. At off-diagonal validation atoms the target mass vanishes and the coefficient is nonpositive. Finally, conditioning on either training mark multiplies all these coefficients by  $1/2$ ; it creates no further optimizing choice. We have therefore optimized every coordinate of the full marked-word response space.

The prior average of the displayed response equals its value at either support point, namely  $(3 + u_\gamma^2)/8$ , by (35). Every other response has prior average at most this number and hence has minimum over fixed  $(p, q)$  at most this number. Together with the lower bound this proves (30), optimality of the response, and least favorability of the prior.  $\square$

**Corollary 9.2** (The exact one-preparation collision value). *For  $Q_* = Q_{1/4}$ ,*

$$(37) \quad U_1(b, Q_*) = u_{\text{ex}} := \frac{85 - 7\sqrt{73}}{64}, \quad u_{1/4} = \frac{\sqrt{73} - 7}{4}, \quad \tau_{1/4} = 2 - \frac{14}{\sqrt{73}}.$$

*If only the target changes to  $Q$ , then  $|U_1(b, Q) - u_{\text{ex}}| \leq \text{TV}(Q, Q_*)$ .*

*Proof.* Substitute  $\gamma = 1/4$  in Theorem 9.1. For a fixed trained response the target perturbation is at most total variation, uniformly in  $(p, q)$ . Taking first the minimum and then the maximum preserves this bound in both directions.  $\square$

**9.1. Complementary slackness and the event alphabet.** The tie in the first coordinate of (36) explains the randomization. Any value of that response coordinate is Bayes-optimal for the two-point prior. The minimax choice makes the uniform payoff stationary at its two support points; solving this condition gives  $\tau_\gamma$  and the square identity (35). This derives the prior and response together, rather than postulating that a numerically effective prior is optimal.

Operationally, for  $K = 0$  one draws once between the events with indicator vectors  $(0, 0, 1, 1)$  and  $(1, 0, 1, 1)$ , with probabilities  $1 - \tau_\gamma$  and  $\tau_\gamma$ . For  $K = 2$  one draws between  $(1, 1, 0, 0)$  and  $(1, 1, 0, 1)$ . For  $K = 1$  the event is  $(1, 1, 1, 1)$ . The resulting event identity is retained and used for both fresh validations. These are exactly the five events in the two-preparation construction below. The one-preparation theorem supplies their complementary-slackness interpretation; it does not prove that the two-preparation selector is optimal. The four-point rational prior retained below is a useful rational certificate, not a least-favorable prior.

The exact response uses an atomic stochastic row. It does not receive free persistent randomness. Replacing  $\tau_\gamma$  by a dyadic number within  $2^{-b}$  changes each conditional response, and hence the score, by at most  $2^{-b}$ . A sequential fair-bit implementation must retain its bit prefix and event identity. None of these implementation costs is needed by the deterministic two-preparation physical audit.

**Proposition 9.3** (The zero-preparation endpoint). *For  $0 \leq \gamma \leq 1$ ,  $U_0(b, Q_\gamma) = \gamma/2$ .*

*Proof.* The fixed event  $\{000, 111\}$  has score  $(1 + \gamma)/2 - (a + c)/2 \geq \gamma/2$  because  $a + c \leq 1$ . Conversely, the equally weighted prior on  $b(0, 0)$  and  $b(1, 1)$  has predictive validation law uniform on the four target atoms. Its total variation from  $Q_\gamma$  is  $\gamma/2$ . Theorem 5.1 with  $N = 0$  gives the matching upper bound.  $\square$

## 10. A SELF-CONTAINED COLLISION INTERFACE

We give the preparation, mechanical estimate, observation law and private simulator class needed for the physical specialization. The following argument does not appeal to an unpublished

physical lemma. It retains the same positive-volume preparation and positive sensor noise as the earlier collision construction.

**Definition 10.1** (The reset row–event architecture). A preparation supplies two sequential report slots and, afterwards, an actual mark. The source reports in the two slots are constant. A private width-one simulator has no retained information between those slots and no persistent hidden seed. It may use fresh independent coins. Its first emission is  $X_1 \sim \text{Ber}(p)$ ; after receiving the current gate  $A \in \{0, 1\}$ , its second emission has a fixed Bernoulli kernel with parameter  $q_A$ . The parameters  $(p, q_0, q_1)$  are fixed throughout the audit. The simulator does not observe the actual mark. All its coins are independent of that mark. Different preparations reset all unretained variables and are independent conditional on the parameters.

The auditor observes the first report, chooses a gate using its retained state and that report, observes the second report, and then observes the mark. During training it may choose rows and stop adaptively, using at most the declared number of candidate preparations. It next freezes one gate policy and one event, with any retained random choice included in its register. It uses that same row–event continuation on one fresh candidate preparation and one independent target preparation and returns the difference of their event indicators, target minus candidate. It may not reselect the event after either validation. Independent target-only calibration is allowed but all retained calibration and randomness are charged. Peak width counts every bit, mark, event and validation-accumulator cut. Clocked schedules are declared externally; an autonomous implementation must retain its phase. An unretained transcript, seed or stopping-time value is not available to a continuation.

In the all-on row the complete private law is  $b(p, q_1)$ , with an independent fair actual mark. For lower bounds it suffices to restrict the adversary to  $q_0 = 0$ ,  $q_1 = q$ . In this subfamily every deterministic gate policy is the pushforward

$$T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$$

of  $b(p, q)$ . The gate, when included in the transcript, is another function of these same coordinates. Randomized gate policies are covered by averaging their independent random tables. This proves both the all-on product characterization for the upper construction and the common-garbling subfamily used for the outer converse. The width-one constraint is a simulator constraint; it is not an uncharged restriction on the auditor’s register.

**10.1. Preparation and elastic scattering.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$ , with no walls and contact distance  $d$ . Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ ,  $V = (v_1 + v_2)/2$ , and let the center of mass position range over any fixed rational box of positive volume. Prepare  $(B, W) \in \{0, 1\}^2$  with probability  $5/16$  at  $B = W$  and  $3/16$  at  $B \neq W$ . Conditional on  $(B, W)$ , use the uniform product preparation on the following boxes:

$$(38) \quad \begin{aligned} r &= (-a_0, (2B - 1)b_0, c_0), & a_0 &\in [29/10, 31/10], & b_0 &\in [9/20, 11/20], \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & & & |V_z - (2W - 1)| &\leq 1/100. \end{aligned}$$

Thus the actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ , preserved by momentum conservation. Set

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector, identically zero on the incoming transverse-velocity range.

**Lemma 10.2** (Uniform collision signal). *For every preparation in (38) and every  $9/10 \leq d \leq 11/10$ , exactly one collision occurs and its time lies in  $(4/5, 3/2)$ . Afterwards*

$$(2B - 1)v_{1,y} > 1/2, \quad (2B - 1)h(v_{1,y}) > 1/4.$$

*For  $0 < d \leq 2/5$  no collision occurs on  $[0, 3]$  and the detector is zero throughout that interval.*

*Proof.* Before contact,  $r(t) = r + tg$ . At  $t \leq 4/5$  its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At  $t = 3/2$  its absolute coordinate bounds are  $1/4$ ,  $113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . The first contact therefore occurs in the claimed interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$ . Hence the entry contact has  $n_x < 0$ , where  $n = r(t_c)/d$ . Its remaining coordinates give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B - 1)n_y \geq 87/220.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The elastic rule gives

$$v_1^+ = V + g/2 - (g \cdot n)n, \quad g^+ = g - 2(g \cdot n)n.$$

Consequently

$$(2B - 1)v_{1,y}^+ > -3/200 + (1443/1000)(87/220) > 1/2.$$

The definition of  $h$  implies the signal bound. Since  $r(t_c) \cdot g^+ > 0$ , squared separation increases strictly afterwards; there is no second collision. Finally, for  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . There is no contact, and the incoming  $|v_{1,y}| \leq 3/200$  makes  $h$  zero.  $\square$

**10.2. Positive noise and the actual mark.** Let  $\mathcal{B}_t$  be Brownian motion independent of the preparation and set

$$Y_t = \int_0^t h(v_{1,y}(s)) ds + \sigma \mathcal{B}_t, \quad 0 < \sigma \leq 1/24.$$

The two potential all-on reports are

$$Z_1 = \mathbf{1}_{\{2(Y_2 - Y_{3/2}) > 0\}}, \quad Z_2 = \mathbf{1}_{\{2(Y_3 - Y_{5/2}) > 0\}}.$$

The actual second report is  $AZ_2$ . The gate changes acquisition, not the mechanical path. The continuous path is implemented by the target sensor; it is not made available to the private simulator or supplied as an uncharged auditor buffer. Denote the law of  $(Z_1, Z_2, W)$  by  $Q_{d,\sigma}$ .

**Theorem 10.3** (Uniform physical presentation). *For  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ ,*

$$(39) \quad \text{TV}(Q_{d,\sigma}, Q_*) < 1/300.$$

*The same estimate holds after every declared feedback gate, including its observable gate value. The all-on private product family and the common-garbling subfamily in Definition 10.1 apply to this very experiment.*

*Proof.* Every collision occurs before  $3/2$ . Conditional on the preparation, the two normalized sensor windows are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . Lemma 10.2 makes their means have sign  $2B - 1$  and magnitude greater than  $1/4$ . Each potential report therefore differs from  $B$  with probability less than  $\Phi(-3)$ . The Gaussian tail estimate

$$\Phi(-x) \leq \frac{e^{-x^2/2}}{x\sqrt{2\pi}}$$

gives  $\Phi(-3) < 1/600$ :  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$  suffice. Couple the ideal and noisy reports using the same preparation, actual mark and gate random table. Except on a set of probability less than  $2\Phi(-3) < 1/300$ , both potential reports equal  $B$  and the entire gated transcript agrees. The ideal marked law is precisely  $Q_*$ , by the prepared  $(B, W)$  table. This proves (39) and the feedback-uniform version. Finally, the source is blind, its actual mark is unobserved by the simulator, and the gate is its only current input at the second emission. The product and subfamily assertions follow from the two independent private-emission kernels specified above.  $\square$

For  $d \leq 2/5$ , the two windows instead contain only independent centered Gaussian noise. Their signs are independent fair bits, independent of  $W$ , and a private width-one simulator reproduces every gated row exactly. Thus the informative regime and its no-collision control use the same detector, preparation convention and actual mark.

### 11. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1-p)(1-q)$  and  $c = pq$ . On the ordered atoms

$$(40) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(41) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \longrightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (41). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in Definition 10.1 and Theorem 10.3, explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem 11.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (2). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(42) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

### 11.1. An exact rational certificate against one preparation.

**Lemma 11.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem 5.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (9) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (40), the signed coefficients in (9), after grouping by  $K$ , are the entries of

$$(43) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1-p_i)^{2-k} \left( Q_{*,j} - \frac{(1-p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (43) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (43) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ . A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**11.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (40) and with indicator zero at every off-diagonal atom:

$$(44) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma 11.3** (Exact uniform score of the selector). *Against the ideal target, the selector (44) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (44) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(45) \quad G(p, q) = H(u, v) = -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} \\ + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}.$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

### 11.3. Causal compilation and the full register profile.

**Lemma 11.4.** *The selector and its two validations admit the deterministic profile (42). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event–function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (44). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem 11.1.* Lemma 11.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas 11.3 and 11.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary 11.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the local microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem 11.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in Theorem 10.3; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark 11.6* (The part of the frontier determined here). The deterministic theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . Theorem 12.1 and Corollary 12.2 below additionally determine the ideal maximum score with two preparations on this width range. The least peak width over all validation orders and the full boundary for  $3 \leq W \leq 11$  remain separate questions. Theorem 14.3 below determines the peak for forward serial validation, and Theorem 14.1 determines the order-independent decision cut. The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by (2, 12) in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

**Corollary 11.7** (The enlarged physical preparation segment). *With the full architecture of Definition 10.1,*

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

*Here  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$  is the exact one-preparation all-on value, rather than the older rational upper bound.*

*Proof.* Restrict the adversary to the common-garbling subfamily in Definition 10.1. Theorem 5.2 and Corollary 9.2 bound every at-most-one-preparation auditor, even with unlimited memory, by  $u_{\text{ex}} + \beta$ . The same deterministic two-preparation machine in Lemmas 11.3 and 11.4 has score at least  $m_2 - \beta$  against the full private candidate family. These inequalities prove the assertion. The four-preparation total, peak twelve and positive-noise specialization are unchanged.  $\square$

## 12. THE EXACT TWO-PREPARATION MARKED SADDLE

The one-preparation saddle has an exact successor. A new zero coefficient of the least-favorable predictive measure makes it necessary to randomize at the two extreme training counts. This randomization changes the value, but does not enlarge the alphabet of frozen validation events.

Let  $b(p, q)$  and  $Q_*$  be as in Section 11. Let  $r$  be the unique root in  $(1/3, 7/20)$  of

$$(46) \quad 2r^3 + 25r^2 - 3 = 0,$$

and define

$$(47) \quad \tau = \frac{6(-r^2 + 4r - 1)}{r(3r + 25)}, \quad v_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad p_{\pm} = \frac{1 \pm \sqrt{r}}{2}.$$

The polynomial in (46) is strictly increasing on the positive half-line and has opposite signs at the indicated endpoints. These observations prove the asserted existence, uniqueness and isolating interval. That interval also gives  $0 < \tau < 1$ .

**Theorem 12.1** (Exact two-preparation value). *For the full marked-word response class of (8),*

$$U_2(b, Q_*) = v_2.$$

*A least-favorable prior gives mass  $1/2$  to each of  $(p_-, p_-)$  and  $(p_+, p_+)$ . An optimal response discards the two training marks, retains the total number  $S$  of ones in the four training report bits, and uses*

$$(48) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & \tau & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & \tau \end{array}$$

*with zero response at off-diagonal validation atoms. Numerically,  $r = 0.3417694155\dots$ ,  $\tau = 0.1688236447\dots$  and  $v_2 = 0.4261127787\dots$ . The exact value is determined by (46)–(47), not by these decimals.*

*Proof.* Write  $a = (1 - p)(1 - q)$ ,  $c = pq$ ,  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ . Both  $u$  and  $v$  belong to  $[0, 1]$ . The score of the deterministic five-event selector is the polynomial  $H(u, v)$  in (45). Only counts zero and four are changed by (48). Their probabilities are  $a^2$  and  $c^2$ . Consequently the new score is

$$G(u, v) = H(u, v) + \tau J(u, v), \quad J = a^2(5/16 - a/2) + c^2(5/16 - c/2).$$

Expansion gives the polynomial identity

$$(49) \quad \begin{aligned} J(u, v) = & -\frac{u^3}{64} + \frac{3u^2v}{64} - \frac{25u^2}{128} - \frac{3uv^2}{64} + \frac{13uv}{64} \\ & + \frac{v^3}{64} - \frac{v^2}{128} - \frac{v}{32} + \frac{3}{128}. \end{aligned}$$

Thus

$$H(u, 0) = \frac{-u^3 + 6u^2 - 3u + 14}{32}, \quad J(u, 0) = \frac{3 - 25u^2 - 2u^3}{128}.$$

Equation (46) says  $J(r, 0) = 0$ , and the choice of  $\tau$  says  $\partial_u G(r, 0) = 0$ . Direct factorization, using these two identities, yields

$$(50) \quad G(u, 0) - v_2 = \frac{(u - r)^2 \{75 + 12r + 6u - 37r^2 - 74ru\}}{64r(3r + 25)}.$$

The expression in braces is strictly positive for  $0 \leq u \leq 1$ : it is at least  $75 - 37(7/20)^2 - 74(7/20) > 0$ . Moreover,

$$\partial_v H = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}, \quad \partial_v J = \frac{3(u-v)^2 + 13u - v - 2}{64} \geq -\frac{3}{64}.$$

Because  $0 < \tau < 1$ ,  $\partial_v G \geq 11/64$  on the unit square. It follows that  $G(u, v) \geq G(u, 0) \geq v_2$ , with equality precisely when  $v = 0$  and  $u = r$ . Both equality points are feasible and are the two parameters in the asserted prior. This proves the global lower bound.

It remains to prove an upper bound against every response, not only those depending on  $S$ . Under the asserted prior the four training report bits are independent Bernoulli variables with common parameter  $p_-$  or  $p_+$ . Conditional on  $S = s$ , their arrangements and the two independent training marks have parameter-independent distributions. The signed predictive coefficients can therefore be grouped by  $S$  without restricting any response coordinate. For the four displayed validation atoms put

$$C_{s,j} = \frac{1}{2} \sum_{p \in \{p_-, p_+\}} \binom{4}{s} p^s (1-p)^{4-s} \{Q_{*,j} - b_j(p, p)\}.$$

The first three rows of  $256C$  are

$$\begin{aligned} s = 0 : & \quad (-(2r^3 + 25r^2 - 3), -(2r^3 + 27r^2 + 12r - 1), \\ & \quad -(2r^3 - 5r^2 - 20r - 1), -(2r^3 - 7r^2 - 32r - 3)), \\ s = 1 : & \quad 4(r-1)(2r^2 + 7r - 3, 2r^2 + 9r - 1, \\ & \quad 2r^2 - 7r - 1, 2r^2 - 9r - 3), \\ s = 2 : & \quad -6(r-1)^2(2r-3, 2r-1, 2r-1, 2r-3). \end{aligned}$$

Rows three and four are the reversals of rows one and zero, respectively. Their signs, using  $1/3 < r < 7/20$ , are

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Every off-diagonal validation coefficient is nonpositive because its target mass is zero. Hence (48) maximizes every signed coefficient: it is one at positive coefficients, zero at negative ones, and arbitrary at the two zeros. The lower-bound equality at both prior points shows that this Bayes maximum is exactly  $v_2$ . The posterior-predictive dual, Theorem 5.1, now gives the matching upper bound for the full response class.  $\square$

**Corollary 12.2** (Exact physical score on the peak-twelve segment). *Use the atomic stochastic-row convention and the original marked interface of Definition 10.1. At two candidate training preparations, every peak budget  $W \geq 12$  has exact ideal worst-case score  $v_2$ . For a target  $Q$  with  $\text{TV}(Q, Q_*) \leq \beta$ , the corresponding value lies in  $[v_2 - \beta, v_2 + \beta]$ . In particular, with  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$ ,*

$$(51) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad u_{\text{ex}} + \beta \leq c < v_2 - \beta.$$

*Proof.* Let  $h_0, \dots, h_4$  be the five deterministic events in (44). At count zero select  $h_1$  with probability  $\tau$  and  $h_0$  otherwise; at count four select  $h_3$  with probability  $\tau$  and  $h_4$  otherwise. At the other counts retain the indicated event. Discard the count and retain the selected event for both validations. This realizes (48); the event alphabet remains five. The full charged profile, now including the separate event-selection update, is

$$(1, 2, 3, 3, 4, 5, 5, 5, 10, 12, 10, 10, 7, 3).$$

The common residual-function compiler in Lemma 11.4 applies unchanged. In particular, no persistent random selector is outside the register. The all-on law for every private candidate is  $b(p, q)$ , so Theorem 12.1 proves the constructive lower bound. For the converse restrict to the admissible common-garbling product subfamily and apply Theorem 5.2 followed by Theorem 12.1. This bounds all architectures, including those using feedback, stopping and more memory. Target perturbation changes each frozen-event expectation by at most  $\beta$ . Finally the exact one-preparation theorem excludes a strict score above  $c$  at  $N \leq 1$ , whereas the displayed machine achieves it at  $N = 2$  under (51).  $\square$

The root  $r$  is larger than  $2 - \sqrt{3}$ . The old diagonal polynomial  $H(u, 0)$  is strictly increasing between these points, whence  $v_2 > m_2$ . The deterministic theorem, including its zero-random-bit implementation, remains valid; the new exact score uses an additional stochastic row.

**Proposition 12.3** (Finite precision for the new row). *Replacing  $\tau$  by a dyadic  $\tau_b = k/2^b \in [0, 1]$  with  $|\tau_b - \tau| \leq 2^{-b}$  loses at most  $(5/16)2^{-b}$  in uniform score. A clocked fair-bit implementation uses  $b$  extra random bits and at most  $\max\{12, 6(b+1) + 5\}$  persistent states, including their phase, in addition to the unchanged preparation count.*

*Proof.* At each affected training word the response changes at a single atom;  $|5/16 - a/2|$  and  $|5/16 - c/2|$  are at most  $5/16$ . The two affected word probabilities sum to at most one. This gives the score estimate. To implement the dyadic coin, compare  $b$  fresh fair bits lexicographically with the fixed  $b$ -bit integer  $k$ . Retain the origin (count zero or four), one of the three comparison flags, and a phase in  $\{0, \dots, b\}$ . Once the comparison ends retain its chosen one of five events. Unaffected counts can wait in their event states. These states total at most  $6(b+1) + 5$ ; the other cuts have peak twelve. The cases  $k = 0, 2^b$  are deterministic. Exact atomic randomization and a finite fair-bit implementation are therefore distinct resource claims.  $\square$

### 13. A CONTINUOUS TWO-PREPARATION MARKED FAMILY

The preceding saddle persists on an explicit interval of target laws, with exact rather than perturbative values. Use the target  $Q_\gamma$  from Section 9 and write  $U_2(\gamma) = U_2(b, Q_\gamma)$ .

**Theorem 13.1** (A two-preparation saddle family). *For  $6/25 \leq \gamma \leq 13/50$ , let  $r_\gamma$  be the unique root in  $(1/3, 7/20)$  of*

$$(52) \quad f_\gamma(r) = r^3 + (13 - 2\gamma)r^2 + (3 - 12\gamma)r - (1 + 2\gamma) = 0.$$

*Set*

$$D_\gamma(r) = 3r^2 + (26 - 4\gamma)r + 3 - 12\gamma, \quad t_\gamma = -\frac{2\{3r_\gamma^2 + (8\gamma - 14)r_\gamma + 3\}}{D_\gamma(r_\gamma)}.$$

*Then  $0 < t_\gamma < 1$ , and*

$$(53) \quad U_2(\gamma) = \frac{-r_\gamma^3 + (7 - 4\gamma)r_\gamma^2 - 3r_\gamma + 13 + 4\gamma}{32}.$$

*The response (48), with  $\tau = t_\gamma$ , is optimal. A least-favorable prior gives equal masses to the two diagonal parameters  $p = q = (1 \pm \sqrt{r_\gamma})/2$ . The response has the same five-event, peak-twelve atomic realization. At  $\gamma = 1/4$  these formulas reduce to Theorem 12.1.*

*Proof.* For brevity write  $r = r_\gamma$ ,  $D = D_\gamma(r)$  and  $t = t_\gamma$ . The derivative  $D_\gamma$  is positive on the rectangle  $\gamma \in [6/25, 13/50]$ ,  $r \in [1/3, 7/20]$ . For example its lower bound is  $1/3 + (26 - 52/50)/3 - 3/25 > 8$ . The polynomial  $f_\gamma$  decreases with  $\gamma$  at a fixed positive argument. Direct rational evaluations give  $f_{6/25}(1/3) < 0$  and  $f_{13/50}(7/20) > 0$ . Monotonicity therefore gives the root and its uniqueness in this interval. The numerator of  $t$  is  $-16\gamma r - 6r^2 + 28r - 6$ . It is bounded

below by  $28/3 - 6 - 16(13/50)(7/20) - 6(7/20)^2 > 0$ , and above by  $28(7/20) - 6 < 4 < D$ . Thus  $0 < t < 1$ .

Let  $H, J$  be the polynomials from (45) and (49). Changing the target masses linearly in  $\gamma$  gives

$$\begin{aligned} H_\gamma(u, v) &= H(u, v) + (\gamma - 1/4) \frac{1 - (u - v)^2}{8}, \\ J_\gamma(u, v) &= J(u, v) + (\gamma - 1/4) \frac{(u - v)^2 + 6u - 2v + 1}{32}. \end{aligned}$$

The response's full-parameter score is  $G_\gamma = H_\gamma + tJ_\gamma$ . One has  $J_\gamma(r, 0) = -f_\gamma(r)/64 = 0$  and  $\partial_u G_\gamma(r, 0) = 0$ . Algebraic division gives

$$(54) \quad G_\gamma(u, 0) - H_\gamma(r, 0) = \frac{(u - r)^2 A_\gamma(r, u)}{16D},$$

where

$$\begin{aligned} A_\gamma(r, u) &= 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru \\ &\quad + 12\gamma r + 6\gamma u - 51\gamma + 30. \end{aligned}$$

For  $0 \leq u \leq 1$  this is at least  $30 - 10(7/20)^2 - 20(7/20) - 51(13/50) > 0$ . The transverse derivatives satisfy

$$\begin{aligned} 32\partial_v H_\gamma &= 3(u - v)^2 + (8\gamma - 10)u + (6 - 8\gamma)v + 15 \geq 5, \\ 64\partial_v J_\gamma &= 3(u - v)^2 + (14 - 4\gamma)u + (4\gamma - 2)v - 4\gamma - 1 \geq -3 \end{aligned}$$

on  $0 \leq u, v \leq 1$ . Consequently  $\partial_v G_\gamma \geq 7/64$ . Equation (54) proves a lower bound  $H_\gamma(r, 0)$ , with equality precisely at the proposed prior points. This quantity is the right side of (53).

For the upper bound group the full training words by  $S$ , as in the preceding theorem. Put  $L(r) = r^2 + 6r + 1$ . Using  $f_\gamma(r) = 0$ , the first three rows of  $256C$  are

$$\begin{aligned} 0: & \quad (0, -8\gamma L(r), 32r(r+1) - 8\gamma L(r), 32r(r+1)), \\ 1: & \quad 8(r-1)(r^2 + 4r - 1 - 2\gamma(r+1), \\ & \quad \quad r^2 + 4r - 1 + 2\gamma(r+1), \\ & \quad \quad r^2 - 4r - 1 + 2\gamma(r+1), r^2 - 4r - 1 - 2\gamma(r+1)), \\ 2: & \quad -12(r-1)^2(r-1-2\gamma, r-1+2\gamma, r-1+2\gamma, r-1-2\gamma). \end{aligned}$$

The other rows are their reversals. The sign pattern is again

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Here are explicit interval checks for the potentially small margins. In row zero the third coordinate is bounded below by  $32(1/3)(4/3) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 0$ . The first parenthesis of row one is at most  $(7/20)^2 + 4(7/20) - 1 - 2(6/25)(4/3) < 0$ ; the third is at most  $(7/20)^2 - 4/3 - 1 + 2(13/50)(27/20) < 0$ . The second parenthesis is positive already from  $r > 1/3$  and  $\gamma > 0$ , and the fourth is negative. Finally  $r - 1 + 2\gamma \leq -13/100 < 0$ . All off-diagonal validation coefficients are nonpositive. Thus the stated response is a Bayes best response for this prior, including its two zero coefficients. Its score at both supporting parameters equals the lower bound. The full posterior-predictive dual proves (53).  $\square$

This interval is a uniform certificate region for the displayed saddle, not a claim that the same masks remain optimal for every mark bias. The theorem supplies a continuous family at genuinely growing training history  $N = 2$ ; it does not infer a recurrence for every  $N$  from the one-preparation formulas.

## 14. EXACT MEMORY FROM A MARKED SADDLE

The realization criterion is now applied to a saddle with genuine Bayes indifference. The zero coefficients in the two-preparation problem are not harmless: their values are fixed by contact with the parameter family. This supplies a converse for all optimal audits, rather than for a preselected response table.

Put  $I = [6/25, 13/50]$ . Throughout this section  $r = r_\gamma$ ,  $t = t_\gamma$ , and  $v = U_2(\gamma)$  are those of Theorem 13.1. Denote the five deterministic events in (44) by  $e_0, \dots, e_4$ . Responses displayed below are ordered on 000, 001, 110, 111 and vanish at the other four atoms.

**Theorem 14.1** (Contact rigidity and exact decision memory). *For every  $\gamma \in I$ , every minimax optimal full-word response with two training preparations has, after averaging the independent training marks at the two extreme report counts, the five rows*

$$(55) \quad (t, 0, 1, 1), \quad (1, 0, 1, 1), \quad (1, 1, 1, 1), \quad (1, 1, 0, 1), \quad (1, 1, 0, t).$$

*At the three interior counts the displayed response is forced at each individual training word, not merely after averaging.*

*In the original reset row–event interface, the least number of states at the post-training cut that permits the exact ideal score  $v$  is five. This converse allows arbitrary upstream finite memory, randomized encoding, adaptive training gates, stopping, independent target-only calibration, and all legal post-cut randomizations. Other cuts are unrestricted in this decision-memory assertion.*

*Proof.* First consider a response to the full two-preparation word. Under the least-favorable prior of Theorem 13.1, every training word has positive probability. The strict coefficient signs force  $e_1, e_2, e_3$  at report counts 1, 2, 3. At count zero only the 000 coordinate is free; at count four only the 111 coordinate is free. All off-diagonal validation coefficients are strictly negative: the prior parameters are interior, each word likelihood is positive, and the target assigns zero mass to those atoms. Thus those coordinates are zero for every optimal response.

Let  $a$  and  $b$  be the averages of the two free coordinates over the four equiprobable training mark words at their respective extreme counts. On the diagonal parameter  $(p, p)$  the score is

$$(56) \quad H_\gamma((2p-1)^2, 0) + aA_\gamma(p) + bB_\gamma(p),$$

where

$$A_\gamma(p) = (1-p)^4 \left( \frac{1+\gamma}{4} - \frac{(1-p)^2}{2} \right), \quad B_\gamma(p) = p^4 \left( \frac{1+\gamma}{4} - \frac{p^2}{2} \right).$$

Here  $H_\gamma$  is the deterministic five-event score in the proof of Theorem 13.1. At  $p_+ = (1 + \sqrt{r})/2$ ,  $A_\gamma(p_+) + B_\gamma(p_+) = J_\gamma(r, 0) = 0$  and  $A_\gamma(p_+) > 0$ . The latter follows from  $p_+ > 1/2$  and  $(1 + \gamma)/4 > 1/4$ . Reflection exchanges  $A$  and  $B$  at  $p_- = 1 - p_+$ . Also  $H_\gamma(r, 0) = v$ . Optimality forces contact at both prior points, by Theorem 8.2. Subtracting  $v$  from (56) therefore gives  $(a - b)A_\gamma(p_+) = 0$ , hence  $a = b$ .

With this common value the diagonal score is  $H_\gamma(u, 0) + aJ_\gamma(u, 0)$ , where

$$H_\gamma(u, 0) = \frac{-u^3 + (7 - 4\gamma)u^2 - 3u + 13 + 4\gamma}{32}, \quad J_\gamma(u, 0) = -\frac{f_\gamma(u)}{64}.$$

The supporting value  $r$  lies in  $(0, 1)$ , so the derivative at  $r$  vanishes. Since  $f'_\gamma(r) = D_\gamma(r) > 8$ , the derivative equation has the unique solution

$$a = b = \frac{64 \partial_u H_\gamma(r, 0)}{D_\gamma(r)} = t_\gamma.$$

This proves (55). Individual extreme mark words may still use different tie values; no unnecessary uniqueness is asserted.

Now take an arbitrary audit with  $K$  states at the decision cut. Restrict the candidate to the common-garbling subfamily in Definition 10.1. Generate two all-on words and simulate the adaptive training and its stopping with independent coins. The retained state is a parameter-independent stochastic function of those two words. Conditional on that state, the frozen row-event continuation pulls back to a response  $D_s \in [0, 1]^8$  on the all-on alphabet. Any calibration is part of the same encoding and retained state. Thus (28) holds without increasing  $K$ . If the audit attains  $v$  against the full physical class, its pullback attains  $v$  against this subfamily, since the unrestricted upper bound is  $v$ . Averaging selected rows preserves their factorization.

The three interior rows in (55) are distinct vertices of  $[0, 1]^8$ , so the generators must include  $e_1, e_2, e_3$  themselves. The first row lies in the face

$$F_0 = \{d : d(001) = 0, d(110) = d(111) = 1, d = 0 \text{ off the diagonal}\}.$$

Of those three obligatory vertices only  $e_1$  lies in  $F_0$ ; since  $t < 1$ , this row is not  $e_1$ . It needs another generator in  $F_0$ . Similarly the last row needs another generator in

$$F_4 = \{d : d(000) = d(001) = 1, d(110) = 0, d = 0 \text{ off the diagonal}\}.$$

Only  $e_3$  among the obligatory vertices lies there. The two faces are disjoint. Lemma 8.4 gives  $K \geq 3 + 2 = 5$ . Conversely the optimal response mixes  $e_0, e_1$  at count zero and  $e_4, e_3$  at count four and otherwise selects the indicated event. Only its five-valued event label survives the cut. The inherited compiler realizes its subsequent validation with finite memory and attains  $v$ . This proves exactness of the decision count.  $\square$

The contact argument is essential. Setting both free coordinates equal to one gives a Bayes best response with only the three events  $e_1, e_2, e_3$ , but its derivative at  $r$  is nonzero because  $t < 1$ . It is not minimax. Counting the states of a Bayes best response alone would give an incorrect resource conclusion.

**Corollary 14.2** (A strict gap and its physical persistence). *There is  $\delta_* > 0$ , uniform for  $\gamma \in I$ , such that every two-preparation audit with at most four states at the decision cut has ideal worst-case score at most  $U_2(\gamma) - \delta_*$ . In particular, this bound holds for every original-interface audit of whole-schedule peak at most four. If only the target changes by total variation at most  $\beta < \delta_*/2$ , the five-state decision construction still strictly outperforms this class.*

*Proof.* Let  $W_4(\gamma)$  be the maximum worst-case score over the relaxed factorizations (28) with  $K = 4$  and two full training words. Their encoder and decoder spaces are compact and fixed, independently of  $\gamma$ . The score is jointly continuous in these variables, the target bias, and  $(p, q)$ . Consequently  $W_4$  is continuous. By Theorem 14.1 it is strictly less than  $U_2(\gamma)$  for each  $\gamma \in I$ . The minimum of this positive continuous gap on compact  $I$  is positive. This defines  $\delta_*$  without pretending to have evaluated it numerically. The domination argument in that theorem makes it an upper bound for every original-interface audit in question. Changing only the target changes any fixed audit's mean score by at most  $\beta$ . The difference between the two classes therefore decreases by at most  $2\beta$ .  $\square$

For the microscopic family at  $\gamma = 1/4$ , the signal is larger than  $1/4$  and the standard deviation of each normalized sensor noise is  $\sqrt{2}\sigma$ . The Gaussian tail bound used in Theorem 10.3 gives the sharper, vanishing estimate

$$(57) \quad \text{TV}(Q_{d,\sigma}, Q_*) \leq \frac{8\sigma}{\sqrt{\pi}} \exp\{-1/(64\sigma^2)\}, \quad 9/10 \leq d \leq 11/10.$$

Thus Corollary 14.2 holds uniformly in  $d$  for all sufficiently small positive  $\sigma$ . This is an existence statement with the displayed physical modulus. The present proof does not certify that every  $\sigma \leq 1/24$  lies below the unknown gap threshold.

**14.1. The sharp serial-validation peak.** A decision cut and the whole execution have different resource costs. We now determine the latter in a declared validation schedule. In the *forward serial class*, both training preparations finish before validation; the candidate validation's two report slots and mark are read before any target validation report is read. The same frozen row–event continuation is used on both preparations, as in Definition 10.1. Training gates, stochastic state updates and frozen gate policies are unrestricted within that interface. No intermediate output can be reread as external memory.

**Theorem 14.3** (Sharp forward serial peak). *For every  $\gamma \in I$ , the least whole-schedule peak width attaining  $U_2(\gamma)$  in the forward serial class is twelve. In particular, a peak of at most eleven in this class incurs a strictly positive loss, which can be chosen uniformly for  $\gamma \in I$ .*

*Proof.* Use the common-garbling subfamily and the two raw all-on training words as in Theorem 14.1. Any optimal audit must finish both training preparations almost surely under its least-favorable prior. Indeed a stopped branch after a first preparation would have a response independent of the unused second word. For each first report count 0, 1, 2, two choices of the unused word force two different interior vertices from  $e_1, e_2, e_3$ . Each has positive conditional probability. A positive stopped component cannot be a convex component of two distinct vertices. The same argument excludes stopping before the first draw. Null branches may be completed arbitrarily.

Consider the cut after the candidate's second report slot and before its mark. On a canonical raw input tape its continuation is a channel from  $(w, y) \in \{0, 1\} \times \{000, 001, 110, 111\}$  to  $\{-1, 0, 1\}$ , where  $w$  is the unread candidate mark and  $y$  the fresh target word. All these target words have positive probability. Each retained state supplies one such continuation channel, common to every past leading to it. Hence the rows indexed by selected pasts factor through at most the peak number of generators.

For the strict interior training counts, the following eight rows are forced deterministic channels:

$$(58) \quad e_1(y) - f(w), \quad f \in \{0, 1 - w, 1\}; \quad e_2(y) - f(w), \quad f \in \{0, 1\}; \quad e_3(y) - f(w), \quad f \in \{0, w, 1\}.$$

For example  $e_1$  has candidate residual 0 after an off-diagonal report pair,  $1 - w$  after 00, and 1 after 11. The other cases follow by restriction of their masks. Each listed past has positive probability under both supporting candidate parameters. The eight functions are distinct: subtracting two with the same mask compares their distinct  $w$  functions; for different masks their difference depends nontrivially on  $y$  and cannot equal a function of  $w$  alone. They are eight distinct vertices of the product of output simplices.

There are four additional required rows. Average the extreme training marks as in Theorem 14.1, and take the candidate raw report pair to be, respectively, off diagonal and 11 at count zero, and off diagonal and 00 at count four. Independence of a fresh raw candidate preparation from the frozen continuation preserves the averaged tie probability  $t$ . On the four target words these rows have means

$$(59) \quad (t, 0, 1, 1), \quad (t - 1, -1, 0, 0), \quad (1, 1, 0, t), \quad (0, 0, -1, t - 1),$$

for both values of  $w$ . More precisely, each integer coordinate here is a point mass at that integer, and the remaining coordinate is the Bernoulli mixture between the two neighboring integers. This stronger channel statement, not a statement about a zero mean alone, follows because the

candidate indicator is fixed at 0 or 1 on the selected raw pair, while the target indicator is a bit. Fresh gate randomness is already part of this channel; it supplies no additional past-dependent argument to a retained state.

The four rows lie in four pairwise disjoint faces of the product of output simplices. These faces fix, for both  $w$ , respectively,

|           | 000 | 001 | 110 | 111 |
|-----------|-----|-----|-----|-----|
| $F_{0,+}$ | *   | 0   | 1   | 1   |
| $F_{0,-}$ | *   | -1  | 0   | 0   |
| $F_{4,+}$ | 1   | 1   | 0   | *   |
| $F_{4,-}$ | 0   | 0   | -1  | *   |

where a number specifies a point mass and  $*$  is unrestricted. Among the eight vertices (58), each face contains exactly one:  $e_1$ ,  $e_1 - 1$ ,  $e_3$ , and  $e_3 - 1$ , respectively. Since  $t < 1$ , none of the four required rows is that vertex. Face packing forces four more generators, for a total of twelve. This argument uses conditional future-output laws and not the continued storage of an event name after a residual has replaced it.

The optimal five-event selection followed by the inherited forward compiler has peak twelve, including its stochastic selection cut. It proves the matching upper bound. To see strictness below twelve, use the finite-protocol normal form of Proposition 8.1 with all logical cuts bounded by eleven, including selection and frozen-continuation buffers. Unobserved internal random computations can be collapsed to common transition kernels on the same register; an unretained random duration cannot be supplied as a later input. The normalized row spaces and closed frozen-interface restrictions are compact. If the constrained value equalled  $U_2$ , the preceding face obstruction would apply. Continuity and compactness in  $\gamma$  give a uniform strictly positive gap, just as in Corollary 14.2.  $\square$

Theorem 14.3 is a minimum-width theorem for a specified serial order, not a claim that an arbitrary validation order has the same minimum. The ideal target has support restrictions that can change future residuals when the target is read first. Reverse-order and interleaved validations require their own continuation analysis. The decision-memory converse in Theorem 14.1 does not make this serial-order assumption. Neither statement replaces the original physical interface by an uncharged atomic validation.

## 15. PREPARATION LIMITS AND LOCALIZATION OF LEAST-FAVORABLE PRIORS

The contact structure has a second consequence, now for an arbitrary number of training preparations. We separate a general localization principle from the special geometry of the marked product family. An exact finite- $N$  two-point prior is not assumed.

**Theorem 15.1** (Nearest-experiment limit and prior localization). *Let  $P_\theta$  be a continuous family on a finite alphabet of size  $d$ , with compact metric parameter space, and let  $Q$  be fixed. Put*

$$d_Q(\theta) = \text{TV}(Q, P_\theta), \quad d_* = \min_{\theta} d_Q(\theta), \quad C_* = \{\theta : d_Q(\theta) = d_*\}.$$

*For  $N \geq 1$ , the unrestricted frozen-validation values satisfy*

$$(60) \quad d_* - \sqrt{(d-1)/N} \leq U_N(P, Q) \leq d_*, \quad U_N \uparrow d_*.$$

*Every least-favorable prior  $\mu_N$  in Theorem 5.1 satisfies*

$$(61) \quad \int (d_Q - d_*) d\mu_N \leq \sqrt{(d-1)/N}.$$

Consequently every weak limit of such priors is supported on  $C_*$ . For every  $a > 0$  their mass on  $\{d_Q - d_* \geq a\}$  is at most  $\sqrt{(d-1)/N}/a$ . More generally, an upper bound  $b_N$  on twice the expected total-variation error of a common empirical reconstruction replaces  $\sqrt{(d-1)/N}$  in both conclusions.

*Proof.* Let  $\hat{P}$  be the empirical law of the  $N$  reports, and choose the indicator  $h_{\hat{P}}$  maximizing  $(Q - \hat{P})h$ . If  $h_\theta$  maximizes  $(Q - P_\theta)h$ , the two event inequalities give

$$(Q - P_\theta)h_{\hat{P}} \geq d_Q(\theta) - 2 \text{TV}(\hat{P}, P_\theta).$$

This inequality holds for the same parameter-independent response rule at every parameter. For any law  $P$  on  $d$  atoms,

$$\mathbb{E} \text{TV}(\hat{P}, P)^2 \leq \frac{d}{4N} \left(1 - \sum_x P(x)^2\right) \leq \frac{d-1}{4N}.$$

Thus its expected score is at least  $d_Q(\theta) - \sqrt{(d-1)/N}$ . Every response has score at most  $d_Q(\theta)$  at that parameter, which proves the upper bound at a minimizing parameter. Ignoring the last observation proves monotonicity and hence the limit.

Against a minimizing prior, the Bayes optimum is  $U_N$ . It is at least the prior average of the same empirical rule. Therefore

$$U_N \geq \int d_Q d\mu_N - \sqrt{(d-1)/N}.$$

Combine this with  $U_N \leq d_*$  to get (61). Markov's inequality proves the mass estimate. The function  $d_Q - d_*$  is nonnegative and continuous on the compact parameter space, so its integral under any weak limit is zero. Such a limit is supported on its zero set. The proof uses only the common reconstruction bound, which proves the last assertion.  $\square$

The empirical estimate in (60) is the same finite-alphabet mechanism underlying the retained decision-spectrum classification. Its role here is different: it controls every least-favorable prior, not merely a constructive selector. In particular, finite-preparation saddle supports cannot remain far from the closest candidate experiments as the preparation number grows.

**Theorem 15.2** (Intrinsic marked contact geometry). *For every  $\gamma \in I$ , set  $s_\gamma = \sqrt{(1+\gamma)/2}$  and*

$$d_\gamma = 2s_\gamma - 1 - \gamma/2, \quad C_\gamma = \{(s_\gamma, s_\gamma), (1 - s_\gamma, 1 - s_\gamma)\}.$$

*Then*

$$(62) \quad \min_{p,q} \text{TV}(Q_\gamma, b(p, q)) = d_\gamma, \quad \operatorname{argmin}_{p,q} \text{TV}(Q_\gamma, b(p, q)) = C_\gamma.$$

*Moreover, for Euclidean distance in  $[0, 1]^2$ ,*

$$(63) \quad \text{TV}(Q_\gamma, b(p, q)) - d_\gamma \geq \frac{7}{2300} \text{dist}((p, q), C_\gamma)^2.$$

*The constant is uniform on  $I$  and is derived from the experiment's atom probabilities, not from a metric-entropy or small-ball assumption.*

*Proof.* Put  $a = (1-p)(1-q)$ ,  $c = pq$ ,  $l = (1-\gamma)/2$  and  $h = (1+\gamma)/2$ . The common mass of target and candidate is  $\psi(a) + \psi(c)$ , where

$$\psi(z) = \begin{cases} z, & 0 \leq z \leq l, \\ z/2 + (1-\gamma)/4, & l \leq z \leq h, \\ 1/2, & h \leq z \leq 1. \end{cases}$$

This follows by summing the smaller mass on each of the two marked atoms corresponding to the report pair. Reflection  $(p, q) \mapsto (1-p, 1-q)$  exchanges  $a, c$ ; assume  $c \geq a$ . If  $c < 1/4$ , both terms are in the first segment of  $\psi$ , and their sum is at most  $1/2$ .

For  $c \geq 1/4$ , put  $x = \sqrt{c} \geq 1/2$ . By the arithmetic-geometric mean inequality,

$$a \leq (1-x)^2 \leq 1/4 < l.$$

Consequently the common mass is at most  $F(x) = (1-x)^2 + \psi(x^2)$ , with equality only when  $p = q = x$ . On the three consecutive intervals with endpoints  $1/2, \sqrt{l}, \sqrt{h}, 1$ , this function is respectively

$$(1-x)^2 + x^2, \quad (1-x)^2 + x^2/2 + (1-\gamma)/4, \quad (1-x)^2 + 1/2.$$

The first two are strictly convex and the last strictly decreases. The first increases away from  $1/2$ . Thus a maximum must occur at  $\sqrt{l}$  or  $\sqrt{h}$ . Their difference is

$$(64) \quad F(\sqrt{h}) - F(\sqrt{l}) = \gamma \left( \frac{3}{2} - \frac{2}{\sqrt{h} + \sqrt{l}} \right) > \frac{7}{575}.$$

Indeed  $\sqrt{h} > 39/50$ ,  $\sqrt{l} > 3/5$ , and  $\gamma \geq 6/25$ , so the right side is greater than  $(6/25)(3/2 - 100/69) = 7/575$ . The unique maximizing diagonal point on this side is  $x = \sqrt{h}$ . Its common mass is  $(1 - \sqrt{h})^2 + 1/2 > 1/2$ , also excluding  $c < 1/4$ . Subtracting it from one gives  $d_\gamma$ . Reflection proves (62) and the assertion about all minimizers.

We record a uniform quantitative form. Write  $s = \sqrt{h}$  and  $\Delta = 7/575$ . For  $1/2 \leq x \leq \sqrt{l}$ , the common mass is at most  $F(\sqrt{l})$ , so its deficit from  $F(s)$  is at least  $\Delta$ . For  $\sqrt{l} \leq x \leq s$ , convexity puts  $F$  below the chord between its endpoint values. Since this interval has length at most one, its deficit is at least  $\Delta(s-x)$ . For  $s \leq x \leq 1$  the deficit is

$$(1-s)^2 - (1-x)^2 = (x-s)(2-s-x) \geq (1-s)(x-s).$$

Since  $s < 4/5$ , this too is at least  $\Delta|x-s|$ . Together the three intervals give  $F(s) - F(x) \geq \Delta|x-s|$ .

Let  $z = (p-q)^2$ . At fixed  $c = x^2$  the additional loss from the nondiagonal candidate is exactly

$$(1-x)^2 - a = p + q - 2x = \frac{z}{p+q+2x} \geq z/4.$$

The geometric mean  $x$  lies between  $p$  and  $q$ , and hence

$$(p-s)^2 + (q-s)^2 \leq 4z + 4(x-s)^2 \leq 4z + 4|x-s|.$$

It follows that the total deficit is at least  $(\Delta/4)((p-s)^2 + (q-s)^2)$ , proving (63) in this case. If  $c < 1/4$ , the total variation is at least  $1/2$ , whereas  $d_\gamma < 12/25$  from  $s < 4/5$  and  $\gamma \geq 6/25$ . The excess is therefore greater than  $1/50$ ; Euclidean squared distance in the square is at most two, and  $1/50 > 2(7/2300)$ . This proves the remaining case. Reflection completes the proof.  $\square$

**Corollary 15.3** (An all-preparation law and a limiting two-point prior). *For all  $N \geq 1$  and  $\gamma \in I$ ,*

$$(65) \quad d_\gamma - \sqrt{3/N} \leq U_N(b, Q_\gamma) \leq d_\gamma, \quad U_N(b, Q_\gamma) \uparrow d_\gamma.$$

*Every least-favorable prior  $\mu_{N,\gamma}$  satisfies*

$$(66) \quad \int \text{dist}(\theta, C_\gamma)^2 d\mu_{N,\gamma}(\theta) \leq \frac{2300}{7} \sqrt{3/N}.$$

*A least-favorable prior can be chosen invariant under simultaneous complementation of the two parameters. Every such symmetric choice satisfies, for the Euclidean quadratic transport distance,*

$$(67) \quad W_2 \left( \mu_{N,\gamma}, \frac{1}{2} \delta_{(s_\gamma, s_\gamma)} + \frac{1}{2} \delta_{(1-s_\gamma, 1-s_\gamma)} \right) \leq \sqrt{2300/7} (3/N)^{1/4}.$$

*In particular, the limiting symmetric least-favorable law is unique.*

*Proof.* Estimate the four-atom report-pair law from training and tensor it with the known fair mark. Tensoring with a common probability preserves total variation. The proof of Theorem 15.1 therefore uses  $d = 4$  rather than eight, proving (65) and an excess bound  $\sqrt{3/N}$ . Combining the latter with (63) gives (66).

Simultaneously complement both report bits and the mark in every training and validation word. This leaves  $Q_\gamma$  invariant and sends  $b(p, q)$  to  $b(1 - p, 1 - q)$ . The Bayes objective in (9) is invariant under this transformation and convex in the prior. Averaging a minimizing prior with its reflected image is therefore again minimizing and is symmetric.

Map each parameter to a closest point of  $C_\gamma$ , choosing the two points with equal probabilities at a tie. This is a Borel kernel, equivariant under reflection. A symmetric prior is pushed forward to the equal two-point law in (67); the induced coupling has squared transport cost exactly the left side of (66). Taking square roots proves the assertion.  $\square$

These conclusions identify the endpoint and limiting contact geometry for every preparation number. They do not assert that the exact prior has two atoms at every finite  $N$ , or that the displayed convergence rates and constants are sharp. The finite- $N = 1, 2$  saddles are preserved as exact results. The new theorem explains their relationship to an intrinsically determined limiting contact set without extrapolating their particular event tables to unproved values of  $N$ .

## 16. AN EXACT PREPARATION–DECISION-MEMORY LAW

A second solvable family separates a genuine joint resource law from an implementation bound. Here the memory coordinate is the number of states at the training–validation cut. It is not identified with the bit-level peak width of the collision audit.

Fix  $m = 2^d$ ,  $0 < \alpha < 1$ , and an unknown parameter  $\theta \in \{1, \dots, m\}$ . A fresh training preparation reports  $\theta$  with probability  $\alpha$  and an erasure  $\perp$  otherwise. Conditional on  $\theta$ , the preparations are independent. Candidate validation has law  $\delta_\theta$  and target validation is uniform on  $\{1, \dots, m\}$ . At the decision cut the auditor retains at most  $K = 2^k$  states,  $0 \leq k \leq d$ . Its subsequent response may depend only on that state, current validation observations and fresh independent randomness. In particular, a calibration table, remembered seed or stopping time outside the retained state is not available. Upstream and downstream memory are otherwise unrestricted for the converse. Let  $V_N^{\text{er}}(K)$  be the best worst-case expected signed validation score with at most  $N$  training preparations.

**Theorem 16.1** (Exact joint law). *For every  $N \geq 0$  and  $K = 2^k \leq m$ ,*

$$(68) \quad V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N) \left(1 - \frac{1}{K}\right).$$

*The converse covers stochastic encoders and arbitrary legal stopping. The value is attained by a clocked machine with  $K$  training states. With atomic preparation and validation outcomes, the complete audit has peak at most  $\max\{2K, 3\}$  and uses at most  $N + 2$  preparations.*

*Proof.* Write  $q = (1 - \alpha)^N$  and pre-generate  $N$  potential training reports. A stopped auditor ignores the unused reports; this does not disclose extra information to it. On the event that all  $N$  reports are erasures, its retained-state law  $r = (r_j)_{j=1}^K$  is independent of  $\theta$ . After padding any smaller register with unused states, its channel to the decision register has the form

$$(69) \quad C(j \mid \theta) = qr_j + (1 - q)S(j \mid \theta)$$

for a stochastic channel  $S$ . This identity remains valid with randomized stopping and randomized state updates.

Use the uniform prior on parameters as an upper certificate. The part  $qr_j$  has zero expected score for every response: averaging  $\delta_\theta$  under this prior gives the target itself. For the other part, optimizing over all responses gives a convex function of  $S$ , a sum of positive parts of linear functions. Every stochastic channel is a convex combination of deterministic channels  $j = g(\theta)$ ; therefore its value is at most the largest deterministic-channel value. This convexification is used only to bound a channel. It does not presuppose that a mixture of width- $K$  machines is realizable at width  $K$ .

If the fibers of  $g$  have sizes  $n_1, \dots, n_K$ , a nonempty fiber has posterior uniform on that fiber, so its total variation from the uniform target is  $1 - n_j/m$ . The prior-averaged optimal score is

$$\sum_j \frac{n_j}{m} \left(1 - \frac{n_j}{m}\right) = 1 - \sum_j (n_j/m)^2 \leq 1 - 1/K.$$

Empty fibers contribute zero. Cauchy–Schwarz proves the inequality. This is an upper bound on the average score and hence on its minimum over fixed parameters. Multiplying by  $1 - q$  proves the upper bound in (68).

For attainment, partition the parameter alphabet into  $K$  equal groups and let  $g(\theta)$  denote its group. Initialize the register uniformly on the  $K$  group labels. On an erasure leave it unchanged; on a revealed parameter overwrite it by  $g(\theta)$ . No extra “revelation occurred” flag is needed. At the decision cut its law is  $q \text{Unif}[K] + (1 - q)\delta_{g(\theta)}$ . For register  $j$ , freeze the event which is the complement of group  $j$ . On a revelation its score is  $1 - 1/K$ . Under a uniformly random initial label, the mean score is zero for each fixed  $\theta$ : one of the  $K$  labels has score  $1 - 1/K$  and the others have score  $-1/K$ . This proves the exact worst-case value.

The  $k$  initialization bits can be accumulated in the  $K$ -state register; all earlier prefix counts are at most  $K$ . Thus no persistent seed lies outside it. Candidate validation retains the group label and its event indicator, using at most  $2K$  states. Target validation produces one of the three values  $-1, 0, 1$ . This proves the atomic-outcome peak bound. The controller uses a declared external schedule; an autonomous stopping implementation must additionally retain its phase. A phase-tagged implementation is finite, but its cost is not included in  $K$ .  $\square$

**Corollary 16.2** (Thresholds and matching resource scales). *For  $K \geq 2$  and  $0 \leq c < 1 - 1/K$ , the least integer number of training preparations giving a score strictly greater than  $c$  is*

$$(70) \quad N_c^{\text{er}}(K) = \left\lfloor \frac{\log(1 - c/(1 - 1/K))}{\log(1 - \alpha)} \right\rfloor + 1.$$

*If  $c \geq 1 - 1/K$ , no finite  $N$  suffices. For  $0 < \varepsilon < 1$ , achieving  $V_N^{\text{er}}(K) \geq 1 - \varepsilon$  requires*

$$K \geq \varepsilon^{-1}, \quad N \geq \frac{\log(1/\varepsilon)}{-\log(1 - \alpha)}.$$

*Conversely, whenever an allowed  $K \leq m$  satisfies  $K \geq 2/\varepsilon$ , the choice  $N \geq \log(2/\varepsilon)/[-\log(1 - \alpha)]$  suffices.*

*Proof.* The strict threshold is equivalent to  $(1 - \alpha)^N < 1 - c/(1 - 1/K)$ . Since the denominator logarithm is negative, the least integer satisfying this strict inequality is (70), including equality cases of the real quotient. Also

$$1 - V_N^{\text{er}}(K) = q + (1 - q)/K.$$

This is at least  $q$  and at least  $1/K$ , and is at most  $q + 1/K$ . These three inequalities prove the necessary and sufficient bounds.  $\square$

The exact law concerns an entire  $(N, K, \alpha, m)$  family, not a single finite diagnostic. Its mechanism is a parameter-independent erasure component followed by the convex geometry of

the decision channel. It demonstrates how a preparation obstruction and a memory obstruction can be matched in one theorem. It does not identify the least physical peak width at two collision preparations. Encoding the  $m$ -symbol reports bit by bit also introduces cuts not present in this atomic model; the physical bit-level accounting is given separately.

## 17. INTEGER MEMORY AND THE FAILURE OF A NAIVE PARTITION FORMULA

The divisibility assumptions in Theorem 16.1 can be removed, but a balanced-partition Bayes bound must not be mistaken for a minimax equality when a persistent random partition is not free. This distinction leads to another exact finite-resource transition.

Keep the revelation interface, but allow any integers  $m \geq 2$  and  $1 \leq K \leq m$ . Put  $\rho = 1 - (1 - \alpha)^N$ , and denote the genuine  $K$ -label minimax value by  $V_{N,m}^{\text{er}}(K)$ . Write  $m = Kq + s$ ,  $0 \leq s < K$ , and set

$$(71) \quad B_{m,K} = 1 - \frac{(K-s)q^2 + s(q+1)^2}{m^2}.$$

Here and below all-erasure initialization randomness is a state initialization, not an unrecorded seed used again at validation.

**Proposition 17.1** (Arbitrary integer alphabet bounds and low-reveal equality). *The optimal uniform-prior Bayes score is  $\rho B_{m,K}$ . The minimax value satisfies*

$$(72) \quad V_{N,m}^{\text{er}}(K) \leq \min \left\{ \rho B_{m,K}, 1 - \frac{\lceil m/K \rceil}{m} \right\}.$$

If  $\rho \leq m/(m+s)$ , equality with the first term holds. At perfect revelation  $\rho = 1$  the exact value is the second term. In particular, when  $s > 0$  the uniform-prior Bayes optimum at perfect revelation is strictly larger than the minimax value.

*Proof.* The all-erasure decomposition (69) holds without any divisibility condition. Its parameter-independent part has zero uniform-prior score. Optimizing the other part over responses gives a convex function of its stochastic channel. A deterministic channel with fiber sizes  $n_j$  has Bayes score  $1 - \sum_j (n_j/m)^2$ . If two nonempty fiber sizes differ by at least two, moving one index from the larger to the smaller strictly decreases the sum of squares. Allowing empty fibers and repeating gives sizes  $q$  and  $q+1$ , proving the Bayes bound. It is attained by this partition and its complementary events, with any parameter-independent initialization. This proves the first upper bound as well as the asserted Bayes optimum.

For perfect revelation, fix any  $K$  response vectors. For each known parameter choose a response maximizing its score; this deterministic assignment cannot decrease any parameter's payoff, even when the original encoder was randomized. Some assigned fiber has size at least  $\lceil m/K \rceil$ . Averaging its parameters, the score of their common response is at most the total variation between the uniform target and the uniform law on that fiber, namely  $1 - |\text{fiber}|/m$ . The minimum is no larger. Balanced fibers with their complementary events attain the resulting upper bound. A perfectly informed encoder can simulate any less informative encoder, so this is an upper bound at every  $\rho$ .

For the low-reveal equality let balanced fibers have weights  $w_j = n_j/m$ . When  $\rho < 1$ , initialize their label register with probabilities

$$(73) \quad r_j = \frac{\rho w_j + (1 - 2\rho)/K}{1 - \rho}.$$

These sum to one, and are nonnegative precisely throughout the stated range: the smallest numerator is  $\rho q/m + (1 - 2\rho)/K$ . On a revealed parameter overwrite the label by its fiber; on

erasure do nothing. No revelation flag is retained. For a parameter in fiber  $i$ , the complementary-event score is

$$\begin{aligned} g_i &= \rho(1 - w_i) + (1 - \rho) \left( r_i - \sum_j r_j w_j \right) \\ &= \rho \left( 1 - \sum_j w_j^2 \right) = \rho B_{m,K}. \end{aligned}$$

This matches the upper bound uniformly in the fixed parameter. If  $\rho = 1$  and  $s = 0$ , the deterministic revealed label already attains that value, so the singular denominator in (73) is not used. Finally, with unequal balanced fibers the weighted average of their sizes is strictly smaller than the largest size; equivalently  $B_{m,K} > 1 - \lceil m/K \rceil / m$ . This proves the last assertion.  $\square$

**Theorem 17.2** (The complete two-label revelation law). *For every  $m \geq 2$ , every  $N \geq 0$ , and  $0 < \alpha < 1$ , set  $w = \lfloor m/2 \rfloor / m$  and  $b = \lceil m/2 \rceil / m$ . Then*

$$(74) \quad V_{N,m}^{\text{er}}(2) = \min\{2wb\rho, w\}, \quad \rho = 1 - (1 - \alpha)^N.$$

*The same formula holds at the limiting endpoints  $\rho = 0, 1$ . For odd  $m$  it changes regime at  $\rho = m/(m+1)$ ; for even  $m$  it reduces to  $\rho/2$ . The attaining machine uses two training labels, a frozen two-event alphabet, and atomic peak at most four.*

*Proof.* Proposition 17.1 gives the upper bound and its attainment for  $\rho \leq 1/(2b)$ . Above this threshold, partition into fibers of weights  $w, b$  and initialize deterministically in the larger fiber's label. Continue to overwrite on a reveal and leave the state unchanged on an erasure. A parameter in the larger fiber has score  $w$ ; a parameter in the smaller fiber has score  $(2\rho - 1)b$ . The latter is at least  $w$  exactly when  $\rho \geq 1/(2b)$ . This attains the second upper bound. For even  $m$  the threshold is one, so the low-reveal construction suffices. The endpoint  $\rho = 0$  may instead freeze a constant event. Candidate validation retains the selected label and its indicator, with at most four states; target validation produces the difference. Initialization is atomic randomization when its probabilities are not dyadic.  $\square$

For example,  $m = 3, K = 2$  gives  $V_{N,3}^{\text{er}}(2) = \min\{4\rho/9, 1/3\}$ , rather than  $4\rho/9$  for all  $\rho$ . The balanced-integer expression is therefore not the unqualified replacement of the divisible minimax formula. For  $K \geq 3$  outside the low-reveal range, (72) remains a bound rather than an asserted equality. The compatible dynamic formulation of Section 7 retains the exact optimization in that regime. These results strengthen the revelation example without identifying its decision-cut coordinate with the collision model's bit-level peak.

## 18. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows, and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r - 1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(75) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma 18.1** (Causal interpretation of the coefficients). *Every coefficient in (75) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (75) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem 18.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_\theta g_\theta(q^C), \quad u_C = \min_\theta \max_\alpha b_{\theta,C,\alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(76) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_\alpha (u_C - b_{\theta_C,C,\alpha}) B_\alpha(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .*

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (75) implies

$$\min_\theta g_\theta(q) \leq \min_\theta \max_\alpha b_{\theta,C,\alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma 18.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (76). Choose  $\theta_C$  attaining

the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

*Remark 18.3.* The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem 5.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

## 19. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [6]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma 19.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-} (L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem 19.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(77) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(78) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma 19.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ , and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (78).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_\pm^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ . Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_\pm^n(i, \cdot), \pi_\pm) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (78). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (77). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (78) is an observation time at which an external analyst reads the autonomous machine, not a free input clock used by its transitions. The adversarial model of [10] is not covered by the independent-report proof above.

## 20. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary 20.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\bar{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\bar{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\bar{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding's inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition 20.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (9); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem. This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

## 21. A SHARPENED PHYSICAL CONSUMER AND ITS SIMULATION BUDGET

The exact two-preparation theorem has a downstream use with explicit hypotheses, rather than a merely renamed dependency arrow. It sharpens the mean margin of a raw-interface confidence test, and the causal morphism theorem transfers that test, with its full memory and calibration costs, to another executable interface.

**Theorem 21.1** (Confidence and transported resource certificate). *Let  $Q$  be a physical marked target with  $\text{TV}(Q, Q_*) \leq \beta$ . Use the two-preparation event selector with a dyadic coin  $\tau_b$  satisfying  $|\tau_b - \tau| \leq 2^{-b}$ , and put*

$$a_b = v_2 - \beta - \frac{5}{16}2^{-b}, \quad W_b = \max\{12, 6(b+1) + 5\}.$$

*If  $0 < c < a_b$ ,  $R$  independent four-preparation blocks, followed by the test  $\overline{D}_R > c$ , have error bounds*

$$(79) \quad \sup_{\text{private}} \mathbb{P}(\overline{D}_R \leq c) \leq \exp\{-R(a_b - c)^2/2\},$$

$$(80) \quad \sup_{\text{equal}} \mathbb{P}(\overline{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*They use  $4R$  preparations, at most  $bR$  fresh random bits, and at most  $W_b(2R+1)$  persistent states under a clocked schedule. With an exact atomic coin, replace  $a_b, W_b$  by  $v_2 - \beta, 12$ .*

*Suppose a source interface simulates this entire repeated audit under Theorem 3.4, uniformly over the private and equal-law families, with path defect  $\Delta_R$ . Then the corresponding source error bounds are the right sides of (79)–(80) plus  $\Delta_R$ , capped at one. At aligned cuts its state bound is  $C_{\text{cal}}R_tM_tW_b(2R+1)$ , and its preparation count is  $N_{\text{cal}}$  plus all source calls required to supply the  $4R$  audit preparations. Calibration is acquired and retained, not supplied as a free real-valued table.*

*Proof.* Corollary 12.2 and Proposition 12.3 give mean block score at least  $a_b$  under every fixed private parameter. Independent fresh preparations and independent coins give independent block scores in  $[-1, 1]$ . Hoeffding’s inequality proves (79). Under the equal-law null, conditional on training and the frozen event, the two validation indicators have the same mean. Each block therefore has mean zero, proving (80) by the same inequality. Retain the integer sum in  $\{-R, \dots, R\}$  alongside the current block register. Updating the sum and resetting the block is a deterministic boundary operation. This proves the raw resource bounds.

Apply Theorem 3.4 to the whole repeated experiment, including its stopping and validation fields. Its defect bound applies to each of the two terminal error events, whose indicators have range one; each probability therefore changes by at most  $\Delta_R$ , not  $2\Delta_R$ . The same theorem gives the state product and preparation count. The source blocks need not be independent after a shared calibration stage: independence was used only for the reference audit, and path-law comparison transfers its final event probability.  $\square$

The first part uses the exact saddle, the original microscopic bridge and the compiled residual machine. The second additionally needs the uniform acquired causal simulation theorem. A source which does not satisfy that theorem’s stability and calibration hypotheses is not covered. Likewise this consumer supplies no reverse simulation and therefore does not transfer an optimal-width lower bound to an arbitrary source. It is an actual conditional theorem interface for subsequent models, not an assertion that the independent geometric A2 chain or the unbounded B4/C2 operator obligations have already been discharged.

## 22. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section 18 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The

physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section 19 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (43), polynomial identity (45), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: CAUSAL EXPERIMENTS, FINITE-MEMORY CONTROL, AND EXACT MINIMAX LAWS

QIAN QI

ABSTRACT. We study which statistical comparisons are attainable when both the choice of experiment and its retained continuation are resources. Prepared positive kernels generate a future-test quotient; causal simulators then transport prediction and decision guarantees with explicit acquisition, quantization and memory costs. At a prescribed finite register profile we give an occupation-state dynamic formulation and an exact controlled family whose value is  $1/(2\lceil m/K \rceil)$ , whereas a free mixture of complete controllers has value  $K/(2m)$ . This strict discrepancy persists under positive-noise perturbations. For a marked product experiment with two unknown Bernoulli parameters, we determine the exact two-preparation minimax value and its least-favorable two-point prior. The value is  $(-r^3 + 6r^2 - 3r + 14)/32$ , where  $2r^3 + 25r^2 - 3 = 0$  and  $1/3 < r < 7/20$ . An explicit interval of mark biases has a corresponding exact two-preparation saddle family. A global polynomial certificate proves optimality over all responses to the full marked training word. The optimal response uses five frozen events and peak register width twelve, yielding an exact ideal physical score and an enlarged preparation boundary for positive-noise collision experiments. We also obtain arbitrary-integer revelation bounds, a complete two-label law, and a matched online prediction-resolution law under explicit dynamical and acquired-mass hypotheses.

## 1. INTRODUCTION

An experiment supplies observations, but a causal procedure must also retain enough information to choose its next experiment and interpret its eventual answer. These are different requirements. A posterior may summarize all relevant observations without fitting into the available register. Conversely, a small register sufficient for one terminal decision may not support a subsequent informative action. The purpose of this paper is to place these questions in one prepared causal model and to determine several of its exact resource boundaries.

The underlying object consists of a preparation, positive normalized experimental kernels, a causal action interface, executable future tests and a resource profile. No information metric or geometric measure is postulated independently of that object. The future-test quotient identifies prepared histories with identical legal continuations. Their actual probability law determines checkpoint resolution, whereas closure of the quotient under observations determines whether a quantization can be updated online. Sections 2 and 3 develop these distinctions. Under contractive updates and an acquired small-ball condition, online squared prediction loss is bounded above and below by constants times  $M^{-2/d}$ . A separate transport theorem simultaneously accounts for acquired calibration, state quantization, primitive model errors and the register used by a downstream controller.

The finite-memory question is not solved by unrestricted belief-state convexification. Section 7 retains the common observable rows in a parameterwise occupation-state recursion. The occupation state belongs to offline design, not to the executing controller. Its exact supersolution formulation contains neither an unobserved parameter oracle nor a free retained strategy tree. The distinction is quantitative. In a routing-and-sensing family with  $m$  incomparable branch-specific experiments and  $K$  labels at the routing cut, we prove

$$V_{m,K} = \frac{1}{2\lceil m/K \rceil}, \quad \bar{V}_{m,K} = \frac{K}{2m}.$$

The second value permits a persistent controller selector without charging it. The first does not. The values differ whenever  $K$  does not divide  $m$ , including  $1/4$  versus  $1/3$  at  $(m, K) = (3, 2)$ .

All other cuts, including the sensing-action buffer and the frozen validation event, are specified. A small full-support perturbation preserves the strict discrepancy.

Our principal explicit statistical calculation concerns

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

The last bit is the mark of the actual preparation. On atoms 000, 001, 110, 111, the target  $Q_*$  has masses  $5/16, 3/16, 3/16, 5/16$ , and it vanishes elsewhere. Training is followed by a frozen event applied to independent candidate and target validations. If  $U_N$  is the unrestricted-memory worst-case mean difference using  $N$  candidate training preparations, the exact values at one and two are

$$(1) \quad U_1 = \frac{85 - 7\sqrt{73}}{64}, \quad U_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad 2r^3 + 25r^2 - 3 = 0,$$

where  $r \in (1/3, 7/20)$ . The first value belongs to the continuous marked-target family in Theorem 8.1. The second is proved in Theorem 11.1. Its optimal response depends on the total of four training bits, with a nontrivial randomization at the two extreme counts. A square factorization and strict transverse monotonicity prove its lower bound on the full parameter square. The upper bound uses a matching least-favorable prior and the signs of all posterior-predictive coefficients, including the real training marks. No restriction to symmetric responses or parameter grids is imposed on the converse. Theorem 12.1 extends this construction to every target mark bias  $6/25 \leq \gamma \leq 13/50$ , with a cubic-defined least-favorable prior and a matching exact  $U_2(\gamma)$  formula.

The physical realization is part of the same argument. The five-event residual machine has peak twelve even after the new randomized selection step is charged. Its all-on law covers the original private candidate class; a common-garbling subfamily suffices for the converse. Thus the ideal two-preparation physical score is exactly  $U_2$  at every  $W \geq 12$ . If  $\text{TV}(Q, Q_*) \leq \beta$ , then

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{whenever} \quad W \geq 12, \quad U_1 + \beta \leq c < U_2 - \beta.$$

One candidate and one target validation are charged in addition to the two training preparations. The local collision geometry and positive-noise estimate are proved in Section 9. The exact atomic stochastic row and its finite fair-bit approximations have distinct, explicit precision costs.

For comparison with the deterministic construction we retain the constants

$$(2) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

The rational  $u_1$  is a valid one-preparation certificate and  $m_2$  is the exact minimum of the deterministic five-event selector. The exact values in (1) sharpen these two distinct bounds without discarding their proofs or implementations.

A revelation family illustrates another integer obstruction. For arbitrary alphabet size  $m$ , two decision labels have the complete law

$$V_{N,m}^{\text{er}}(2) = \min\{2wb[1 - (1 - \alpha)^N], w\}, \quad w = \lfloor m/2 \rfloor / m, \quad b = \lceil m/2 \rceil / m.$$

For odd  $m$  there is a saturation transition before perfect revelation. The corresponding balanced-partition Bayes formula is not the minimax value at all reveal probabilities. General integer bounds and an exact low-reveal range accompany this calculation. This example is a controlled comparison of decision-cut resources; it is not a surrogate for the collision model's bit-level width.

**1.1. Relation to comparison, control and finite memory.** Blackwell comparison and minimax theory provide the statistical mechanisms [2, 3]. The finite-horizon belief-state piecewise-linear representation is classical [1]. The unrestricted controlled dual in Section 6 specializes that machinery to a fixed adversarial parameter and a frozen validation score. It is not a new principle of dynamic programming. Its relation to the genuine constrained value is separated by Theorem 7.2.

Controlled information acquisition has a substantial sequential-design history, beginning with Chernoff [13]. Naghshvar and Javidi [14], Section 3 and equation (4), formulate a posterior-state stopping problem minimizing expected observation count plus a wrong-declaration penalty. Their continuation operator is the same Bayesian mechanism that underlies our unrestricted recursion. Our terminal functional instead compares fresh candidate and target draws, and our finite-profile recursion optimizes common row prescriptions without storing the full posterior. Their cost and asymptotic optimality results are not replaced by a finite-horizon validation formula.

Nitinawarat, Atia and Veeravalli [15], Theorem 2 and its controlled sensing example, already distinguish causal from open-loop experiments in a multihypothesis error-exponent problem. Thus informative adaptation or a strict adaptive advantage alone is not a novelty claim here. The exact ceiling law and its charged-selector discrepancy concern a different, fixed-horizon resource constraint; the marked saddle concerns a continuous two-parameter composite family and an exact finite- $N$  validation value rather than an asymptotic error exponent.

Finite-memory testing and the role of randomization are treated in [6, 7, 8, 9]. Our autonomous stationary comparison explicitly retains the Hellman–Cover attribution. Managoli and Prabhakaran [10] study a time-invariant finite-state tester against adaptive sample-distribution choices. Here the unknown parameter is fixed throughout an execution. The lack of mixed/behavioral equivalence with imperfect recall is also established; Zheng, Sim and Varvitsiotis [16] develop sum-of-squares methods over behavioral strategies. We do not claim polynomial policy optimization, the mixed/behavioral distinction or a general positivity hierarchy as new [4, 5]. Our explicit finite-family values and full-parameter saddle certificates are the mathematical claims requiring comparison.

Norberg’s filtered comparison [11] remains relevant to the general object-level setting. No non-overlap theorem is asserted without a proof-level comparison of that original work. The foundational kernel, barycenter and quantization arguments here are proved to fix their resource and preparation meanings, not to establish priority for their classical ingredients.

**1.2. Organization.** The causal object, acquired resolution and simultaneous simulation budget come first. Compatible finite architectures and the posterior-predictive dual then lead to controlled finite memory, exact marked minimax laws and the physical realization. Integer revelation, quantitative finite-architecture certification and the autonomous comparison follow. A final consumer theorem transfers the sharpened physical audit to repeated confidence tests and causally simulated interfaces. The predecessor’s complete mathematical and development volumes are preserved separately. In particular, preservation of A2, B4 and C2 derivations is not a claim that their geometric or operator hypotheses follow from finite stochastic kernels.

## 2. CAUSAL EXPERIMENTS AND THEIR PREDICTIVE QUOTIENTS

We begin with the object and morphism structure. Its elementary probability statements fix the meaning of later resource theorems; classical kernel construction, conditional expectation and quantization are not assigned a new priority. The substantive comparisons below retain their preparation, memory and approximation coordinates simultaneously.

**2.1. The experimental object.** An experiment has a fixed unknown parameter  $\theta \in \Theta$ , hidden states  $X_t$ , visible actions  $A_t$ , reports  $Y_{t+1}$ , and preparation laws  $\mu_\theta$ . We impose the following six conventions.

**A0 (types and visibility).** These spaces are standard Borel. Visible histories include actions, reports and publicly recorded resource increments. A legal-action set and its remaining budget are part of the visible protocol type. Two histories with different legal continuations are not identified.

**A1 (positive kernels).** There are jointly measurable normalized nonnegative kernels  $K_t^\theta(dx', dy, dc \mid x, a)$ , with  $c$  a nonnegative resource increment. An absorbing symbol represents termination or failure. Dirac kernels are allowed. Positivity here does not require every outcome to have strictly positive probability. A hidden state can contain the necessary physical past; this notation does not assume a finite-dimensional physical closure.

**A2 (causality).** A policy is a kernel  $\alpha_t(da \mid h_t)$  depending only on visible past data and allowed independent randomization. It cannot read the unknown parameter. Stopping is with respect to the visible filtration.

**A3 (executable tests).** The specified bounded future tests include constants, required report events and their legal one-step continuations. For discrete reports the one-step instrument is

$$(\mathbb{T}_{t,a,y}f)(\theta, x) = \int f(\theta, x') K_t^\theta(dx', \{y\}, dc \mid x, a).$$

The test spaces are closed under the required instruments, finite linear combinations and the bounded monotone limits needed to recover the stated event laws. For general reports one uses event instruments and regular conditional distributions, not division by the probability of a continuous singleton.

**A4 (actual preparation).** Average risks and acquired state laws refer to the specified preparation and exploration protocol. Failed trials, calibration, resets and conditioning events retain their probabilities and implementation costs. A convenient measure on a reachable set does not replace its acquired law.

**A5 (executable resources).** Persistent labels, temporary buffers, program constants, calibration precision, preparations and clocks are distinguished. A retained selector is a state. A parameter-dependent table is not a known program constant. A simulator with  $R_t$  labels composed with a controller with  $K_t$  labels has the direct product bound  $R_t K_t$ , before any justified quotient is taken. Atomic stochastic rows and fair-bit implementations are separately specified.

**Proposition 2.1** (Prepared path laws). *For every fixed parameter and causal policy, the preparation and kernels uniquely determine their finite-dimensional path laws. On a finite horizon they are the iterated kernel product*

$$\mu_\theta(dx_0) \prod_{t < T} \alpha_t(da_t \mid h_t) K_t^\theta(dx_{t+1}, dy_{t+1}, dc_t \mid x_t, a_t).$$

*These laws are consistent under marginalization. For a countable horizon they determine the usual kernel extension. Deterministic dynamics give their original trajectory laws when represented by Dirac kernels.*

*Proof.* Successive integration constructs each finite law. Normalization of the last two kernels gives its preceding marginal, and induction proves consistency and uniqueness on cylinder events. The countable kernel extension gives the full law; equivalently one applies the standard extension theorem to these consistent iterated kernels. Integration against a Dirac transition is evaluation along that transition, which proves the last assertion.  $\square$

**2.2. Prepared predictive equivalence.** For Bayesian predictions additionally fix a prior on the parameter, and regard  $(\theta, X_t)$  as the hidden variable. A prepared posterior  $\pi$  at a given protocol type evaluates the future tests. Define  $\pi \sim_t \tilde{\pi}$  if their evaluations agree on every specified future test. This definition concerns one prepared experiment; it does not identify a prior-dependent posterior with a statistic sufficient simultaneously for all fixed parameters.

**Theorem 2.2** (Predictive quotient and causal closure). *For finite report alphabets, predictive equivalence is preserved by every legal positive-probability report update. Its class determines the laws of all specified future experiments. Every deterministic history statistic that determines those laws factors onto this quotient. For a measurable realization it is sufficient that a countable separating test family gives a measurable evaluation map with standard Borel image, and that the chosen statistic admits a measurable factor. In finite history spaces the latter conditions are automatic.*

*Proof.* For a legal action and report, Bayes' rule gives

$$\pi'(f) = \frac{\pi(\mathbb{T}_{t,a,y}f)}{\pi(\mathbb{T}_{t,a,y}1)}.$$

Both numerator and denominator depend only on the old class by A3. Equivalent posteriors assign the same probability to the report, so updates agree on the next test space whenever that probability is positive. Null reports do not affect the prepared law and may be assigned a fixed admissible version. Induction determines every finite future report word; the monotone-class extension gives the required future events. Conversely those event laws determine the tests. If two histories have the same sufficient statistic, they have the same future evaluations; the quotient is therefore constant on its fibers. This gives the factor set-theoretically. The stated measurable factor assumption supplies its measurable version; no claim that every abstract quotient of a standard Borel space is standard Borel is used.  $\square$

**Proposition 2.3** (Barycenters, entropy and normalized response). *In a fixed preparation, suppose a hidden target  $Z$ , observation  $Y$  and postprocessing  $W$  form a Markov chain  $Z \rightarrow Y \rightarrow W$ . For any bounded vector of tests  $f$ ,*

$$p_W = \mathbb{E}[p_Y | W], \quad p_Y = \mathbb{E}[f(Z) | Y], \quad \mathbb{E}\varphi(p_W) \leq \mathbb{E}\varphi(p_Y)$$

*for every convex  $\varphi$  for which these expectations exist. For a parameter-independent kernel  $G$ ,  $P \ll Q$ , and finite  $D(P\|Q)$ , regular conditional laws give*

$$\begin{aligned} D(P\|Q) &= D(PG\|QG) \\ &\quad + \int D(P(dx | w)\|Q(dx | w)) (PG)(dw). \end{aligned}$$

*Finally, if  $f, g$  are bounded and  $\pi_u(dx) = e^{ug(x)}\pi(dx)/\pi(e^{ug})$ , then*

$$\left. \frac{d}{du} \pi_u(f) \right|_{u=0} = \text{Cov}_\pi(f, g).$$

*Proof.* The Markov property and the tower rule give the conditional barycenter; conditional Jensen gives convex order. The joint laws  $P(dx)G(dw | x)$  and  $Q(dx)G(dw | x)$  have relative entropy  $D(P\|Q)$ . Disintegrating by  $w$  and applying the entropy chain rule gives the identity, and hence data processing. The last equality follows by quotient differentiation; boundedness justifies differentiation under the integral.  $\square$

The barycenter statement concerns a law of predictions, not a pointwise map between reachable sets. Likewise the covariance in the last formula is a normalized response, not an independently postulated Fisher matrix or a global sufficiency theorem.

## 3. ATTAINABLE RESOLUTION AND RESOURCE-AWARE SIMULATION

**3.1. Checkpoint and online prediction.** Fix an actual exploration protocol and its history law. Let  $p(h)$  be a bounded  $d$ -dimensional conditional prediction vector, with law  $\nu$ . For instance, a future test is sampled independently after encoding, and the coordinates include its sampling weights. Squared excess prediction loss is then  $\mathbb{E}\|p(h) - \hat{p}\|^2$ .

**Proposition 3.1** (Checkpoint resolution). *For at most  $M$  retained labels the least checkpoint excess loss is*

$$(3) \quad \inf_{c_1, \dots, c_M} \int \min_{1 \leq j \leq M} \|p - c_j\|^2 \nu(dp).$$

*Independent randomized encoders or decoders cannot improve it. This formula concerns the stated preparation and does not provide a common codebook by separately optimizing at each unknown true parameter.*

*Proof.* Conditional squared loss decomposes into its Bayes loss and squared distance from the conditional mean. For each retained label replace a random decoder by its mean. Random assignment to the resulting centers cannot do better than a nearest center. Conversely a nearest-center assignment attains the infimum over codebooks arbitrarily closely. Conditioning on an independent shared random seed, if such a seed is allowed, gives a codebook for each seed, each with risk at least (3). Averaging cannot improve the bound. The formula does not charge the computation of a checkpoint assignment as an online algorithm; online compatibility is a separate condition.  $\square$

**Theorem 3.2** (A matched online resolution law). *Suppose a fixed prepared experiment has a predictive state  $s_t$  in a compact metric space  $S$ , a known initial state, and updates  $s_{t+1} = F_{t,a,y}(s_t)$ . Assume every permitted update is  $\rho$ -Lipschitz for one  $0 \leq \rho < 1$ , and the prediction map  $p : S \rightarrow \mathbb{R}^d$  is  $L$ -Lipschitz. Suppose  $S$  has a  $\delta$ -net of at most  $C\delta^{-d}$  points for all sufficiently small  $\delta$ . At a checkpoint  $T$ , assume the actual law  $\nu$  of  $p(s_T)$  satisfies the small-ball bound  $\nu(B(z, a)) \leq Aa^d$  for every center  $z$  and all sufficiently small  $a > 0$ . Then for all sufficiently large  $M$ , the minimum online excess prediction loss with  $M$  retained predictive labels satisfies*

$$(4) \quad c_0 M^{-2/d} \leq R_M^{\text{on}} \leq C_0 M^{-2/d}.$$

*Here one may take*

$$c_0 = \frac{1}{2}(2A)^{-2/d}, \quad C_0 = \frac{L^2 C^{2/d}}{(1-\rho)^2},$$

*Any separate exploration controller, report buffer or clock is charged in addition to these  $M$  labels. The exploration protocol and the preparation are fixed before optimizing the encoder.*

*Proof.* Any online  $M$ -label state is also a checkpoint encoder, so Proposition 3.1 applies. For any  $M$  centers, the union of balls of radius  $a = (2AM)^{-1/d}$  has  $\nu$ -mass at most one half. On its complement squared distance is at least  $a^2$ . Integration gives  $c_0 M^{-2/d}$ . This argument also permits randomized online encoders.

For the upper bound take a  $\delta$ -net with  $\delta = (C/M)^{1/d}$ , and a fixed measurable nearest-net assignment (with a fixed tie rule). Quantize the known initial state and, after each legal update, quantize again. The state error obeys  $e_{t+1} \leq \rho e_t + \delta$ ,  $e_0 \leq \delta$ , and hence  $e_t \leq \delta/(1-\rho)$ . The prediction error is at most  $Le_t$ . Squaring proves the upper bound, uniformly in time. Each update uses only the current net label and the current permitted input, so the construction is online. It does not grant the encoder free access to the original discarded history. If the exploration policy needs another register, that register is combined by a product construction.  $\square$

For example, a Lebesgue density bounded above by  $B$  gives the small-ball hypothesis with  $A = Bv_d$ , where  $v_d$  is unit-ball volume. The lower hypothesis is a condition on the *acquired prediction law*. A reachable set of dimension  $d$  without a mass condition does not imply the lower bound. Similarly, the contraction assumption is additional dynamics, not a consequence of kernel positivity.

**3.2. Causal morphisms and simultaneous error budgets.** A causal simulator  $\Gamma : \mathfrak{E} \rightarrow \mathfrak{F}$  is a parameter-independent executable transducer that uses source preparations to supply the target interface under every allowed target policy. Its defect  $\varepsilon$  is a uniform total-variation bound on the resulting path laws, including the fields required by the task. Its resource map  $\rho_\Gamma$  bounds the source resources of the transducer composed with a target controller.

**Proposition 3.3** (Composition and risk transfer). *Causal simulators compose. Their uniform defects add, capped at one, and their resource maps compose in the order  $\rho_{\Gamma_1} \circ \rho_{\Gamma_2}$ . For a terminal loss in  $[0, L]$  and a common target task,*

$$\mathcal{R}_{\mathfrak{E}}(\rho_\Gamma(B)) \leq \mathcal{R}_{\mathfrak{F}}(B) + L\varepsilon.$$

For reward in  $[-1, 1]$ , the corresponding maximum worst-case rewards satisfy the reverse inequality with an error  $2\varepsilon$ .

*Proof.* Interleave the two transducers; their pair of internal states is a causal implementation. Total variation contracts under a kernel and obeys the triangle inequality, proving the defect sum. If their state counts are  $R_t$  and  $M_t$ , the pair has at most  $R_t M_t$  states. Other declared resource bounds compose by execution of the two protocols. A bounded loss changes expectation by at most its range times total variation. Apply this bound to every fixed parameter and target controller and take the appropriate infimum or supremum. Uniformity in the controller is essential to this step.  $\square$

**Theorem 3.4** (Acquisition, quantization and model-error transport). *Suppose an exact source transducer has predictive state  $s_t \in S_t$  and additional charged buffers of size  $R_t$ , supplies  $T$  target operations, and has uniform model defect at most  $\varepsilon_{\text{mod}}$ . Its initialization and update depend on a calibration quantity  $\xi$ . From  $N_{\text{cal}}$  source preparations acquire an estimate  $\hat{\xi}$  with at most  $C_{\text{cal}}$  retained labels, such that*

$$\sup_{\theta} \mathbb{P}_{\theta}(d(\hat{\xi}, \xi) > a) \leq \eta.$$

Subsequent preparation noises are independent of calibration conditional on the fixed parameter. Let finite nets of sizes  $M_t$  have radii  $\delta_t$ . Assume, on matching input/output histories and on the good calibration event, that the quantized transducer's state error satisfies

$$(5) \quad e_0 \leq d_0 + a_0 a + \delta_0, \quad e_{t+1} \leq \rho_t e_t + d_{t+1} + a_{t+1} a + \delta_{t+1}.$$

Assume its next output kernel and the exact transducer's output kernel differ in total variation by at most  $\epsilon_t + L_t e_t + b_t a$ , uniformly in the fixed parameter and legal policy. All constants and nets are declared independently of that unknown parameter. Then the quantized acquired transducer has defect at most

$$(6) \quad \Delta = \min \left\{ 1, \varepsilon_{\text{mod}} + \eta + \sum_{t < T} (\epsilon_t + L_t e_t + b_t a) \right\}.$$

Composing it with any target controller of cut widths  $K_t$  requires at most  $C_{\text{cal}} R_t M_t K_t$  labels at aligned execution cuts and transfers its bounded reward with loss at most  $2\Delta$ . Its preparations are  $N_{\text{cal}}$  plus all source preparations specified by the transducer; no successful-trial conditioning removes the failures.

*Proof.* On the good calibration event, iterate (5). More explicitly, with  $D_0 = d_0 + a_0 a + \delta_0$  and  $D_j = d_j + a_j a + \delta_j$ ,

$$e_t \leq \sum_{j=0}^t D_j \prod_{k=j}^{t-1} \rho_k.$$

Couple each pair of output kernels maximally while their external histories agree. On agreement the target controller sees the same inputs, so it uses the same legal action and may use the same independent randomization. Its discontinuous action choices require no Lipschitz assumption: before a disagreement their arguments are identical. The chance of a first discrepancy is bounded by the sum in (6). Add the probability of bad calibration and the exact transducer's model defect. This proves the path bound, including stopping after padding by absorbing states.

The executable approximate transducer stores its calibration label, additional buffer, and net index. Combine these with the actual target register, not its full history or an uncharged belief. The resulting product gives the state count. If an operation contains further buffer cuts, apply the same product at each such cut;  $R_t$  was assumed to include them. Preparation costs add by execution. Finally apply Proposition 3.3.  $\square$

**Corollary 3.5** (A finite acquisition register). *Suppose  $r_0$  calibration rows have at most  $d$  outcomes, and take  $n$  independent preparations from each row on a fixed schedule. Their empirical rows satisfy, with probability at least  $1 - \eta$  uniformly in the row probabilities,*

$$\max \text{TV}(\hat{P}, P) \leq \frac{dz}{2}, \quad \eta = \min\{1, 2r_0 d \exp(-2nz^2)\}.$$

*Their counts can be retained in at most  $(n+1)^{r_0(d-1)}$  labels. Thus Theorem 3.4 can use  $N_{\text{cal}} = r_0 n$ ,  $a = dz/2$  and this finite calibration register when its calibration metric is the maximum row total variation.*

*Proof.* For each outcome the empirical frequency is the mean of independent Bernoulli indicators. Hoeffding's bound and a union bound over at most  $r_0 d$  coordinates give the event stated. The total-variation estimate is half the sum of coordinate errors. Retain  $d - 1$  counts per row; the last is reconstructed from the known number of draws at that stage of the clocked schedule. Each retained count takes at most  $n + 1$  values. An autonomous implementation must additionally charge its schedule.  $\square$

These results separate exact predictive equivalence, average checkpoint resolution, online realizability, and uniform simulation risk. In particular, neither an optimal checkpoint codebook nor the proof-state bundle of Section 7 is automatically an executable finite register.

#### 4. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition 4.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous

architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{s_r}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller's random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(7) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition 4.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (7) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row. Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section 15 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

## 5. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(8) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z) (Q - P_\theta) h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem 5.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(9) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_{\theta}^{\otimes N}(z) \{Q(\omega) - P_{\theta}(\omega)\} d\mu(\theta) \right]_+$$

$$(10) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_{\mu}(z) \text{TV}(Q, \bar{P}_{\mu}(\cdot | z)).$$

Here  $m_{\mu}(z) = \int P_{\theta}^{\otimes N}(z) d\mu(\theta)$  and, when  $m_{\mu}(z) > 0$ ,

$$\bar{P}_{\mu}(\omega | z) = \frac{\int P_{\theta}^{\otimes N}(z) P_{\theta}(\omega) d\mu(\theta)}{m_{\mu}(z)}.$$

A zero-mass term in (10) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (8) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [3] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (9). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_{\mu}(z)$  it equals  $m_{\mu}(z)(Q - \bar{P}_{\mu}(\cdot | z))$ , proving (10). If  $m_{\mu}(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem 5.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_{\theta}$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^{\Omega}$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (8). This proves the upper bound for the union of all architectures. Conversely, retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (8).  $\square$

*Remark 5.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_{\theta}^{\otimes N} d\mu(\theta)$ , not  $(\int P_{\theta} d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (10) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further

observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary 5.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (9) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (9) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory's theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

## 6. CONTROLLED EXPERIMENTS WITHOUT A DOMINATING ACTION

The reduction to one dominating row is not needed for a statistical dual, provided causal action choice is retained in the dual recursion. We give the finite-action theorem with a compact parameter space and an explicit protocol state. Its equality is an unrestricted-memory statement; its upper certificates apply to every smaller-memory class.

Let  $\Theta$  be compact metric and  $E$  a finite set of protocol states. At  $e \in E$  let  $\mathcal{A}_e$  be a finite set of training actions. Action  $a$  produces  $x$  in a finite alphabet  $X_a$  with law  $P_\theta^a$  and changes the protocol state to  $T(e, a, x)$ . The functions  $\theta \mapsto P_\theta^a(x)$  are continuous. An unknown  $\theta$  is fixed throughout the experiment. Conditional on it, each requested preparation uses a fresh independent draw from the selected row. Legal validation designs form a nonempty finite set  $\mathcal{B}_e$ . Design  $b$  has a finite outcome alphabet  $Y_b$ , target law  $Q^b$  and continuous candidate law  $V_\theta^b$ . A policy may stop after at most  $N$  training actions. It then freezes  $b \in \mathcal{B}_e$  and an event on  $Y_b$ , before one candidate and one target validation. Randomization is independent of  $\theta$ . No training action is assumed to dominate another.

For a finite nonnegative measure  $\nu$  on  $\Theta$  write  $\nu_{a,x}(d\theta) = P_\theta^a(x)\nu(d\theta)$  and set

$$(11) \quad \Phi_e(\nu) = \max_{b \in \mathcal{B}_e} \sum_{y \in Y_b} \left[ Q^b(y)\nu(\Theta) - \int V_\theta^b(y) d\nu \right]_+,$$

$$F_0(e, \nu) = \Phi_e(\nu),$$

$$(12) \quad F_n(e, \nu) = \max \left\{ \Phi_e(\nu), \max_{a \in \mathcal{A}_e} \sum_{x \in X_a} F_{n-1}(T(e, a, x), \nu_{a,x}) \right\}.$$

If no training action is legal, only the stopping term is retained. All the functions vanish at the zero measure, so no posterior division is required on null histories. For positive mass, (11) is the mass times the largest posterior-predictive total variation.

**Theorem 6.1** (Controlled posterior-predictive dual). *Let  $\mathcal{U}_N(e_0)$  be the maximum worst-case expected validation score over all randomized causal policies in the declared protocol, with at*

most  $N$  training preparations and no memory cap. Then

$$(13) \quad \mathcal{U}_N(e_0) = \min_{\mu \in \mathcal{P}(\Theta)} F_N(e_0, \mu).$$

Both extrema are attained. Each  $F_n(e, \cdot)$  is the maximum of finitely many continuous linear functionals on the cone of measures; in particular it is convex, continuous and positively homogeneous. For every prior  $\mu$ ,  $F_N(e_0, \mu)$  bounds the worst-case score of every finite-memory architecture implementing this protocol.

*Proof.* There are finitely many histories of length at most  $N$  and finitely many event masks at each stopping history. Consequently there are finitely many deterministic policy trees, denoted by  $\Pi_N(e_0)$ . For  $\pi \in \Pi_N(e_0)$  its payoff  $g_\pi(\theta)$  is a finite sum of finite products of continuous primitive probabilities and is continuous in  $\theta$ .

A randomized causal policy induces the same outcome laws as a probability distribution on these trees: sample its finite random decision table in advance and condition on it. Conversely, with no memory cap, a sampled tree can be retained and followed. Thus the unrestricted payoff vectors are exactly the convex hull of the  $g_\pi$ . This step is not an assertion that mixing machines preserves a specified register width.

The simplex on  $\Pi_N(e_0)$  and  $\mathcal{P}(\Theta)$  are compact and convex. The expected payoff is continuous and bilinear. Minimax therefore gives

$$\max_{\lambda \in \Delta(\Pi_N)} \min_{\theta} \sum_{\pi} \lambda_{\pi} g_{\pi}(\theta) = \min_{\mu} \max_{\pi \in \Pi_N} \int g_{\pi} d\mu.$$

For a fixed measure, the terminal maximum is (11), because an event includes precisely the positive coordinates of its signed predictive measure. At a training node one selects an action and, after its observed outcome, selects a continuation tree separately on that branch. The unnormalized branch measure is exactly  $\nu_{a,x}$ . Backward induction proves (12) and identifies the right side with (13). It also proves the finite-linear-functional representation. Compactness gives an optimizing prior and an optimizing mixed tree. Finally, the minimum over fixed parameters of any policy is at most its average under  $\mu$ , which is at most  $F_N(e_0, \mu)$ . This remains true after restricting its memory or architecture.  $\square$

The minimization in (13) occurs once, outside the recursion. It cannot be replaced by fresh adversarial choices after observations. The posterior carries dependence on one fixed unknown parameter. Also, a Bayes-optimal tree for a minimizing prior need not by itself be a minimax policy; the saddle-point mixture is supplied by the finite game in the proof.

**Corollary 6.2** (Bellman upper certificates). *Suppose functions  $\Psi_n(e, \nu)$  satisfy  $\Psi_0 \geq \Phi$  and, for  $n \geq 1$ , satisfy*

$$\Psi_n(e, \nu) \geq \Phi_e(\nu), \quad \Psi_n(e, \nu) \geq \sum_x \Psi_{n-1}(T(e, a, x), \nu_{a,x}) \quad (a \in \mathcal{A}_e).$$

*Then  $\Psi_N(e_0, \mu)$  is an upper certificate for every admissible architecture and every prior  $\mu$ . The family  $F_n$  is the least such family. An optimal prior can be chosen with at most  $d + 1$  support points, where  $d$  is the affine dimension of  $\{(g_\pi(\theta))_{\pi \in \Pi_N} : \theta \in \Theta\}$ .*

*Proof.* Induction in (12) gives  $F_n \leq \Psi_n$ . The equality case is the recursion itself. The objective depends on a prior only through its vector of integrals of the finitely many  $g_\pi$ . An optimal such vector belongs to the convex hull of their compact evaluation image. Carathéodory's theorem gives the stated support bound while preserving every pure-tree payoff.  $\square$

**Proposition 6.3** (Causal stability). *Consider two models with the same protocol, alphabets and policy class. Suppose their training rows differ uniformly in total variation by at most  $\epsilon$ , their*

candidate validation rows by at most  $\eta$ , and their target validation rows by at most  $\beta$ . Their unrestricted values, or their values in any common specified memory class, differ by at most  $2N\epsilon + \eta + \beta$ .

*Proof.* Use the same policy randomization and couple corresponding training rows while the histories agree. The probability of a first discrepancy is at most  $N\epsilon$ , even with feedback and stopping. Conditional expected validation rewards lie in  $[-1, 1]$ , so differing training histories contribute at most  $2N\epsilon$ . On agreeing histories the same frozen design and event are used, and their conditional mean rewards differ by at most  $\eta + \beta$ . The bound is uniform in the fixed parameter and in the policy. Taking minima and suprema preserves it, with the reverse inequality obtained by interchanging the models.  $\square$

**6.1. An informative action choice.** The following calculation distinguishes the controlled theorem from a common-row reduction. Let  $\Theta = \{(i, j) : i, j \in \{0, 1\}\}$ . Action  $R$  reports  $i$ . Action  $L$  reports  $j$  when  $i = 0$  and otherwise reports an independent fair bit. Action  $H$  reports  $j$  when  $i = 1$  and otherwise reports an independent fair bit. The candidate validation is  $\delta_{(i,j)}$  and the target is uniform on  $\Theta$ .

**Proposition 6.4** (Strict adaptive advantage). *With two training preparations, the unrestricted adaptive value is  $3/4$  and the best nonadaptive value is  $5/8$ . Nonadaptive policies here include mixtures of schedules, with their random schedule retained. No available single training action dominates all the others.*

*Proof.* Take  $R$  first, and then  $L$  or  $H$  according to the observed  $i$ . The parameter is recovered exactly. The complement of its validation atom has score  $3/4$ . No policy can exceed  $\text{TV}(Q, \delta_\theta) = 3/4$  even with full information.

For the converse for fixed schedules, use the uniform prior. For a pair of actions  $a, b$  its Bayes value is explicitly

$$(14) \quad \sum_{x,y,\theta} \left[ \frac{1}{16} \sum_{\vartheta} P_{\vartheta}^a(x) P_{\vartheta}^b(y) - \frac{1}{4} P_{\theta}^a(x) P_{\theta}^b(y) \right]_+.$$

Substitution of the three displayed kernels gives

|     | $R$   | $L$    | $H$    |
|-----|-------|--------|--------|
| $R$ | $1/2$ | $5/8$  | $5/8$  |
| $L$ | $5/8$ | $7/16$ | $1/2$  |
| $H$ | $5/8$ | $1/2$  | $7/16$ |

This is an exact finite sum, not a parameter-grid estimate. It bounds any mixture of fixed schedules by  $5/8$ ; an early stop can be padded with an ignored observation. To attain the bound uniformly in  $\theta$ , choose with equal probabilities the schedules  $(R, L)$  and  $(R, H)$ . When the chosen branch-specific action matches  $i$ , the parameter is known and the score is  $3/4$ . Otherwise only  $i$  is known, and the complement of its two-atom fiber gives score  $1/2$ . Each fixed parameter therefore has mean score  $5/8$ .

Action  $R$  cannot distinguish parameters differing only in  $j$ . Action  $L$  cannot distinguish  $(1, 0)$  and  $(1, 1)$ , and  $H$  cannot distinguish  $(0, 0)$  and  $(0, 1)$ . An experiment which fails to distinguish such a pair cannot garble to one that distinguishes it. Hence no action is a common dominating row.  $\square$

If every binary report is additionally passed through an independent binary symmetric channel of crossover  $\epsilon$ , the primitive training rows change by at most  $\epsilon$  and have full support for  $0 < \epsilon < 1/2$ . Proposition 6.3, applied to both policy classes, leaves an adaptive advantage at

least  $1/8 - 8\epsilon$ , which is positive for  $0 < \epsilon < 1/64$ . Thus the distinction is not confined to disjoint observation supports. The finite-horizon belief recursion and its piecewise-linear structure are classical [1]. The contribution here is their explicit integration with the frozen validation score, one fixed adversarial parameter, outer certificates, and the resource conventions; no priority for Bellman recursion itself is claimed.

## 7. CONTROLLED EXPERIMENTS AT A PRESCRIBED MEMORY PROFILE

An unrestricted posterior is a useful information state for a proof, but it is not a free runtime state. We first give a resource-exact dynamic formulation and then solve a controlled family in which replacing that formulation by a policy-tree mixture changes the value strictly.

**7.1. A parameterwise occupation state.** Fix a finite horizon  $T$ , a compact metric parameter space  $\Theta$ , finite hidden execution spaces  $H_t$ , and register alphabets  $S_t$  of sizes at most  $K_t$ . The visible inputs to each stochastic row and all legal actions are specified. Any input that must survive a cut belongs to  $S_t$ : this includes a chosen action, an unread report buffer, a stop flag, a selected validation event and a validation accumulator. One may subdivide an operation into several cuts to expose these costs. The scheduled time is available only in the clocked convention.

For now rows at different scheduled times are independently prescribed. Let  $\mathcal{Q}_t$  be the finite product of legal row simplices at stage  $t$ . A prescription  $q \in \mathcal{Q}_t$  is a table, chosen at design time, whose runtime arguments are exactly the declared visible inputs. After summing the fixed environmental kernels its one-stage transition is a stochastic matrix  $M_{t,\theta}^q$  on the hidden-state/register pairs. We assume this matrix is jointly continuous in  $(q, \theta)$ . Both action selection and state updating occur in this matrix, in their specified causal order; it is not an arbitrary matrix chosen separately for each hidden state or each parameter.

For a continuous bundle of probability vectors  $x = (x_\theta(h, s))_{\theta \in \Theta}$  define

$$(\mathcal{T}_{t,q}x)_\theta(h', s') = \sum_{h,s} x_\theta(h, s) M_{t,\theta}^q((h, s), (h', s')).$$

The initial bundle  $x_0$  is fixed by preparation. Terminal rewards  $r_\theta(h, s) \in [-1, 1]$  are continuous in  $\theta$ . Absorbing stopped states and frozen validation phases are included in this execution, not added afterwards without charge. Put

$$(15) \quad B_T(x) = \min_{\theta \in \Theta} \sum_{h,s} x_\theta(h, s) r_\theta(h, s),$$

$$(16) \quad B_t(x) = \max_{q \in \mathcal{Q}_t} B_{t+1}(\mathcal{T}_{t,q}x), \quad 0 \leq t < T.$$

The argument  $x$  is an *offline occupation bundle*, not the realized history, not an observed parameter, and not an additional register made available to the machine.

**Theorem 7.1** (Resource-exact dynamic value and supersolutions). *For the specified clocked profile and observable-row interface,  $B_0(x_0)$  is the exact maximum worst-case reward over all stochastic controllers. The maximum is attained by a sequence of legal common prescriptions. With the norm  $\|x - x'\| = \sup_\theta \sum_{h,s} |x_\theta(h, s) - x'_\theta(h, s)|$ , each  $B_t$  is 1-Lipschitz. Moreover,*

$$(17) \quad B_0(x_0) = \inf_H H_0(x_0),$$

where the infimum ranges over families of functions on occupation bundles satisfying

$$H_T \geq B_T, \quad H_t(x) \geq H_{t+1}(\mathcal{T}_{t,q}x) \quad (q \in \mathcal{Q}_t).$$

The infimum is attained by  $H = B$ . No convexification over retained controllers and no new adversarial choice after a report occurs in these identities.

*Proof.* For a fixed sequence  $q_0, \dots, q_{T-1}$ , iteration of the displayed transition gives its actual terminal law for every fixed  $\theta$ . The terminal minimum is therefore exactly its worst-case reward. A runtime randomized controller in this interface is precisely such a sequence of common conditional rows; independence of fresh randomization and the declared register specify all its conditional choices. Persistent random correlations are allowed only through that register.

The occupation bundle at the next stage is determined by the current bundle and the prescription, without drawing a realized history in the design problem. Hence optimizing over the remaining prescription sequence gives (16) by ordinary backward induction. This does not select a different continuation for each unrecorded history. Each maximizing  $q$  is still a single legal table common to all hidden histories and parameters. At  $x_0$  one follows the maximizing sequence of design prescriptions, computing their occupation bundles offline; the runtime controller only reads its allowed inputs.

Stochastic matrices contract the  $\ell^1$  norm. The terminal minimum is 1-Lipschitz in the displayed norm. Induction, using the same  $q$  when comparing two bundles and then taking the two maxima, proves the Lipschitz assertion. Joint continuity and compactness of  $\mathcal{Q}_t$  give attainment at each stage, and compactness of  $\Theta$  gives the terminal minimum. Any family  $H$  in (17) bounds the terminal reward along every prescription sequence. Backward induction therefore gives  $H_t \geq B_t$ . Equality is admissible, proving (17) and its attainment.  $\square$

This is a nonlinear supersolution dual, not a least-favorable-prior saddle theorem at fixed width. Its optimization can be large and nonconvex. The principle of dynamic programming is classical; the point of this formulation is that the common-row and memory constraints remain in the maximizations. If rows are shared across scheduled times, as for an autonomous controller, choose the shared rows once and hold them fixed in all subsequent transitions; equivalently augment the *design* problem by that immutable prescription. Maximizing a shared row anew at each time would solve a different problem. A finite union of allowed interfaces can be handled by taking their maximum, or by a fully wired interface with the prescribed profile and its legal observable inputs. Neither operation enlarges a runtime register invisibly.

**7.2. An exact informative-control bottleneck.** Fix integers  $m \geq 2$  and  $1 \leq K \leq m$ . The fixed parameter is  $\theta = (i, j) \in [m] \times \{0, 1\}$ . The first training experiment  $R$  reports  $i$ . Across the next cut the controller retains at most  $K$  labels, with an arbitrary stochastic encoder  $E(s | i)$ . It then chooses one of the  $m$  sensing actions with probabilities  $D(a | s)$ . The selected action is kept in a charged  $m$ -state action buffer and the old label is discarded. Action  $a$  reports  $j$  when  $a = i$  and reports  $\perp$  otherwise. The first report is no longer available.

The candidate validation law on  $\{0, 1\}$  is  $\delta_j$ ; the target is uniform. An event is frozen before one fresh candidate and one fresh target validation. Stopping before either training action is permitted. No independent persistent selector is given to the controller. The observation symbols are atomic; a bitwise input implementation would have additional cuts. Denote the maximum worst-case score by  $V_{m,K}$ .

**Theorem 7.2** (Exact finite-memory control and its convexification gap). *In this protocol,*

$$(18) \quad V_{m,K} = \frac{1}{2\lceil m/K \rceil}.$$

*The value obtained by allowing an uncharged ex ante mixture of complete  $K$ -label controllers is instead*

$$(19) \quad \bar{V}_{m,K} = \frac{K}{2m}.$$

*The inequality is strict whenever  $K$  does not divide  $m$ . The matching controller for (18) has charged cut profile bounded by  $(1, K, m, 3, 6, 3)$ . The  $K$ -label cut controls both retention of the routing observation and the subsequent informative action choice.*

*Proof.* For a fixed  $i$ , let

$$p_i = \sum_s E(s \mid i) D(i \mid s).$$

This is the probability of taking the informative action. On its complement, all retained information is independent of  $j$ . Averaging over the two values of  $j$  makes the expected validation score zero there, for any frozen event or randomized response. On the informative part the score is at most  $\text{TV}(\text{Ber}(1/2), \delta_j) = 1/2$ . Thus the minimum over  $j$  at a given  $i$  is at most  $p_i/2$ . A stop before sensing is also uninformative about  $j$  and obeys the same bound; it can be padded by an ignored sensing operation.

Set  $L = \lceil m/K \rceil$ . Since  $p_i \leq \max_s D(i \mid s)$ , a value  $\min_i p_i > 1/L$  would require every  $i$  to have some row  $s$  with  $D(i \mid s) > 1/L$ . Each stochastic row has at most  $L - 1$  such indices. But  $K(L - 1) < m$ . This contradiction proves the upper bound. Partition  $[m]$  into at most  $K$  fibers of size at most  $L$ , retain the fiber label after  $R$ , and choose uniformly inside that fiber. On a successful report freeze  $\{1\}$  when  $j = 0$  and  $\{0\}$  when  $j = 1$ ; on  $\perp$  freeze the empty event. The score for every  $j$  is  $1/(2|\text{fiber}(i)|)$ , proving equality. The event alphabet has three labels. Storing the event and its candidate indicator requires at most six labels, and the final difference has three. The chosen sensing action was separately charged, proving the displayed profile.

For the convexified upper bound use the uniform prior on  $(i, j)$ . For any one controller,

$$\frac{1}{m} \sum_i p_i = \frac{1}{m} \sum_{i,s} E(s \mid i) D(i \mid s) \leq \frac{1}{m} \sum_{i,s} D(i \mid s) = \frac{K}{m}.$$

The same upper bound holds for mixtures. For the matching mixture, choose uniformly one of the  $m$  cyclic intervals of  $K$  indices. For that interval hardcode a deterministic  $K$ -label encoder which routes each included index to its own sensing action, and assigns other indices arbitrarily. Each  $i$  belongs to exactly  $K$  intervals. A successful action is followed by the complementary singleton event and failure by the empty event, as above. Every fixed  $(i, j)$  has mean score  $K/(2m)$ . This proves (19).  $\square$

For example,  $V_{3,2} = 1/4$  whereas  $\bar{V}_{3,2} = 1/3$ . The mixture just constructed can be implemented with a retained interval selector and a local label, using at most  $mK$  labels at the bottleneck. It cannot be declared a  $K$ -label realization: when the displayed gap is positive, (18) proves that no such realization exists. The action buffer of size  $m$  is not part of the  $K$  coordinate and has not been omitted from the profile. The theorem is a multicut resource law, not an assertion that its uniform peak equals  $K$ .

The actions are statistically incomparable.  $R$  cannot distinguish the two values of  $j$  at any fixed  $i$ , while action  $a$  does distinguish them at  $i = a$ . For  $a \neq b$ , action  $a$  does not distinguish the pair with  $i = b$ , while  $b$  does. A parameter-independent garbling cannot create a distinction absent from its input experiment.

**Corollary 7.3** (A strict gap with positive report probabilities). *Replace each of the two training kernels by a mixture with weight  $\epsilon > 0$  of the uniform law on its report alphabet. Let  $\Delta_{m,K} = K/(2m) - 1/(2\lceil m/K \rceil) > 0$ . For  $\epsilon < \Delta_{m,K}/8$  the resulting full-support model still has a strict gap between the genuine profile-constrained value and its free-selector convexification.*

*Proof.* Each training row changes by at most  $\epsilon$  in total variation. Couple corresponding rows until the first disagreement. For any fixed controller or mixed controller the probability of such a disagreement is at most  $2\epsilon$ , and its conditional reward lies in  $[-1, 1]$ . Each of the two optimal

values changes by at most  $4\epsilon$ . Their difference is therefore at least  $\Delta_{m,K} - 8\epsilon > 0$ . All row arguments and register alphabets are unchanged.  $\square$

The distinction between mixed and behavioral strategies without perfect recall is classical; it is not first asserted here. Contemporary polynomial formulations over behavioral simplices include [16]. Theorem 7.2 evaluates the discrepancy in this specific frozen-validation experiment for every  $m, K$ , with a matching actual register and a noisy persistence statement. In particular, a single prior followed by an unrestricted policy-tree best response cannot be substituted for (16).

## 8. EXACT MINIMAX LAWS FOR A MARKED PRODUCT FAMILY

The posterior-predictive dual can be solved explicitly for a continuous family containing the collision target. Throughout this section, the training and candidate validation law is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

In the order 000, 001, 110, 111, let  $Q_\gamma$  have masses

$$((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4),$$

and zero mass elsewhere. Write  $U_1(\gamma) = U_1(b, Q_\gamma)$ , with exactly the training-validation convention of (8). Set

$$(20) \quad \gamma_* = 1 - 1/\sqrt{2}, \quad s_\gamma = \sqrt{\gamma^2 - 2\gamma + 5}, \quad u_\gamma = \gamma - 2 + s_\gamma, \quad \tau_\gamma = \frac{2u_\gamma}{u_\gamma + 2 - \gamma}.$$

**Theorem 8.1** (Exact marked minimax family). *For every  $0 \leq \gamma \leq \gamma_*$ ,*

$$(21) \quad U_1(\gamma) = \frac{3 + u_\gamma^2}{8}.$$

*An optimal response depends on the training word only through the report count  $K = X_1 + X_2$ . On the four target atoms its rows are*

$$(22) \quad h_0 = (\tau_\gamma, 0, 1, 1), \quad h_1 = (1, 1, 1, 1), \quad h_2 = (1, 1, 0, \tau_\gamma),$$

*and all responses are zero off these atoms. A least-favorable prior is*

$$(23) \quad \mu_\gamma = \frac{1}{2}\delta_{(t_\gamma, t_\gamma)} + \frac{1}{2}\delta_{(1-t_\gamma, 1-t_\gamma)}, \quad t_\gamma = \frac{1 - \sqrt{u_\gamma}}{2}.$$

*The assertion optimizes over all stochastic responses to the full marked training word, not merely over count-based or symmetric responses.*

*Proof.* First,  $u_\gamma$  is the positive root of

$$(24) \quad u^2 + (4 - 2\gamma)u - (1 + 2\gamma) = 0.$$

On the asserted interval,  $0 < u_\gamma < 1$  and  $0 < \tau_\gamma < 1$ . Indeed the polynomial is negative at zero and positive at one; also  $u_\gamma < 2 - \gamma$  because  $\gamma < 1/2$ . Substitution of  $1 - 2\gamma$  into the polynomial gives  $8(\gamma^2 - 2\gamma + 1/2)$ , which is nonnegative precisely on the present interval. Monotonicity on  $[0, \infty)$  therefore gives

$$(25) \quad u_\gamma \leq 1 - 2\gamma.$$

Put  $a = (1 - p)(1 - q)$ ,  $c = pq$ , and  $z = 1 - a - c$ . The probabilities of the three training counts are  $a, z, c$ . The independent training mark may be discarded by the displayed construction. Let  $G_\gamma(p, q)$  denote its score. With  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ , direct expansion gives

$$(26) \quad G_\gamma(p, q) - \frac{3 + u_\gamma^2}{8} = \frac{2 - \tau_\gamma}{16} \{(u - v - u_\gamma)^2 + 4v\}.$$

For clarity, this identity follows by substituting the three rows of (22) into

$$a(Q_\gamma - b)h_0 + z(Q_\gamma - b)h_1 + c(Q_\gamma - b)h_2,$$

using  $a + c = (1 + u - v)/2$ ,  $a - c = -(p + q - 1)$ , and then eliminating  $u_\gamma^2$  by (24). The coefficient of the resulting square is  $(2 - \tau_\gamma)/16$  and that of  $v$  is four times this coefficient. Both are nonnegative. Equality holds at both points of (23), since there  $v = 0$  and  $u = u_\gamma$ . This proves the lower bound and identifies its equality set.

It remains to bound every response, including nonsymmetric ones. Use (23) in Theorem 5.1. At  $t = t_\gamma$  put  $a = (1 - t)^2$ ,  $c = t^2$ , and  $T = a + c = (1 + u_\gamma)/2$ . For the training report pair 00, the four dual coefficients, apart from a common positive factor, are

$$(27) \quad \left( Q_H T - \frac{a^2 + c^2}{2}, \quad Q_L T - \frac{a^2 + c^2}{2}, \quad Q_L T - ac, \quad Q_H T - ac \right),$$

where  $Q_H = (1 + \gamma)/4$  and  $Q_L = (1 - \gamma)/4$ . The first coordinate is zero by (24); the second is  $-\gamma T/2 \leq 0$ . The last two are positive:  $T \geq 1/2$ ,  $ac \leq 1/16$ , and  $\gamma < 1/2$  imply  $Q_L T > 1/16 \geq ac$ . Thus  $(\tau_\gamma, 0, 1, 1)$  maximizes this linear functional. For the training pair 11, reversing all report bits and the mark reverses the four coordinates and gives the row  $h_2$ .

For either training pair 01 or 10, the two prior support points have the same likelihood  $t(1 - t)$ . The posterior is still equally weighted, and the candidate predictive mass at each target atom is  $T/4$ . Every one of the four coefficients is therefore nonnegative by  $Q_L - T/4 = (1 - 2\gamma - u_\gamma)/8 \geq 0$ . The response  $h_1$  is optimal. At off-diagonal validation atoms the target mass vanishes and the coefficient is nonpositive. Finally, conditioning on either training mark multiplies all these coefficients by  $1/2$ ; it creates no further optimizing choice. We have therefore optimized every coordinate of the full marked-word response space.

The prior average of the displayed response equals its value at either support point, namely  $(3 + u_\gamma^2)/8$ , by (26). Every other response has prior average at most this number and hence has minimum over fixed  $(p, q)$  at most this number. Together with the lower bound this proves (21), optimality of the response, and least favorability of the prior.  $\square$

**Corollary 8.2** (The exact one-preparation collision value). *For  $Q_* = Q_{1/4}$ ,*

$$(28) \quad U_1(b, Q_*) = u_{\text{ex}} := \frac{85 - 7\sqrt{73}}{64}, \quad u_{1/4} = \frac{\sqrt{73} - 7}{4}, \quad \tau_{1/4} = 2 - \frac{14}{\sqrt{73}}.$$

*If only the target changes to  $Q$ , then  $|U_1(b, Q) - u_{\text{ex}}| \leq \text{TV}(Q, Q_*)$ .*

*Proof.* Substitute  $\gamma = 1/4$  in Theorem 8.1. For a fixed trained response the target perturbation is at most total variation, uniformly in  $(p, q)$ . Taking first the minimum and then the maximum preserves this bound in both directions.  $\square$

**8.1. Complementary slackness and the event alphabet.** The tie in the first coordinate of (27) explains the randomization. Any value of that response coordinate is Bayes-optimal for the two-point prior. The minimax choice makes the uniform payoff stationary at its two support points; solving this condition gives  $\tau_\gamma$  and the square identity (26). This derives the prior and response together, rather than postulating that a numerically effective prior is optimal.

Operationally, for  $K = 0$  one draws once between the events with indicator vectors  $(0, 0, 1, 1)$  and  $(1, 0, 1, 1)$ , with probabilities  $1 - \tau_\gamma$  and  $\tau_\gamma$ . For  $K = 2$  one draws between  $(1, 1, 0, 0)$  and  $(1, 1, 0, 1)$ . For  $K = 1$  the event is  $(1, 1, 1, 1)$ . The resulting event identity is retained and used for both fresh validations. These are exactly the five events in the two-preparation construction below. The one-preparation theorem supplies their complementary-slackness interpretation;

it does not prove that the two-preparation selector is optimal. The four-point rational prior retained below is a useful rational certificate, not a least-favorable prior.

The exact response uses an atomic stochastic row. It does not receive free persistent randomness. Replacing  $\tau_\gamma$  by a dyadic number within  $2^{-b}$  changes each conditional response, and hence the score, by at most  $2^{-b}$ . A sequential fair-bit implementation must retain its bit prefix and event identity. None of these implementation costs is needed by the deterministic two-preparation physical audit.

**Proposition 8.3** (The zero-preparation endpoint). *For  $0 \leq \gamma \leq 1$ ,  $U_0(b, Q_\gamma) = \gamma/2$ .*

*Proof.* The fixed event  $\{000, 111\}$  has score  $(1 + \gamma)/2 - (a + c)/2 \geq \gamma/2$  because  $a + c \leq 1$ . Conversely, the equally weighted prior on  $b(0, 0)$  and  $b(1, 1)$  has predictive validation law uniform on the four target atoms. Its total variation from  $Q_\gamma$  is  $\gamma/2$ . Theorem 5.1 with  $N = 0$  gives the matching upper bound.  $\square$

## 9. A SELF-CONTAINED COLLISION INTERFACE

We give the preparation, mechanical estimate, observation law and private simulator class needed for the physical specialization. The following argument does not appeal to an unpublished physical lemma. It retains the same positive-volume preparation and positive sensor noise as the earlier collision construction.

**Definition 9.1** (The reset row–event architecture). A preparation supplies two sequential report slots and, afterwards, an actual mark. The source reports in the two slots are constant. A private width-one simulator has no retained information between those slots and no persistent hidden seed. It may use fresh independent coins. Its first emission is  $X_1 \sim \text{Ber}(p)$ ; after receiving the current gate  $A \in \{0, 1\}$ , its second emission has a fixed Bernoulli kernel with parameter  $q_A$ . The parameters  $(p, q_0, q_1)$  are fixed throughout the audit. The simulator does not observe the actual mark. All its coins are independent of that mark. Different preparations reset all unretained variables and are independent conditional on the parameters.

The auditor observes the first report, chooses a gate using its retained state and that report, observes the second report, and then observes the mark. During training it may choose rows and stop adaptively, using at most the declared number of candidate preparations. It next freezes one gate policy and one event, with any retained random choice included in its register. It uses that same row–event continuation on one fresh candidate preparation and one independent target preparation and returns the difference of their event indicators, target minus candidate. It may not reselect the event after either validation. Independent target-only calibration is allowed but all retained calibration and randomness are charged. Peak width counts every bit, mark, event and validation-accumulator cut. Clocked schedules are declared externally; an autonomous implementation must retain its phase. An unretained transcript, seed or stopping-time value is not available to a continuation.

In the all-on row the complete private law is  $b(p, q_1)$ , with an independent fair actual mark. For lower bounds it suffices to restrict the adversary to  $q_0 = 0$ ,  $q_1 = q$ . In this subfamily every deterministic gate policy is the pushforward

$$T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$$

of  $b(p, q)$ . The gate, when included in the transcript, is another function of these same coordinates. Randomized gate policies are covered by averaging their independent random tables. This proves both the all-on product characterization for the upper construction and the common-garbling subfamily used for the outer converse. The width-one constraint is a simulator constraint; it is not an uncharged restriction on the auditor’s register.

**9.1. Preparation and elastic scattering.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$ , with no walls and contact distance  $d$ . Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ ,  $V = (v_1 + v_2)/2$ , and let the center of mass position range over any fixed rational box of positive volume. Prepare  $(B, W) \in \{0, 1\}^2$  with probability  $5/16$  at  $B = W$  and  $3/16$  at  $B \neq W$ . Conditional on  $(B, W)$ , use the uniform product preparation on the following boxes:

$$(29) \quad \begin{aligned} r &= (-a_0, (2B - 1)b_0, c_0), & a_0 &\in [29/10, 31/10], & b_0 &\in [9/20, 11/20], \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & & & |V_z - (2W - 1)| &\leq 1/100. \end{aligned}$$

Thus the actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ , preserved by momentum conservation. Set

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector, identically zero on the incoming transverse-velocity range.

**Lemma 9.2** (Uniform collision signal). *For every preparation in (29) and every  $9/10 \leq d \leq 11/10$ , exactly one collision occurs and its time lies in  $(4/5, 3/2)$ . Afterwards*

$$(2B - 1)v_{1,y} > 1/2, \quad (2B - 1)h(v_{1,y}) > 1/4.$$

For  $0 < d \leq 2/5$  no collision occurs on  $[0, 3]$  and the detector is zero throughout that interval.

*Proof.* Before contact,  $r(t) = r + tg$ . At  $t \leq 4/5$  its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At  $t = 3/2$  its absolute coordinate bounds are  $1/4$ ,  $113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . The first contact therefore occurs in the claimed interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$ . Hence the entry contact has  $n_x < 0$ , where  $n = r(t_c)/d$ . Its remaining coordinates give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B - 1)n_y \geq 87/220.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The elastic rule gives

$$v_1^+ = V + g/2 - (g \cdot n)n, \quad g^+ = g - 2(g \cdot n)n.$$

Consequently

$$(2B - 1)v_{1,y}^+ > -3/200 + (1443/1000)(87/220) > 1/2.$$

The definition of  $h$  implies the signal bound. Since  $r(t_c) \cdot g^+ > 0$ , squared separation increases strictly afterwards; there is no second collision. Finally, for  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . There is no contact, and the incoming  $|v_{1,y}| \leq 3/200$  makes  $h$  zero.  $\square$

**9.2. Positive noise and the actual mark.** Let  $\mathcal{B}_t$  be Brownian motion independent of the preparation and set

$$Y_t = \int_0^t h(v_{1,y}(s)) ds + \sigma \mathcal{B}_t, \quad 0 < \sigma \leq 1/24.$$

The two potential all-on reports are

$$Z_1 = \mathbf{1}_{\{2(Y_2 - Y_{3/2}) > 0\}}, \quad Z_2 = \mathbf{1}_{\{2(Y_3 - Y_{5/2}) > 0\}}.$$

The actual second report is  $AZ_2$ . The gate changes acquisition, not the mechanical path. The continuous path is implemented by the target sensor; it is not made available to the private simulator or supplied as an uncharged auditor buffer. Denote the law of  $(Z_1, Z_2, W)$  by  $Q_{d,\sigma}$ .

**Theorem 9.3** (Uniform physical presentation). *For  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ ,*

$$(30) \quad \text{TV}(Q_{d,\sigma}, Q_*) < 1/300.$$

*The same estimate holds after every declared feedback gate, including its observable gate value. The all-on private product family and the common-garbling subfamily in Definition 9.1 apply to this very experiment.*

*Proof.* Every collision occurs before  $3/2$ . Conditional on the preparation, the two normalized sensor windows are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . Lemma 9.2 makes their means have sign  $2B - 1$  and magnitude greater than  $1/4$ . Each potential report therefore differs from  $B$  with probability less than  $\Phi(-3)$ . The Gaussian tail estimate

$$\Phi(-x) \leq \frac{e^{-x^2/2}}{x\sqrt{2\pi}}$$

gives  $\Phi(-3) < 1/600$ :  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$  suffice. Couple the ideal and noisy reports using the same preparation, actual mark and gate random table. Except on a set of probability less than  $2\Phi(-3) < 1/300$ , both potential reports equal  $B$  and the entire gated transcript agrees. The ideal marked law is precisely  $Q_*$ , by the prepared  $(B, W)$  table. This proves (30) and the feedback-uniform version. Finally, the source is blind, its actual mark is unobserved by the simulator, and the gate is its only current input at the second emission. The product and subfamily assertions follow from the two independent private-emission kernels specified above.  $\square$

For  $d \leq 2/5$ , the two windows instead contain only independent centered Gaussian noise. Their signs are independent fair bits, independent of  $W$ , and a private width-one simulator reproduces every gated row exactly. Thus the informative regime and its no-collision control use the same detector, preparation convention and actual mark.

## 10. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1 - p)(1 - q)$  and  $c = pq$ . On the ordered atoms

$$(31) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(32) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \longrightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (32). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in Definition 9.1 and Theorem 9.3, explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem 10.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (2). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(33) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

*from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.*

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

### 10.1. An exact rational certificate against one preparation.

**Lemma 10.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem 5.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (9) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (31), the signed coefficients in (9), after grouping by  $K$ , are the entries of

$$(34) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1 - p_i)^{2-k} \left( Q_{*,j} - \frac{(1 - p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (34) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (34) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ .

A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**10.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (31) and with indicator zero at every off-diagonal atom:

$$(35) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma 10.3** (Exact uniform score of the selector). *Against the ideal target, the selector (35) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (35) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(36) \quad \begin{aligned} G(p, q) = H(u, v) = & -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} \\ & + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}. \end{aligned}$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

### 10.3. Causal compilation and the full register profile.

**Lemma 10.4.** *The selector and its two validations admit the deterministic profile (33). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event-function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2 w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (35). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem 10.1.* Lemma 10.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas 10.3 and 10.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary 10.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the local microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem 10.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in Theorem 9.3; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark 10.6* (The part of the frontier determined here). The deterministic theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . Theorem 11.1 and Corollary 11.2 below additionally determine the ideal maximum score with two preparations on this width range. The least peak width at  $N = 2$  and the full boundary for  $3 \leq W \leq 11$  remain separate questions. The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and

$(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by  $(2, 12)$  in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

**Corollary 10.7** (The enlarged physical preparation segment). *With the full architecture of Definition 9.1,*

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

Here  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$  is the exact one-preparation all-on value, rather than the older rational upper bound.

*Proof.* Restrict the adversary to the common-garbling subfamily in Definition 9.1. Theorem 5.2 and Corollary 8.2 bound every at-most-one-preparation auditor, even with unlimited memory, by  $u_{\text{ex}} + \beta$ . The same deterministic two-preparation machine in Lemmas 10.3 and 10.4 has score at least  $m_2 - \beta$  against the full private candidate family. These inequalities prove the assertion. The four-preparation total, peak twelve and positive-noise specialization are unchanged.  $\square$

## 11. THE EXACT TWO-PREPARATION MARKED SADDLE

The one-preparation saddle has an exact successor. A new zero coefficient of the least-favorable predictive measure makes it necessary to randomize at the two extreme training counts. This randomization changes the value, but does not enlarge the alphabet of frozen validation events.

Let  $b(p, q)$  and  $Q_*$  be as in Section 10. Let  $r$  be the unique root in  $(1/3, 7/20)$  of

$$(37) \quad 2r^3 + 25r^2 - 3 = 0,$$

and define

$$(38) \quad \tau = \frac{6(-r^2 + 4r - 1)}{r(3r + 25)}, \quad v_2 = \frac{-r^3 + 6r^2 - 3r + 14}{32}, \quad p_{\pm} = \frac{1 \pm \sqrt{r}}{2}.$$

The polynomial in (37) is strictly increasing on the positive half-line and has opposite signs at the indicated endpoints. These observations prove the asserted existence, uniqueness and isolating interval. That interval also gives  $0 < \tau < 1$ .

**Theorem 11.1** (Exact two-preparation value). *For the full marked-word response class of (8),*

$$U_2(b, Q_*) = v_2.$$

*A least-favorable prior gives mass  $1/2$  to each of  $(p_-, p_-)$  and  $(p_+, p_+)$ . An optimal response discards the two training marks, retains the total number  $S$  of ones in the four training report bits, and uses*

$$(39) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & \tau & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & \tau \end{array}$$

*with zero response at off-diagonal validation atoms. Numerically,  $r = 0.3417694155\dots$ ,  $\tau = 0.1688236447\dots$  and  $v_2 = 0.4261127787\dots$ . The exact value is determined by (37)–(38), not by these decimals.*

*Proof.* Write  $a = (1 - p)(1 - q)$ ,  $c = pq$ ,  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ . Both  $u$  and  $v$  belong to  $[0, 1]$ . The score of the deterministic five-event selector is the polynomial  $H(u, v)$  in (36). Only counts zero and four are changed by (39). Their probabilities are  $a^2$  and  $c^2$ . Consequently the new score is

$$G(u, v) = H(u, v) + \tau J(u, v), \quad J = a^2(5/16 - a/2) + c^2(5/16 - c/2).$$

Expansion gives the polynomial identity

$$(40) \quad \begin{aligned} J(u, v) = & -\frac{u^3}{64} + \frac{3u^2v}{64} - \frac{25u^2}{128} - \frac{3uv^2}{64} + \frac{13uv}{64} \\ & + \frac{v^3}{64} - \frac{v^2}{128} - \frac{v}{32} + \frac{3}{128}. \end{aligned}$$

Thus

$$H(u, 0) = \frac{-u^3 + 6u^2 - 3u + 14}{32}, \quad J(u, 0) = \frac{3 - 25u^2 - 2u^3}{128}.$$

Equation (37) says  $J(r, 0) = 0$ , and the choice of  $\tau$  says  $\partial_u G(r, 0) = 0$ . Direct factorization, using these two identities, yields

$$(41) \quad G(u, 0) - v_2 = \frac{(u - r)^2 \{75 + 12r + 6u - 37r^2 - 74ru\}}{64r(3r + 25)}.$$

The expression in braces is strictly positive for  $0 \leq u \leq 1$ : it is at least  $75 - 37(7/20)^2 - 74(7/20) > 0$ . Moreover,

$$\partial_v H = \frac{3(u - v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}, \quad \partial_v J = \frac{3(u - v)^2 + 13u - v - 2}{64} \geq -\frac{3}{64}.$$

Because  $0 < \tau < 1$ ,  $\partial_v G \geq 11/64$  on the unit square. It follows that  $G(u, v) \geq G(u, 0) \geq v_2$ , with equality precisely when  $v = 0$  and  $u = r$ . Both equality points are feasible and are the two parameters in the asserted prior. This proves the global lower bound.

It remains to prove an upper bound against every response, not only those depending on  $S$ . Under the asserted prior the four training report bits are independent Bernoulli variables with common parameter  $p_-$  or  $p_+$ . Conditional on  $S = s$ , their arrangements and the two independent training marks have parameter-independent distributions. The signed predictive coefficients can therefore be grouped by  $S$  without restricting any response coordinate. For the four displayed validation atoms put

$$C_{s,j} = \frac{1}{2} \sum_{p \in \{p_-, p_+\}} \binom{4}{s} p^s (1 - p)^{4-s} \{Q_{*,j} - b_j(p, p)\}.$$

The first three rows of  $256C$  are

$$\begin{aligned} s = 0 : & \quad (-(2r^3 + 25r^2 - 3), -(2r^3 + 27r^2 + 12r - 1), \\ & \quad -(2r^3 - 5r^2 - 20r - 1), -(2r^3 - 7r^2 - 32r - 3)), \\ s = 1 : & \quad 4(r - 1)(2r^2 + 7r - 3, 2r^2 + 9r - 1, \\ & \quad 2r^2 - 7r - 1, 2r^2 - 9r - 3), \\ s = 2 : & \quad -6(r - 1)^2(2r - 3, 2r - 1, 2r - 1, 2r - 3). \end{aligned}$$

Rows three and four are the reversals of rows one and zero, respectively. Their signs, using  $1/3 < r < 7/20$ , are

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Every off-diagonal validation coefficient is nonpositive because its target mass is zero. Hence (39) maximizes every signed coefficient: it is one at positive coefficients, zero at negative ones, and arbitrary at the two zeros. The lower-bound equality at both prior points shows that this Bayes maximum is exactly  $v_2$ . The posterior-predictive dual, Theorem 5.1, now gives the matching upper bound for the full response class.  $\square$

**Corollary 11.2** (Exact physical score on the peak-twelve segment). *Use the atomic stochastic-row convention and the original marked interface of Definition 9.1. At two candidate training preparations, every peak budget  $W \geq 12$  has exact ideal worst-case score  $v_2$ . For a target  $Q$  with  $\text{TV}(Q, Q_*) \leq \beta$ , the corresponding value lies in  $[v_2 - \beta, v_2 + \beta]$ . In particular, with  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$ ,*

$$(42) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad u_{\text{ex}} + \beta \leq c < v_2 - \beta.$$

*Proof.* Let  $h_0, \dots, h_4$  be the five deterministic events in (35). At count zero select  $h_1$  with probability  $\tau$  and  $h_0$  otherwise; at count four select  $h_3$  with probability  $\tau$  and  $h_4$  otherwise. At the other counts retain the indicated event. Discard the count and retain the selected event for both validations. This realizes (39); the event alphabet remains five. The full charged profile, now including the separate event-selection update, is

$$(1, 2, 3, 3, 4, 5, 5, 5, 10, 12, 10, 10, 7, 3).$$

The common residual-function compiler in Lemma 10.4 applies unchanged. In particular, no persistent random selector is outside the register. The all-on law for every private candidate is  $b(p, q)$ , so Theorem 11.1 proves the constructive lower bound. For the converse restrict to the admissible common-garbling product subfamily and apply Theorem 5.2 followed by Theorem 11.1. This bounds all architectures, including those using feedback, stopping and more memory. Target perturbation changes each frozen-event expectation by at most  $\beta$ . Finally the exact one-preparation theorem excludes a strict score above  $c$  at  $N \leq 1$ , whereas the displayed machine achieves it at  $N = 2$  under (42).  $\square$

The root  $r$  is larger than  $2 - \sqrt{3}$ . The old diagonal polynomial  $H(u, 0)$  is strictly increasing between these points, whence  $v_2 > m_2$ . The deterministic theorem, including its zero-random-bit implementation, remains valid; the new exact score uses an additional stochastic row.

**Proposition 11.3** (Finite precision for the new row). *Replacing  $\tau$  by a dyadic  $\tau_b = k/2^b \in [0, 1]$  with  $|\tau_b - \tau| \leq 2^{-b}$  loses at most  $(5/16)2^{-b}$  in uniform score. A clocked fair-bit implementation uses  $b$  extra random bits and at most  $\max\{12, 6(b+1) + 5\}$  persistent states, including their phase, in addition to the unchanged preparation count.*

*Proof.* At each affected training word the response changes at a single atom;  $|5/16 - a/2|$  and  $|5/16 - c/2|$  are at most  $5/16$ . The two affected word probabilities sum to at most one. This gives the score estimate. To implement the dyadic coin, compare  $b$  fresh fair bits lexicographically with the fixed  $b$ -bit integer  $k$ . Retain the origin (count zero or four), one of the three comparison flags, and a phase in  $\{0, \dots, b\}$ . Once the comparison ends retain its chosen one of five events. Unaffected counts can wait in their event states. These states total at most  $6(b+1) + 5$ ; the other cuts have peak twelve. The cases  $k = 0, 2^b$  are deterministic. Exact atomic randomization and a finite fair-bit implementation are therefore distinct resource claims.  $\square$

## 12. A CONTINUOUS TWO-PREPARATION MARKED FAMILY

The preceding saddle persists on an explicit interval of target laws, with exact rather than perturbative values. Use the target  $Q_\gamma$  from Section 8 and write  $U_2(\gamma) = U_2(b, Q_\gamma)$ .

**Theorem 12.1** (A two-preparation saddle family). *For  $6/25 \leq \gamma \leq 13/50$ , let  $r_\gamma$  be the unique root in  $(1/3, 7/20)$  of*

$$(43) \quad f_\gamma(r) = r^3 + (13 - 2\gamma)r^2 + (3 - 12\gamma)r - (1 + 2\gamma) = 0.$$

Set

$$D_\gamma(r) = 3r^2 + (26 - 4\gamma)r + 3 - 12\gamma, \quad t_\gamma = -\frac{2\{3r_\gamma^2 + (8\gamma - 14)r_\gamma + 3\}}{D_\gamma(r_\gamma)}.$$

Then  $0 < t_\gamma < 1$ , and

$$(44) \quad U_2(\gamma) = \frac{-r_\gamma^3 + (7 - 4\gamma)r_\gamma^2 - 3r_\gamma + 13 + 4\gamma}{32}.$$

The response (39), with  $\tau = t_\gamma$ , is optimal. A least-favorable prior gives equal masses to the two diagonal parameters  $p = q = (1 \pm \sqrt{r_\gamma})/2$ . The response has the same five-event, peak-twelve atomic realization. At  $\gamma = 1/4$  these formulas reduce to Theorem 11.1.

*Proof.* For brevity write  $r = r_\gamma$ ,  $D = D_\gamma(r)$  and  $t = t_\gamma$ . The derivative  $D_\gamma$  is positive on the rectangle  $\gamma \in [6/25, 13/50]$ ,  $r \in [1/3, 7/20]$ . For example its lower bound is  $1/3 + (26 - 52/50)/3 - 3/25 > 8$ . The polynomial  $f_\gamma$  decreases with  $\gamma$  at a fixed positive argument. Direct rational evaluations give  $f_{6/25}(1/3) < 0$  and  $f_{13/50}(7/20) > 0$ . Monotonicity therefore gives the root and its uniqueness in this interval. The numerator of  $t$  is  $-16\gamma r - 6r^2 + 28r - 6$ . It is bounded below by  $28/3 - 6 - 16(13/50)(7/20) - 6(7/20)^2 > 0$ , and above by  $28(7/20) - 6 < 4 < D$ . Thus  $0 < t < 1$ .

Let  $H, J$  be the polynomials from (36) and (40). Changing the target masses linearly in  $\gamma$  gives

$$\begin{aligned} H_\gamma(u, v) &= H(u, v) + (\gamma - 1/4) \frac{1 - (u - v)^2}{8}, \\ J_\gamma(u, v) &= J(u, v) + (\gamma - 1/4) \frac{(u - v)^2 + 6u - 2v + 1}{32}. \end{aligned}$$

The response's full-parameter score is  $G_\gamma = H_\gamma + tJ_\gamma$ . One has  $J_\gamma(r, 0) = -f_\gamma(r)/64 = 0$  and  $\partial_u G_\gamma(r, 0) = 0$ . Algebraic division gives

$$(45) \quad G_\gamma(u, 0) - H_\gamma(r, 0) = \frac{(u - r)^2 A_\gamma(r, u)}{16D},$$

where

$$\begin{aligned} A_\gamma(r, u) &= 24\gamma^2 + (3\gamma - 10)r^2 + (6\gamma - 20)ru \\ &\quad + 12\gamma r + 6\gamma u - 51\gamma + 30. \end{aligned}$$

For  $0 \leq u \leq 1$  this is at least  $30 - 10(7/20)^2 - 20(7/20) - 51(13/50) > 0$ . The transverse derivatives satisfy

$$\begin{aligned} 32\partial_v H_\gamma &= 3(u - v)^2 + (8\gamma - 10)u + (6 - 8\gamma)v + 15 \geq 5, \\ 64\partial_v J_\gamma &= 3(u - v)^2 + (14 - 4\gamma)u + (4\gamma - 2)v - 4\gamma - 1 \geq -3 \end{aligned}$$

on  $0 \leq u, v \leq 1$ . Consequently  $\partial_v G_\gamma \geq 7/64$ . Equation (45) proves a lower bound  $H_\gamma(r, 0)$ , with equality precisely at the proposed prior points. This quantity is the right side of (44).

For the upper bound group the full training words by  $S$ , as in the preceding theorem. Put  $L(r) = r^2 + 6r + 1$ . Using  $f_\gamma(r) = 0$ , the first three rows of  $256C$  are

$$\begin{aligned} 0 : & (0, -8\gamma L(r), 32r(r+1) - 8\gamma L(r), 32r(r+1)), \\ 1 : & 8(r-1)(r^2 + 4r - 1 - 2\gamma(r+1), \\ & \quad r^2 + 4r - 1 + 2\gamma(r+1), \\ & \quad r^2 - 4r - 1 + 2\gamma(r+1), r^2 - 4r - 1 - 2\gamma(r+1)), \\ 2 : & -12(r-1)^2(r-1-2\gamma, r-1+2\gamma, r-1+2\gamma, r-1-2\gamma). \end{aligned}$$

The other rows are their reversals. The sign pattern is again

$$(0, -, +, +), \quad (+, -, +, +), \quad (+, +, +, +), \quad (+, +, -, +), \quad (+, +, -, 0).$$

Here are explicit interval checks for the potentially small margins. In row zero the third coordinate is bounded below by  $32(1/3)(4/3) - 8(13/50)((7/20)^2 + 6(7/20) + 1) > 0$ . The first parenthesis of row one is at most  $(7/20)^2 + 4(7/20) - 1 - 2(6/25)(4/3) < 0$ ; the third is at most  $(7/20)^2 - 4/3 - 1 + 2(13/50)(27/20) < 0$ . The second parenthesis is positive already from  $r > 1/3$  and  $\gamma > 0$ , and the fourth is negative. Finally  $r - 1 + 2\gamma \leq -13/100 < 0$ . All off-diagonal validation coefficients are nonpositive. Thus the stated response is a Bayes best response for this prior, including its two zero coefficients. Its score at both supporting parameters equals the lower bound. The full posterior-predictive dual proves (44).  $\square$

This interval is a uniform certificate region for the displayed saddle, not a claim that the same masks remain optimal for every mark bias. The theorem supplies a continuous family at genuinely growing training history  $N = 2$ ; it does not infer a recurrence for every  $N$  from the one-preparation formulas.

### 13. AN EXACT PREPARATION-DECISION-MEMORY LAW

A second solvable family separates a genuine joint resource law from an implementation bound. Here the memory coordinate is the number of states at the training-validation cut. It is not identified with the bit-level peak width of the collision audit.

Fix  $m = 2^d$ ,  $0 < \alpha < 1$ , and an unknown parameter  $\theta \in \{1, \dots, m\}$ . A fresh training preparation reports  $\theta$  with probability  $\alpha$  and an erasure  $\perp$  otherwise. Conditional on  $\theta$ , the preparations are independent. Candidate validation has law  $\delta_\theta$  and target validation is uniform on  $\{1, \dots, m\}$ . At the decision cut the auditor retains at most  $K = 2^k$  states,  $0 \leq k \leq d$ . Its subsequent response may depend only on that state, current validation observations and fresh independent randomness. In particular, a calibration table, remembered seed or stopping time outside the retained state is not available. Upstream and downstream memory are otherwise unrestricted for the converse. Let  $V_N^{\text{er}}(K)$  be the best worst-case expected signed validation score with at most  $N$  training preparations.

**Theorem 13.1** (Exact joint law). *For every  $N \geq 0$  and  $K = 2^k \leq m$ ,*

$$(46) \quad V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N) \left(1 - \frac{1}{K}\right).$$

*The converse covers stochastic encoders and arbitrary legal stopping. The value is attained by a clocked machine with  $K$  training states. With atomic preparation and validation outcomes, the complete audit has peak at most  $\max\{2K, 3\}$  and uses at most  $N + 2$  preparations.*

*Proof.* Write  $q = (1 - \alpha)^N$  and pre-generate  $N$  potential training reports. A stopped auditor ignores the unused reports; this does not disclose extra information to it. On the event that all

$N$  reports are erasures, its retained-state law  $r = (r_j)_{j=1}^K$  is independent of  $\theta$ . After padding any smaller register with unused states, its channel to the decision register has the form

$$(47) \quad C(j \mid \theta) = qr_j + (1 - q)S(j \mid \theta)$$

for a stochastic channel  $S$ . This identity remains valid with randomized stopping and randomized state updates.

Use the uniform prior on parameters as an upper certificate. The part  $qr_j$  has zero expected score for every response: averaging  $\delta_\theta$  under this prior gives the target itself. For the other part, optimizing over all responses gives a convex function of  $S$ , a sum of positive parts of linear functions. Every stochastic channel is a convex combination of deterministic channels  $j = g(\theta)$ ; therefore its value is at most the largest deterministic-channel value. This convexification is used only to bound a channel. It does not presuppose that a mixture of width- $K$  machines is realizable at width  $K$ .

If the fibers of  $g$  have sizes  $n_1, \dots, n_K$ , a nonempty fiber has posterior uniform on that fiber, so its total variation from the uniform target is  $1 - n_j/m$ . The prior-averaged optimal score is

$$\sum_j \frac{n_j}{m} \left(1 - \frac{n_j}{m}\right) = 1 - \sum_j (n_j/m)^2 \leq 1 - 1/K.$$

Empty fibers contribute zero. Cauchy–Schwarz proves the inequality. This is an upper bound on the average score and hence on its minimum over fixed parameters. Multiplying by  $1 - q$  proves the upper bound in (46).

For attainment, partition the parameter alphabet into  $K$  equal groups and let  $g(\theta)$  denote its group. Initialize the register uniformly on the  $K$  group labels. On an erasure leave it unchanged; on a revealed parameter overwrite it by  $g(\theta)$ . No extra “revelation occurred” flag is needed. At the decision cut its law is  $q \text{Unif}[K] + (1 - q)\delta_{g(\theta)}$ . For register  $j$ , freeze the event which is the complement of group  $j$ . On a revelation its score is  $1 - 1/K$ . Under a uniformly random initial label, the mean score is zero for each fixed  $\theta$ : one of the  $K$  labels has score  $1 - 1/K$  and the others have score  $-1/K$ . This proves the exact worst-case value.

The  $k$  initialization bits can be accumulated in the  $K$ -state register; all earlier prefix counts are at most  $K$ . Thus no persistent seed lies outside it. Candidate validation retains the group label and its event indicator, using at most  $2K$  states. Target validation produces one of the three values  $-1, 0, 1$ . This proves the atomic-outcome peak bound. The controller uses a declared external schedule; an autonomous stopping implementation must additionally retain its phase. A phase-tagged implementation is finite, but its cost is not included in  $K$ .  $\square$

**Corollary 13.2** (Thresholds and matching resource scales). *For  $K \geq 2$  and  $0 \leq c < 1 - 1/K$ , the least integer number of training preparations giving a score strictly greater than  $c$  is*

$$(48) \quad N_c^{\text{er}}(K) = \left\lceil \frac{\log(1 - c/(1 - 1/K))}{\log(1 - \alpha)} \right\rceil + 1.$$

*If  $c \geq 1 - 1/K$ , no finite  $N$  suffices. For  $0 < \varepsilon < 1$ , achieving  $V_N^{\text{er}}(K) \geq 1 - \varepsilon$  requires*

$$K \geq \varepsilon^{-1}, \quad N \geq \frac{\log(1/\varepsilon)}{-\log(1 - \alpha)}.$$

*Conversely, whenever an allowed  $K \leq m$  satisfies  $K \geq 2/\varepsilon$ , the choice  $N \geq \log(2/\varepsilon)/[-\log(1 - \alpha)]$  suffices.*

*Proof.* The strict threshold is equivalent to  $(1 - \alpha)^N < 1 - c/(1 - 1/K)$ . Since the denominator logarithm is negative, the least integer satisfying this strict inequality is (48), including equality

cases of the real quotient. Also

$$1 - V_N^{\text{er}}(K) = q + (1 - q)/K.$$

This is at least  $q$  and at least  $1/K$ , and is at most  $q + 1/K$ . These three inequalities prove the necessary and sufficient bounds.  $\square$

The exact law concerns an entire  $(N, K, \alpha, m)$  family, not a single finite diagnostic. Its mechanism is a parameter-independent erasure component followed by the convex geometry of the decision channel. It demonstrates how a preparation obstruction and a memory obstruction can be matched in one theorem. It does not identify the least physical peak width at two collision preparations. Encoding the  $m$ -symbol reports bit by bit also introduces cuts not present in this atomic model; the physical bit-level accounting is given separately.

#### 14. INTEGER MEMORY AND THE FAILURE OF A NAIVE PARTITION FORMULA

The divisibility assumptions in Theorem 13.1 can be removed, but a balanced-partition Bayes bound must not be mistaken for a minimax equality when a persistent random partition is not free. This distinction leads to another exact finite-resource transition.

Keep the revelation interface, but allow any integers  $m \geq 2$  and  $1 \leq K \leq m$ . Put  $\rho = 1 - (1 - \alpha)^N$ , and denote the genuine  $K$ -label minimax value by  $V_{N,m}^{\text{er}}(K)$ . Write  $m = Kq + s$ ,  $0 \leq s < K$ , and set

$$(49) \quad B_{m,K} = 1 - \frac{(K - s)q^2 + s(q + 1)^2}{m^2}.$$

Here and below all-erasure initialization randomness is a state initialization, not an unrecorded seed used again at validation.

**Proposition 14.1** (Arbitrary integer alphabet bounds and low-reveal equality). *The optimal uniform-prior Bayes score is  $\rho B_{m,K}$ . The minimax value satisfies*

$$(50) \quad V_{N,m}^{\text{er}}(K) \leq \min \left\{ \rho B_{m,K}, 1 - \frac{\lceil m/K \rceil}{m} \right\}.$$

*If  $\rho \leq m/(m + s)$ , equality with the first term holds. At perfect revelation  $\rho = 1$  the exact value is the second term. In particular, when  $s > 0$  the uniform-prior Bayes optimum at perfect revelation is strictly larger than the minimax value.*

*Proof.* The all-erasure decomposition (47) holds without any divisibility condition. Its parameter-independent part has zero uniform-prior score. Optimizing the other part over responses gives a convex function of its stochastic channel. A deterministic channel with fiber sizes  $n_j$  has Bayes score  $1 - \sum_j (n_j/m)^2$ . If two nonempty fiber sizes differ by at least two, moving one index from the larger to the smaller strictly decreases the sum of squares. Allowing empty fibers and repeating gives sizes  $q$  and  $q + 1$ , proving the Bayes bound. It is attained by this partition and its complementary events, with any parameter-independent initialization. This proves the first upper bound as well as the asserted Bayes optimum.

For perfect revelation, fix any  $K$  response vectors. For each known parameter choose a response maximizing its score; this deterministic assignment cannot decrease any parameter's payoff, even when the original encoder was randomized. Some assigned fiber has size at least  $\lceil m/K \rceil$ . Averaging its parameters, the score of their common response is at most the total variation between the uniform target and the uniform law on that fiber, namely  $1 - \lceil m/K \rceil/m$ . The minimum is no larger. Balanced fibers with their complementary events attain the resulting upper bound. A perfectly informed encoder can simulate any less informative encoder, so this is an upper bound at every  $\rho$ .

For the low-reveal equality let balanced fibers have weights  $w_j = n_j/m$ . When  $\rho < 1$ , initialize their label register with probabilities

$$(51) \quad r_j = \frac{\rho w_j + (1 - 2\rho)/K}{1 - \rho}.$$

These sum to one, and are nonnegative precisely throughout the stated range: the smallest numerator is  $\rho q/m + (1 - 2\rho)/K$ . On a revealed parameter overwrite the label by its fiber; on erasure do nothing. No revelation flag is retained. For a parameter in fiber  $i$ , the complementary-event score is

$$\begin{aligned} g_i &= \rho(1 - w_i) + (1 - \rho) \left( r_i - \sum_j r_j w_j \right) \\ &= \rho \left( 1 - \sum_j w_j^2 \right) = \rho B_{m,K}. \end{aligned}$$

This matches the upper bound uniformly in the fixed parameter. If  $\rho = 1$  and  $s = 0$ , the deterministic revealed label already attains that value, so the singular denominator in (51) is not used. Finally, with unequal balanced fibers the weighted average of their sizes is strictly smaller than the largest size; equivalently  $B_{m,K} > 1 - \lceil m/K \rceil/m$ . This proves the last assertion.  $\square$

**Theorem 14.2** (The complete two-label revelation law). *For every  $m \geq 2$ , every  $N \geq 0$ , and  $0 < \alpha < 1$ , set  $w = \lfloor m/2 \rfloor/m$  and  $b = \lceil m/2 \rceil/m$ . Then*

$$(52) \quad V_{N,m}^{\text{er}}(2) = \min\{2wb\rho, w\}, \quad \rho = 1 - (1 - \alpha)^N.$$

*The same formula holds at the limiting endpoints  $\rho = 0, 1$ . For odd  $m$  it changes regime at  $\rho = m/(m + 1)$ ; for even  $m$  it reduces to  $\rho/2$ . The attaining machine uses two training labels, a frozen two-event alphabet, and atomic peak at most four.*

*Proof.* Proposition 14.1 gives the upper bound and its attainment for  $\rho \leq 1/(2b)$ . Above this threshold, partition into fibers of weights  $w, b$  and initialize deterministically in the larger fiber's label. Continue to overwrite on a reveal and leave the state unchanged on an erasure. A parameter in the larger fiber has score  $w$ ; a parameter in the smaller fiber has score  $(2\rho - 1)b$ . The latter is at least  $w$  exactly when  $\rho \geq 1/(2b)$ . This attains the second upper bound. For even  $m$  the threshold is one, so the low-reveal construction suffices. The endpoint  $\rho = 0$  may instead freeze a constant event. Candidate validation retains the selected label and its indicator, with at most four states; target validation produces the difference. Initialization is atomic randomization when its probabilities are not dyadic.  $\square$

For example,  $m = 3, K = 2$  gives  $V_{N,3}^{\text{er}}(2) = \min\{4\rho/9, 1/3\}$ , rather than  $4\rho/9$  for all  $\rho$ . The balanced-integer expression is therefore not the unqualified replacement of the divisible minimax formula. For  $K \geq 3$  outside the low-reveal range, (50) remains a bound rather than an asserted equality. The compatible dynamic formulation of Section 7 retains the exact optimization in that regime. These results strengthen the revelation example without identifying its decision-cut coordinate with the collision model's bit-level peak.

## 15. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows,

and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r-1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(53) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma 15.1** (Causal interpretation of the coefficients). *Every coefficient in (53) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (53) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem 15.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_\theta g_\theta(q^C), \quad u_C = \min_\theta \max_\alpha b_{\theta,C,\alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(54) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_\alpha (u_C - b_{\theta_C,C,\alpha}) B_\alpha(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients*

and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (53) implies

$$\min_{\theta} g_{\theta}(q) \leq \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma 15.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (54). Choose  $\theta_C$  attaining the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

*Remark 15.3.* The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem 5.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

## 16. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [6]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma 16.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-} (L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem 16.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(55) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(56) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma 16.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ , and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (56).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_\pm^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ . Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_\pm^n(i, \cdot), \pi_\pm) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (56). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (55). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (56) is an observation time at which an external analyst reads the autonomous

machine, not a free input clock used by its transitions. The adversarial model of [10] is not covered by the independent-report proof above.

#### 17. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary 17.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\bar{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\bar{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\bar{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding's inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition 17.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (9); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem.

This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

## 18. A SHARPENED PHYSICAL CONSUMER AND ITS SIMULATION BUDGET

The exact two-preparation theorem has a downstream use with explicit hypotheses, rather than a merely renamed dependency arrow. It sharpens the mean margin of a raw-interface confidence test, and the causal morphism theorem transfers that test, with its full memory and calibration costs, to another executable interface.

**Theorem 18.1** (Confidence and transported resource certificate). *Let  $Q$  be a physical marked target with  $\text{TV}(Q, Q_*) \leq \beta$ . Use the two-preparation event selector with a dyadic coin  $\tau_b$  satisfying  $|\tau_b - \tau| \leq 2^{-b}$ , and put*

$$a_b = v_2 - \beta - \frac{5}{16}2^{-b}, \quad W_b = \max\{12, 6(b+1) + 5\}.$$

*If  $0 < c < a_b$ ,  $R$  independent four-preparation blocks, followed by the test  $\bar{D}_R > c$ , have error bounds*

$$(57) \quad \sup_{\text{private}} \mathbb{P}(\bar{D}_R \leq c) \leq \exp\{-R(a_b - c)^2/2\},$$

$$(58) \quad \sup_{\text{equal}} \mathbb{P}(\bar{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*They use  $4R$  preparations, at most  $bR$  fresh random bits, and at most  $W_b(2R+1)$  persistent states under a clocked schedule. With an exact atomic coin, replace  $a_b, W_b$  by  $v_2 - \beta, 12$ .*

*Suppose a source interface simulates this entire repeated audit under Theorem 3.4, uniformly over the private and equal-law families, with path defect  $\Delta_R$ . Then the corresponding source error bounds are the right sides of (57)–(58) plus  $\Delta_R$ , capped at one. At aligned cuts its state bound is  $C_{\text{cal}}R_tM_tW_b(2R+1)$ , and its preparation count is  $N_{\text{cal}}$  plus all source calls required to supply the  $4R$  audit preparations. Calibration is acquired and retained, not supplied as a free real-valued table.*

*Proof.* Corollary 11.2 and Proposition 11.3 give mean block score at least  $a_b$  under every fixed private parameter. Independent fresh preparations and independent coins give independent block scores in  $[-1, 1]$ . Hoeffding's inequality proves (57). Under the equal-law null, conditional on training and the frozen event, the two validation indicators have the same mean. Each block therefore has mean zero, proving (58) by the same inequality. Retain the integer sum in  $\{-R, \dots, R\}$  alongside the current block register. Updating the sum and resetting the block is a deterministic boundary operation. This proves the raw resource bounds.

Apply Theorem 3.4 to the whole repeated experiment, including its stopping and validation fields. Its defect bound applies to each of the two terminal error events, whose indicators have range one; each probability therefore changes by at most  $\Delta_R$ , not  $2\Delta_R$ . The same theorem gives the state product and preparation count. The source blocks need not be independent after a shared calibration stage: independence was used only for the reference audit, and path-law comparison transfers its final event probability.  $\square$

The first part uses the exact saddle, the original microscopic bridge and the compiled residual machine. The second additionally needs the uniform acquired causal simulation theorem. A source which does not satisfy that theorem's stability and calibration hypotheses is not covered. Likewise this consumer supplies no reverse simulation and therefore does not transfer an optimal-width lower bound to an arbitrary source. It is an actual conditional theorem interface for

subsequent models, not an assertion that the independent geometric A2 chain or the unbounded B4/C2 operator obligations have already been discharged.

## 19. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section 15 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section 16 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (34), polynomial identity (36), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: CONTROLLED EXPERIMENT DUALITY AND EXACT MARKED MINIMAX LAWS

QIAN QI

**ABSTRACT.** We study finite-resource statistical comparison when training operations are chosen causally and a validation test is frozen before fresh candidate and target preparations. For finite controlled experiments with a compact parameter space, we prove an architecture-uniform posterior-predictive dual in which action choice remains inside a Bellman recursion and the adversarial prior is chosen only once. The actions need not be garblings of a common experiment. We solve the one-preparation minimax problem for a continuous family of marked product experiments, identifying both an optimal response and a two-point least-favorable prior by an explicit sum-of-squares identity. For the collision target the exact value is  $(85 - 7\sqrt{73})/64$ . Combined with a deterministic two-preparation audit, this gives an enlarged exact preparation segment at every peak width at least twelve. The microscopic collision and positive-noise bridge are proved within the article. A separate revelation family has the exact joint law  $(1 - (1 - \alpha)^N)(1 - 1/K)$  for preparations and decision memory. Compatible finite-architecture certificates and a priced classical autonomous comparison complete the resource analysis.

## 1. INTRODUCTION

A statistical experiment determines not only which decisions can be made, but which observations and retained continuations are required to make them. In a controlled experiment, an action may change the information available at the next preparation. In a finite-memory experiment, retaining one continuation may preclude retaining another. A resource theorem must distinguish these two constraints rather than replace both by optimization within one chosen execution graph.

We consider an unknown parameter fixed throughout an audit. Training preparations are conditionally independent draws from causally selected experimental rows. The auditor then freezes a validation design and an event and compares fresh candidate and target draws through that event. All persistent randomness, report buffers and validation accumulators belong to the register. This model separates the simulator's resources from those of its auditor and keeps the mark of the actual preparation inside the statistical comparison.

The first result is a controlled posterior-predictive dual (Theorem 4.1). Its state is an unnormalized posterior measure together with the legal protocol state. At the terminal step, optimization over an event gives a positive-part functional, equivalently a posterior-predictive total variation. Earlier steps optimize the causal experimental action. One minimization over initial priors yields the exact unrestricted-memory minimax value. Every such prior, or a Bellman supersolution, gives a converse uniform over admissible finite-memory architectures. The common-dominating-row theorem becomes a specialization in which the experimental choice can be removed. The controlled formulation also applies when the available actions are statistically incomparable. A strict adaptive advantage persists under full-support perturbations (Proposition 4.4).

Our principal explicit minimax calculation concerns the product family  $b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2)$  and targets  $Q_\gamma$  on the four marked diagonal atoms. For  $0 \leq \gamma \leq 1 - 1/\sqrt{2}$ , put

$$u_\gamma = \gamma - 2 + \sqrt{\gamma^2 - 2\gamma + 5}.$$

Theorem 5.1 gives

$$U_1(b, Q_\gamma) = (3 + u_\gamma^2)/8.$$

The optimal response and least-favorable prior are explicit. Their matching is certified over the entire parameter square by a square identity, not by an optimization grid. The endpoint of the displayed  $\gamma$  interval is the point where a posterior response coefficient changes sign. The zero-preparation value is also exact. At the physical mark bias  $\gamma = 1/4$  the one-preparation value is

$$u_{\text{ex}} = (85 - 7\sqrt{73})/64.$$

This resolves the optimization problem hidden behind the earlier rational one-preparation certificate.

The physical consequence uses the same marked collision experiment, not a surrogate alphabet with a different cost convention. Define

$$(1) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

The older rational bound  $u_1$  remains a valid explicit certificate. The exact value  $u_{\text{ex}}$  improves it. We prove

$$(2) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{for} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

Here  $N$  counts candidate training preparations, and one candidate and one target validation are charged in addition. The upper construction is deterministic and has the complete bit-level profile  $(1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$ . Definition 6.1 and Theorem 6.3 prove locally every interface and physical approximation fact used in this deduction. Equation (2) is sharp in preparation count on its stated width range; it does not assert width optimality at two preparations or an exact value of  $U_2$ .

A different theorem determines both coordinates in a revelation family. With reveal probability  $\alpha$ ,  $N$  preparations and  $K$  retained decision states, Theorem 8.1 proves

$$V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N)(1 - 1/K).$$

The converse allows every stochastic encoder and legal stopping rule; the matching machine requires no uncharged revelation flag. The formula yields exact strict thresholds and matching sample and state scales. The memory coordinate here is a decision-cut width, not the collision machine's bit-level peak. Keeping those coordinates distinct is part of the resource theorem.

For a specified finite architecture, compatible occupation arrays retain all common-row constraints, including autonomous row reuse. The subdivision theorem gives an explicit  $HS/m$  certification error with controlled row-block degree. These are effective finite-architecture certificates, not a sharp universal complexity law. We also retain a resource-accounted autonomous binary comparison whose stationary formula is classical. None of these auxiliary results replaces the exact minimax or physical arguments.

**1.1. Relation to earlier work.** The comparison and minimax mechanisms are classical [2, 3]. Finite-horizon belief-state control and piecewise-linear value functions are established in [1]. Our controlled dual uses these mechanisms with a fixed adversarial parameter, frozen validation and explicit causal resource accounting. It is not a claim to have invented belief-state control or the minimax theorem. The exact marked-family saddle points, their equality certificate and their physical use are stated separately from these general mechanisms.

Polynomial stochastic-policy formulations and positivity certificates have substantial antecedents [4, 5]. Finite-memory testing, randomization and time-invariant rules are treated in [6, 7, 8, 9]. The stationary formula in Section 10 is explicitly attributed to Hellman and Cover. The May 2026 work of Managoli and Prabhakaran [10] treats memory-constrained adversarial binary hypothesis testing, including randomized time-invariant machines and adaptive distribution choices. Its objective and adversarial mechanism differ from the fixed-parameter, training-validation score here. No general priority for randomized state savings is asserted.

Norberg's filtered comparison [11] belongs to the surrounding comparison theory. We make no non-overlap or originality claim about that general theory without a proof-level comparison of the original paper. The novelty claims under consideration are the explicit theorems and resource realizations proved here, not an asserted absence of filtered-experiment predecessors.

**1.2. Organization and preserved development.** We first fix the architecture and common-row framework, then prove the controlled dual and exact marked minimax law. The physical bridge and charged two-preparation construction give (2). The joint revelation law, finite-architecture certification and autonomous comparison follow. Complete mathematical volumes retain the unaltered predecessor article and development, including the general continuation, Gaussian transport and historical pipeline proofs [12]. These remain mathematical content, not substitutes for a proof in the present article. The independent A2 geometric chain and

the original B4 and broad C2 obligations are not claimed to follow from the finite statistical theorems alone.

## 2. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition 2.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{s_r}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller's random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(3) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition 2.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (3) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row. Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section 9 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

### 3. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(4) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z)(Q - P_\theta)h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem 3.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(5) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_\theta^{\otimes N}(z) \{Q(\omega) - P_\theta(\omega)\} d\mu(\theta) \right]_+$$

$$(6) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_\mu(z) \text{TV}(Q, \bar{P}_\mu(\cdot | z)).$$

Here  $m_\mu(z) = \int P_\theta^{\otimes N}(z) d\mu(\theta)$  and, when  $m_\mu(z) > 0$ ,

$$\bar{P}_\mu(\omega | z) = \frac{\int P_\theta^{\otimes N}(z) P_\theta(\omega) d\mu(\theta)}{m_\mu(z)}.$$

A zero-mass term in (6) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (4) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [3] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (5). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_\mu(z)$  it equals  $m_\mu(z)(Q - \bar{P}_\mu(\cdot | z))$ , proving (6). If  $m_\mu(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem 3.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_\theta$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^\Omega$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (4). This proves the upper bound for the union of all architectures. Conversely,

retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (4).  $\square$

*Remark 3.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_\theta^{\otimes N} d\mu(\theta)$ , not  $(\int P_\theta d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (6) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary 3.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (5) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (5) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory's theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

#### 4. CONTROLLED EXPERIMENTS WITHOUT A DOMINATING ACTION

The reduction to one dominating row is not needed for a statistical dual, provided causal action choice is retained in the dual recursion. We give the finite-action theorem with a compact parameter space and an explicit protocol state. Its equality is an unrestricted-memory statement; its upper certificates apply to every smaller-memory class.

Let  $\Theta$  be compact metric and  $E$  a finite set of protocol states. At  $e \in E$  let  $\mathcal{A}_e$  be a finite set of training actions. Action  $a$  produces  $x$  in a finite alphabet  $X_a$  with law  $P_\theta^a$  and changes the protocol state to  $T(e, a, x)$ . The functions  $\theta \mapsto P_\theta^a(x)$  are continuous. An unknown  $\theta$  is fixed throughout the experiment. Conditional on it, each requested preparation uses a fresh independent draw from the selected row. Legal validation designs form a nonempty finite set  $\mathcal{B}_e$ . Design  $b$  has a finite outcome alphabet  $Y_b$ , target law  $Q^b$  and continuous candidate law  $V_\theta^b$ . A policy may stop after at most  $N$  training actions. It then freezes  $b \in \mathcal{B}_e$  and an event on  $Y_b$ , before one candidate and one target validation. Randomization is independent of  $\theta$ . No training action is assumed to dominate another.

For a finite nonnegative measure  $\nu$  on  $\Theta$  write  $\nu_{a,x}(d\theta) = P_\theta^a(x)\nu(d\theta)$  and set

$$(7) \quad \Phi_e(\nu) = \max_{b \in \mathcal{B}_e} \sum_{y \in Y_b} \left[ Q^b(y)\nu(\Theta) - \int V_\theta^b(y) d\nu \right]_+,$$

$$F_0(e, \nu) = \Phi_e(\nu),$$

$$(8) \quad F_n(e, \nu) = \max \left\{ \Phi_e(\nu), \max_{a \in \mathcal{A}_e} \sum_{x \in X_a} F_{n-1}(T(e, a, x), \nu_{a,x}) \right\}.$$

If no training action is legal, only the stopping term is retained. All the functions vanish at the zero measure, so no posterior division is required on null histories. For positive mass, (7) is the mass times the largest posterior-predictive total variation.

**Theorem 4.1** (Controlled posterior-predictive dual). *Let  $\mathcal{U}_N(e_0)$  be the maximum worst-case expected validation score over all randomized causal policies in the declared protocol, with at most  $N$  training preparations and no memory cap. Then*

$$(9) \quad \mathcal{U}_N(e_0) = \min_{\mu \in \mathcal{P}(\Theta)} F_N(e_0, \mu).$$

*Both extrema are attained. Each  $F_n(e, \cdot)$  is the maximum of finitely many continuous linear functionals on the cone of measures; in particular it is convex, continuous and positively homogeneous. For every prior  $\mu$ ,  $F_N(e_0, \mu)$  bounds the worst-case score of every finite-memory architecture implementing this protocol.*

*Proof.* There are finitely many histories of length at most  $N$  and finitely many event masks at each stopping history. Consequently there are finitely many deterministic policy trees, denoted by  $\Pi_N(e_0)$ . For  $\pi \in \Pi_N(e_0)$  its payoff  $g_\pi(\theta)$  is a finite sum of finite products of continuous primitive probabilities and is continuous in  $\theta$ .

A randomized causal policy induces the same outcome laws as a probability distribution on these trees: sample its finite random decision table in advance and condition on it. Conversely, with no memory cap, a sampled tree can be retained and followed. Thus the unrestricted payoff vectors are exactly the convex hull of the  $g_\pi$ . This step is not an assertion that mixing machines preserves a specified register width.

The simplex on  $\Pi_N(e_0)$  and  $\mathcal{P}(\Theta)$  are compact and convex. The expected payoff is continuous and bilinear. Minimax therefore gives

$$\max_{\lambda \in \Delta(\Pi_N)} \min_{\theta} \sum_{\pi} \lambda_{\pi} g_{\pi}(\theta) = \min_{\mu} \max_{\pi \in \Pi_N} \int g_{\pi} d\mu.$$

For a fixed measure, the terminal maximum is (7), because an event includes precisely the positive coordinates of its signed predictive measure. At a training node one selects an action and, after its observed outcome, selects a continuation tree separately on that branch. The unnormalized branch measure is exactly  $\nu_{a,x}$ . Backward induction proves (8) and identifies the right side with (9). It also proves the finite-linear-functional representation. Compactness gives an optimizing prior and an optimizing mixed tree. Finally, the minimum over fixed parameters of any policy is at most its average under  $\mu$ , which is at most  $F_N(e_0, \mu)$ . This remains true after restricting its memory or architecture.  $\square$

The minimization in (9) occurs once, outside the recursion. It cannot be replaced by fresh adversarial choices after observations. The posterior carries dependence on one fixed unknown parameter. Also, a Bayes-optimal tree for a minimizing prior need not by itself be a minimax policy; the saddle-point mixture is supplied by the finite game in the proof.

**Corollary 4.2** (Bellman upper certificates). *Suppose functions  $\Psi_n(e, \nu)$  satisfy  $\Psi_0 \geq \Phi$  and, for  $n \geq 1$ , satisfy*

$$\Psi_n(e, \nu) \geq \Phi_e(\nu), \quad \Psi_n(e, \nu) \geq \sum_x \Psi_{n-1}(T(e, a, x), \nu_{a,x}) \quad (a \in \mathcal{A}_e).$$

*Then  $\Psi_N(e_0, \mu)$  is an upper certificate for every admissible architecture and every prior  $\mu$ . The family  $F_n$  is the least such family. An optimal prior can be chosen with at most  $d + 1$  support points, where  $d$  is the affine dimension of  $\{(g_\pi(\theta))_{\pi \in \Pi_N} : \theta \in \Theta\}$ .*

*Proof.* Induction in (8) gives  $F_n \leq \Psi_n$ . The equality case is the recursion itself. The objective depends on a prior only through its vector of integrals of the finitely many  $g_\pi$ . An optimal such vector belongs to the convex hull of their compact evaluation image. Carathéodory's theorem gives the stated support bound while preserving every pure-tree payoff.  $\square$

**Proposition 4.3** (Causal stability). *Consider two models with the same protocol, alphabets and policy class. Suppose their training rows differ uniformly in total variation by at most  $\epsilon$ , their candidate validation rows by at most  $\eta$ , and their target validation rows by at most  $\beta$ . Their unrestricted values, or their values in any common specified memory class, differ by at most  $2N\epsilon + \eta + \beta$ .*

*Proof.* Use the same policy randomization and couple corresponding training rows while the histories agree. The probability of a first discrepancy is at most  $N\epsilon$ , even with feedback and stopping. Conditional expected validation rewards lie in  $[-1, 1]$ , so differing training histories contribute at most  $2N\epsilon$ . On agreeing histories the same frozen design and event are used, and their conditional mean rewards differ by at most  $\eta + \beta$ . The bound is uniform in the fixed parameter and in the policy. Taking minima and suprema preserves it, with the reverse inequality obtained by interchanging the models.  $\square$

**4.1. An informative action choice.** The following calculation distinguishes the controlled theorem from a common-row reduction. Let  $\Theta = \{(i, j) : i, j \in \{0, 1\}\}$ . Action  $R$  reports  $i$ . Action  $L$  reports  $j$  when  $i = 0$  and otherwise reports an independent fair bit. Action  $H$  reports  $j$  when  $i = 1$  and otherwise reports an independent fair bit. The candidate validation is  $\delta_{(i,j)}$  and the target is uniform on  $\Theta$ .

**Proposition 4.4** (Strict adaptive advantage). *With two training preparations, the unrestricted adaptive value is  $3/4$  and the best nonadaptive value is  $5/8$ . Nonadaptive policies here include mixtures of schedules, with their random schedule retained. No available single training action dominates all the others.*

*Proof.* Take  $R$  first, and then  $L$  or  $H$  according to the observed  $i$ . The parameter is recovered exactly. The complement of its validation atom has score  $3/4$ . No policy can exceed  $\text{TV}(Q, \delta_\theta) = 3/4$  even with full information.

For the converse for fixed schedules, use the uniform prior. For a pair of actions  $a, b$  its Bayes value is explicitly

$$(10) \quad \sum_{x,y,\theta} \left[ \frac{1}{16} \sum_{\vartheta} P_{\vartheta}^a(x) P_{\vartheta}^b(y) - \frac{1}{4} P_{\theta}^a(x) P_{\theta}^b(y) \right]_+.$$

Substitution of the three displayed kernels gives

|     | $R$   | $L$    | $H$    |
|-----|-------|--------|--------|
| $R$ | $1/2$ | $5/8$  | $5/8$  |
| $L$ | $5/8$ | $7/16$ | $1/2$  |
| $H$ | $5/8$ | $1/2$  | $7/16$ |

This is an exact finite sum, not a parameter-grid estimate. It bounds any mixture of fixed schedules by  $5/8$ ; an early stop can be padded with an ignored observation. To attain the bound uniformly in  $\theta$ , choose with equal probabilities the schedules  $(R, L)$  and  $(R, H)$ . When the chosen branch-specific action matches  $i$ , the parameter is known and the score is  $3/4$ . Otherwise only  $i$  is known, and the complement of its two-atom fiber gives score  $1/2$ . Each fixed parameter therefore has mean score  $5/8$ .

Action  $R$  cannot distinguish parameters differing only in  $j$ . Action  $L$  cannot distinguish  $(1, 0)$  and  $(1, 1)$ , and  $H$  cannot distinguish  $(0, 0)$  and  $(0, 1)$ . An experiment which fails to distinguish such a pair cannot garble to one that distinguishes it. Hence no action is a common dominating row.  $\square$

If every binary report is additionally passed through an independent binary symmetric channel of crossover  $\epsilon$ , the primitive training rows change by at most  $\epsilon$  and have full support for  $0 < \epsilon < 1/2$ . Proposition 4.3, applied to both policy classes, leaves an adaptive advantage at least  $1/8 - 8\epsilon$ , which is positive for  $0 < \epsilon < 1/64$ . Thus the distinction is not confined to disjoint observation supports. The finite-horizon belief recursion and its piecewise-linear structure are classical [1]. The contribution here is their explicit integration with the frozen validation score, one fixed adversarial parameter, outer certificates, and the resource conventions; no priority for Bellman recursion itself is claimed.

## 5. EXACT MINIMAX LAWS FOR A MARKED PRODUCT FAMILY

The posterior-predictive dual can be solved explicitly for a continuous family containing the collision target. Throughout this section, the training and candidate validation law is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad (p, q) \in [0, 1]^2.$$

In the order 000, 001, 110, 111, let  $Q_\gamma$  have masses

$$((1 + \gamma)/4, (1 - \gamma)/4, (1 - \gamma)/4, (1 + \gamma)/4),$$

and zero mass elsewhere. Write  $U_1(\gamma) = U_1(b, Q_\gamma)$ , with exactly the training-validation convention of (4). Set

$$(11) \quad \gamma_* = 1 - 1/\sqrt{2}, \quad s_\gamma = \sqrt{\gamma^2 - 2\gamma + 5}, \quad u_\gamma = \gamma - 2 + s_\gamma, \quad \tau_\gamma = \frac{2u_\gamma}{u_\gamma + 2 - \gamma}.$$

**Theorem 5.1** (Exact marked minimax family). *For every  $0 \leq \gamma \leq \gamma_*$ ,*

$$(12) \quad U_1(\gamma) = \frac{3 + u_\gamma^2}{8}.$$

*An optimal response depends on the training word only through the report count  $K = X_1 + X_2$ . On the four target atoms its rows are*

$$(13) \quad h_0 = (\tau_\gamma, 0, 1, 1), \quad h_1 = (1, 1, 1, 1), \quad h_2 = (1, 1, 0, \tau_\gamma),$$

*and all responses are zero off these atoms. A least-favorable prior is*

$$(14) \quad \mu_\gamma = \frac{1}{2}\delta_{(t_\gamma, t_\gamma)} + \frac{1}{2}\delta_{(1-t_\gamma, 1-t_\gamma)}, \quad t_\gamma = \frac{1 - \sqrt{u_\gamma}}{2}.$$

*The assertion optimizes over all stochastic responses to the full marked training word, not merely over count-based or symmetric responses.*

*Proof.* First,  $u_\gamma$  is the positive root of

$$(15) \quad u^2 + (4 - 2\gamma)u - (1 + 2\gamma) = 0.$$

On the asserted interval,  $0 < u_\gamma < 1$  and  $0 < \tau_\gamma < 1$ . Indeed the polynomial is negative at zero and positive at one; also  $u_\gamma < 2 - \gamma$  because  $\gamma < 1/2$ . Substitution of  $1 - 2\gamma$  into the polynomial gives  $8(\gamma^2 - 2\gamma + 1/2)$ , which is nonnegative precisely on the present interval. Monotonicity on  $[0, \infty)$  therefore gives

$$(16) \quad u_\gamma \leq 1 - 2\gamma.$$

Put  $a = (1 - p)(1 - q)$ ,  $c = pq$ , and  $z = 1 - a - c$ . The probabilities of the three training counts are  $a, z, c$ . The independent training mark may be discarded by the displayed construction. Let  $G_\gamma(p, q)$  denote its score. With  $u = (p + q - 1)^2$  and  $v = (p - q)^2$ , direct expansion gives

$$(17) \quad G_\gamma(p, q) - \frac{3 + u_\gamma^2}{8} = \frac{2 - \tau_\gamma}{16} \{(u - v - u_\gamma)^2 + 4v\}.$$

For clarity, this identity follows by substituting the three rows of (13) into

$$a(Q_\gamma - b)h_0 + z(Q_\gamma - b)h_1 + c(Q_\gamma - b)h_2,$$

using  $a + c = (1 + u - v)/2$ ,  $a - c = -(p + q - 1)$ , and then eliminating  $u_\gamma^2$  by (15). The coefficient of the resulting square is  $(2 - \tau_\gamma)/16$  and that of  $v$  is four times this coefficient. Both are nonnegative. Equality holds at both points of (14), since there  $v = 0$  and  $u = u_\gamma$ . This proves the lower bound and identifies its equality set.

It remains to bound every response, including nonsymmetric ones. Use (14) in Theorem 3.1. At  $t = t_\gamma$  put  $a = (1 - t)^2$ ,  $c = t^2$ , and  $T = a + c = (1 + u_\gamma)/2$ . For the training report pair 00, the four dual coefficients, apart from a common positive factor, are

$$(18) \quad \left( Q_H T - \frac{a^2 + c^2}{2}, \quad Q_L T - \frac{a^2 + c^2}{2}, \quad Q_L T - ac, \quad Q_H T - ac \right),$$

where  $Q_H = (1 + \gamma)/4$  and  $Q_L = (1 - \gamma)/4$ . The first coordinate is zero by (15); the second is  $-\gamma T/2 \leq 0$ . The last two are positive:  $T \geq 1/2$ ,  $ac \leq 1/16$ , and  $\gamma < 1/2$  imply  $Q_L T > 1/16 \geq ac$ . Thus  $(\tau_\gamma, 0, 1, 1)$  maximizes this linear functional. For the training pair 11, reversing all report bits and the mark reverses the four coordinates and gives the row  $h_2$ .

For either training pair 01 or 10, the two prior support points have the same likelihood  $t(1 - t)$ . The posterior is still equally weighted, and the candidate predictive mass at each target atom is  $T/4$ . Every one of the four coefficients is therefore nonnegative by  $Q_L - T/4 = (1 - 2\gamma - u_\gamma)/8 \geq 0$ . The response  $h_1$  is optimal. At off-diagonal validation atoms the target mass vanishes and the coefficient is nonpositive. Finally, conditioning on either training mark multiplies all these coefficients by  $1/2$ ; it creates no further optimizing choice. We have therefore optimized every coordinate of the full marked-word response space.

The prior average of the displayed response equals its value at either support point, namely  $(3 + u_\gamma^2)/8$ , by (17). Every other response has prior average at most this number and hence has minimum over fixed  $(p, q)$  at most this number. Together with the lower bound this proves (12), optimality of the response, and least favorability of the prior.  $\square$

**Corollary 5.2** (The exact one-preparation collision value). *For  $Q_* = Q_{1/4}$ ,*

$$(19) \quad U_1(b, Q_*) = u_{\text{ex}} := \frac{85 - 7\sqrt{73}}{64}, \quad u_{1/4} = \frac{\sqrt{73} - 7}{4}, \quad \tau_{1/4} = 2 - \frac{14}{\sqrt{73}}.$$

*If only the target changes to  $Q$ , then  $|U_1(b, Q) - u_{\text{ex}}| \leq \text{TV}(Q, Q_*)$ .*

*Proof.* Substitute  $\gamma = 1/4$  in Theorem 5.1. For a fixed trained response the target perturbation is at most total variation, uniformly in  $(p, q)$ . Taking first the minimum and then the maximum preserves this bound in both directions.  $\square$

**5.1. Complementary slackness and the event alphabet.** The tie in the first coordinate of (18) explains the randomization. Any value of that response coordinate is Bayes-optimal for the two-point prior. The minimax choice makes the uniform payoff stationary at its two support points; solving this condition gives  $\tau_\gamma$  and the square identity (17). This derives the prior and response together, rather than postulating that a numerically effective prior is optimal.

Operationally, for  $K = 0$  one draws once between the events with indicator vectors  $(0, 0, 1, 1)$  and  $(1, 0, 1, 1)$ , with probabilities  $1 - \tau_\gamma$  and  $\tau_\gamma$ . For  $K = 2$  one draws between  $(1, 1, 0, 0)$  and  $(1, 1, 0, 1)$ . For  $K = 1$  the event is  $(1, 1, 1, 1)$ . The resulting event identity is retained and used for both fresh validations. These are exactly the five events in the two-preparation construction below. The one-preparation theorem supplies their complementary-slackness interpretation; it does not prove that the two-preparation selector is optimal. The four-point rational prior retained below is a useful rational certificate, not a least-favorable prior.

The exact response uses an atomic stochastic row. It does not receive free persistent randomness. Replacing  $\tau_\gamma$  by a dyadic number within  $2^{-b}$  changes each conditional response, and hence the score, by at most  $2^{-b}$ . A sequential fair-bit implementation must retain its bit prefix and event identity. None of these implementation costs is needed by the deterministic two-preparation physical audit.

**Proposition 5.3** (The zero-preparation endpoint). *For  $0 \leq \gamma \leq 1$ ,  $U_0(b, Q_\gamma) = \gamma/2$ .*

*Proof.* The fixed event  $\{000, 111\}$  has score  $(1 + \gamma)/2 - (a + c)/2 \geq \gamma/2$  because  $a + c \leq 1$ . Conversely, the equally weighted prior on  $b(0, 0)$  and  $b(1, 1)$  has predictive validation law uniform on the four target atoms. Its total variation from  $Q_\gamma$  is  $\gamma/2$ . Theorem 3.1 with  $N = 0$  gives the matching upper bound.  $\square$

## 6. A SELF-CONTAINED COLLISION INTERFACE

We give the preparation, mechanical estimate, observation law and private simulator class needed for the physical specialization. The following argument does not appeal to an unpublished physical lemma. It retains the same positive-volume preparation and positive sensor noise as the earlier collision construction.

**Definition 6.1** (The reset row–event architecture). A preparation supplies two sequential report slots and, afterwards, an actual mark. The source reports in the two slots are constant. A private width-one simulator has no retained information between those slots and no persistent hidden seed. It may use fresh independent coins. Its first emission is  $X_1 \sim \text{Ber}(p)$ ; after receiving the current gate  $A \in \{0, 1\}$ , its second emission has a fixed Bernoulli kernel with parameter  $q_A$ . The parameters  $(p, q_0, q_1)$  are fixed throughout the audit. The simulator does not observe the actual mark. All its coins are independent of that mark. Different preparations reset all unretained variables and are independent conditional on the parameters.

The auditor observes the first report, chooses a gate using its retained state and that report, observes the second report, and then observes the mark. During training it may choose rows and stop adaptively, using at most the declared number of candidate preparations. It next freezes one gate policy and one event, with any retained random choice included in its register. It uses that same row–event continuation on one fresh candidate preparation and one independent target preparation and returns the difference of their event indicators, target minus candidate. It may not reselect the event after either validation. Independent target-only calibration is allowed but all retained calibration and randomness are charged. Peak width counts every bit, mark, event and validation-accumulator cut. Clocked schedules are declared externally; an autonomous implementation must retain its phase. An unretained transcript, seed or stopping-time value is not available to a continuation.

In the all-on row the complete private law is  $b(p, q_1)$ , with an independent fair actual mark. For lower bounds it suffices to restrict the adversary to  $q_0 = 0$ ,  $q_1 = q$ . In this subfamily every deterministic gate policy is the pushforward

$$T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$$

of  $b(p, q)$ . The gate, when included in the transcript, is another function of these same coordinates. Randomized gate policies are covered by averaging their independent random tables. This proves both the all-on product characterization for the upper construction and the common-garbbling subfamily used for the outer converse. The width-one constraint is a simulator constraint; it is not an uncharged restriction on the auditor's register.

**6.1. Preparation and elastic scattering.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$ , with no walls and contact distance  $d$ . Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ ,  $V = (v_1 + v_2)/2$ , and let the center of mass position range over any fixed rational box of positive volume. Prepare  $(B, W) \in \{0, 1\}^2$  with probability  $5/16$  at  $B = W$  and  $3/16$  at  $B \neq W$ . Conditional on  $(B, W)$ , use the uniform product preparation on the following boxes:

$$(20) \quad \begin{aligned} r &= (-a_0, (2B-1)b_0, c_0), & a_0 &\in [29/10, 31/10], & b_0 &\in [9/20, 11/20], \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & & & |V_z - (2W-1)| &\leq 1/100. \end{aligned}$$

Thus the actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ , preserved by momentum conservation. Set

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector, identically zero on the incoming transverse-velocity range.

**Lemma 6.2** (Uniform collision signal). *For every preparation in (20) and every  $9/10 \leq d \leq 11/10$ , exactly one collision occurs and its time lies in  $(4/5, 3/2)$ . Afterwards*

$$(2B-1)v_{1,y} > 1/2, \quad (2B-1)h(v_{1,y}) > 1/4.$$

*For  $0 < d \leq 2/5$  no collision occurs on  $[0, 3]$  and the detector is zero throughout that interval.*

*Proof.* Before contact,  $r(t) = r + tg$ . At  $t \leq 4/5$  its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At  $t = 3/2$  its absolute coordinate bounds are  $1/4$ ,  $113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . The first contact therefore occurs in the claimed interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$ . Hence the entry contact has  $n_x < 0$ , where  $n = r(t_c)/d$ . Its remaining coordinates give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B-1)n_y \geq 87/220.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The elastic rule gives

$$v_1^+ = V + g/2 - (g \cdot n)n, \quad g^+ = g - 2(g \cdot n)n.$$

Consequently

$$(2B-1)v_{1,y}^+ > -3/200 + (1443/1000)(87/220) > 1/2.$$

The definition of  $h$  implies the signal bound. Since  $r(t_c) \cdot g^+ > 0$ , squared separation increases strictly afterwards; there is no second collision. Finally, for  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . There is no contact, and the incoming  $|v_{1,y}| \leq 3/200$  makes  $h$  zero.  $\square$

**6.2. Positive noise and the actual mark.** Let  $\mathcal{B}_t$  be Brownian motion independent of the preparation and set

$$Y_t = \int_0^t h(v_{1,y}(s)) ds + \sigma \mathcal{B}_t, \quad 0 < \sigma \leq 1/24.$$

The two potential all-on reports are

$$Z_1 = \mathbf{1}_{\{2(Y_2 - Y_{3/2}) > 0\}}, \quad Z_2 = \mathbf{1}_{\{2(Y_3 - Y_{5/2}) > 0\}}.$$

The actual second report is  $AZ_2$ . The gate changes acquisition, not the mechanical path. The continuous path is implemented by the target sensor; it is not made available to the private simulator or supplied as an uncharged auditor buffer. Denote the law of  $(Z_1, Z_2, W)$  by  $Q_{d,\sigma}$ .

**Theorem 6.3** (Uniform physical presentation). *For  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ ,*

$$(21) \quad \text{TV}(Q_{d,\sigma}, Q_*) < 1/300.$$

*The same estimate holds after every declared feedback gate, including its observable gate value. The all-on private product family and the common-garbling subfamily in Definition 6.1 apply to this very experiment.*

*Proof.* Every collision occurs before  $3/2$ . Conditional on the preparation, the two normalized sensor windows are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . Lemma 6.2 makes their means have sign  $2B - 1$  and magnitude greater than  $1/4$ . Each potential report therefore differs from  $B$  with probability less than  $\Phi(-3)$ . The Gaussian tail estimate

$$\Phi(-x) \leq \frac{e^{-x^2/2}}{x\sqrt{2\pi}}$$

gives  $\Phi(-3) < 1/600$ :  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$  suffice. Couple the ideal and noisy reports using the same preparation, actual mark and gate random table. Except on a set of probability less than  $2\Phi(-3) < 1/300$ , both potential reports equal  $B$  and the entire gated transcript agrees. The ideal marked law is precisely  $Q_*$ , by the prepared  $(B, W)$  table. This proves (21) and the feedback-uniform version. Finally, the source is blind, its actual mark is unobserved by the simulator, and the gate is its only current input at the second emission. The product and subfamily assertions follow from the two independent private-emission kernels specified above.  $\square$

For  $d \leq 2/5$ , the two windows instead contain only independent centered Gaussian noise. Their signs are independent fair bits, independent of  $W$ , and a private width-one simulator reproduces every gated row exactly. Thus the informative regime and its no-collision control use the same detector, preparation convention and actual mark.

## 7. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1 - p)(1 - q)$  and  $c = pq$ . On the ordered atoms

$$(22) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(23) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \longrightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (23). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in Definition 6.1 and Theorem 6.3, explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem 7.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (1). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(24) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

*from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.*

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

### 7.1. An exact rational certificate against one preparation.

**Lemma 7.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem 3.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (5) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (22), the signed coefficients in (5), after grouping by  $K$ , are the entries of

$$(25) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1-p_i)^{2-k} \left( Q_{*,j} - \frac{(1-p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (25) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (25) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ . A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**7.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (22) and with indicator zero at every off-diagonal atom:

$$(26) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma 7.3** (Exact uniform score of the selector). *Against the ideal target, the selector (26) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (26) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(27) \quad \begin{aligned} G(p, q) = H(u, v) = & -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} \\ & + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}. \end{aligned}$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all

selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

### 7.3. Causal compilation and the full register profile.

**Lemma 7.4.** *The selector and its two validations admit the deterministic profile (24). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event–function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2 w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (26). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem 7.1.* Lemma 7.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas 7.3 and 7.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary 7.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the local microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem 7.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in Theorem 6.3; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark 7.6* (The part of the frontier determined here). The theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . It does not determine  $N_c^{\text{phys}}(W, Q)$  for  $3 \leq W \leq 11$ , the maximum score with two preparations, or the least peak width at  $N = 2$ . The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by (2, 12) in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

**Corollary 7.7** (The enlarged physical preparation segment). *With the full architecture of Definition 6.1,*

$$N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_{\text{ex}} + \beta \leq c < m_2 - \beta.$$

Here  $u_{\text{ex}} = (85 - 7\sqrt{73})/64$  is the exact one-preparation all-on value, rather than the older rational upper bound.

*Proof.* Restrict the adversary to the common-garbling subfamily in Definition 6.1. Theorem 3.2 and Corollary 5.2 bound every at-most-one-preparation auditor, even with unlimited memory, by  $u_{\text{ex}} + \beta$ . The same deterministic two-preparation machine in Lemmas 7.3 and 7.4 has score at least  $m_2 - \beta$  against the full private candidate family. These inequalities prove the assertion. The four-preparation total, peak twelve and positive-noise specialization are unchanged.  $\square$

## 8. AN EXACT PREPARATION–DECISION-MEMORY LAW

A second solvable family separates a genuine joint resource law from an implementation bound. Here the memory coordinate is the number of states at the training–validation cut. It is not identified with the bit-level peak width of the collision audit.

Fix  $m = 2^d$ ,  $0 < \alpha < 1$ , and an unknown parameter  $\theta \in \{1, \dots, m\}$ . A fresh training preparation reports  $\theta$  with probability  $\alpha$  and an erasure  $\perp$  otherwise. Conditional on  $\theta$ , the preparations are independent. Candidate validation has law  $\delta_\theta$  and target validation is uniform on  $\{1, \dots, m\}$ . At the decision cut the auditor retains at most  $K = 2^k$  states,  $0 \leq k \leq d$ . Its subsequent response may depend only on that state, current validation observations and fresh independent randomness. In particular, a calibration table, remembered seed or stopping time outside the retained state is not available. Upstream and downstream memory are otherwise unrestricted for the converse. Let  $V_N^{\text{er}}(K)$  be the best worst-case expected signed validation score with at most  $N$  training preparations.

**Theorem 8.1** (Exact joint law). *For every  $N \geq 0$  and  $K = 2^k \leq m$ ,*

$$(28) \quad V_N^{\text{er}}(K) = (1 - (1 - \alpha)^N) \left(1 - \frac{1}{K}\right).$$

*The converse covers stochastic encoders and arbitrary legal stopping. The value is attained by a clocked machine with  $K$  training states. With atomic preparation and validation outcomes, the complete audit has peak at most  $\max\{2K, 3\}$  and uses at most  $N + 2$  preparations.*

*Proof.* Write  $q = (1 - \alpha)^N$  and pre-generate  $N$  potential training reports. A stopped auditor ignores the unused reports; this does not disclose extra information to it. On the event that all  $N$  reports are erasures, its retained-state law  $r = (r_j)_{j=1}^K$  is independent of  $\theta$ . After padding any smaller register with unused states, its channel to the decision register has the form

$$(29) \quad C(j \mid \theta) = qr_j + (1 - q)S(j \mid \theta)$$

for a stochastic channel  $S$ . This identity remains valid with randomized stopping and randomized state updates.

Use the uniform prior on parameters as an upper certificate. The part  $qr_j$  has zero expected score for every response: averaging  $\delta_\theta$  under this prior gives the target itself. For the other part, optimizing over all responses gives a convex function of  $S$ , a sum of positive parts of linear functions. Every stochastic channel is a convex combination of deterministic channels  $j = g(\theta)$ ; therefore its value is at most the largest deterministic-channel value. This convexification is used only to bound a channel. It does not presuppose that a mixture of width- $K$  machines is realizable at width  $K$ .

If the fibers of  $g$  have sizes  $n_1, \dots, n_K$ , a nonempty fiber has posterior uniform on that fiber, so its total variation from the uniform target is  $1 - n_j/m$ . The prior-averaged optimal score is

$$\sum_j \frac{n_j}{m} \left(1 - \frac{n_j}{m}\right) = 1 - \sum_j (n_j/m)^2 \leq 1 - 1/K.$$

Empty fibers contribute zero. Cauchy–Schwarz proves the inequality. This is an upper bound on the average score and hence on its minimum over fixed parameters. Multiplying by  $1 - q$  proves the upper bound in (28).

For attainment, partition the parameter alphabet into  $K$  equal groups and let  $g(\theta)$  denote its group. Initialize the register uniformly on the  $K$  group labels. On an erasure leave it unchanged; on a revealed parameter overwrite it by  $g(\theta)$ . No extra “revelation occurred” flag is needed. At the decision cut its law is  $q \text{Unif}[K] + (1 - q)\delta_{g(\theta)}$ . For register  $j$ , freeze the event which is the complement of group  $j$ . On a revelation its score is  $1 - 1/K$ . Under a uniformly random initial label, the mean score is zero for each fixed  $\theta$ : one of the  $K$  labels has score  $1 - 1/K$  and the others have score  $-1/K$ . This proves the exact worst-case value.

The  $k$  initialization bits can be accumulated in the  $K$ -state register; all earlier prefix counts are at most  $K$ . Thus no persistent seed lies outside it. Candidate validation retains the group label and its event indicator, using at most  $2K$  states. Target validation produces one of the three values  $-1, 0, 1$ . This proves the atomic-outcome peak bound. The controller uses a declared external schedule; an autonomous stopping implementation must additionally retain its phase. A phase-tagged implementation is finite, but its cost is not included in  $K$ .  $\square$

**Corollary 8.2** (Thresholds and matching resource scales). *For  $K \geq 2$  and  $0 \leq c < 1 - 1/K$ , the least integer number of training preparations giving a score strictly greater than  $c$  is*

$$(30) \quad N_c^{\text{er}}(K) = \left\lceil \frac{\log(1 - c/(1 - 1/K))}{\log(1 - \alpha)} \right\rceil + 1.$$

*If  $c \geq 1 - 1/K$ , no finite  $N$  suffices. For  $0 < \varepsilon < 1$ , achieving  $V_N^{\text{er}}(K) \geq 1 - \varepsilon$  requires*

$$K \geq \varepsilon^{-1}, \quad N \geq \frac{\log(1/\varepsilon)}{-\log(1 - \alpha)}.$$

*Conversely, whenever an allowed  $K \leq m$  satisfies  $K \geq 2/\varepsilon$ , the choice  $N \geq \log(2/\varepsilon)/[-\log(1 - \alpha)]$  suffices.*

*Proof.* The strict threshold is equivalent to  $(1 - \alpha)^N < 1 - c/(1 - 1/K)$ . Since the denominator logarithm is negative, the least integer satisfying this strict inequality is (30), including equality cases of the real quotient. Also

$$1 - V_N^{\text{er}}(K) = q + (1 - q)/K.$$

This is at least  $q$  and at least  $1/K$ , and is at most  $q + 1/K$ . These three inequalities prove the necessary and sufficient bounds.  $\square$

The exact law concerns an entire  $(N, K, \alpha, m)$  family, not a single finite diagnostic. Its mechanism is a parameter-independent erasure component followed by the convex geometry of the decision channel. It demonstrates how a preparation obstruction and a memory obstruction can be matched in one theorem. It does not identify the least physical peak width at two collision preparations. Encoding the  $m$ -symbol reports bit by bit also introduces cuts not present in this atomic model; the physical bit-level accounting is given separately.

## 9. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows, and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r - 1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(31) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma 9.1** (Causal interpretation of the coefficients). *Every coefficient in (31) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (31) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation

at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem 9.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_{\theta} g_{\theta}(q^C), \quad u_C = \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(32) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_{\alpha} (u_C - b_{\theta_C, C, \alpha}) B_{\alpha}(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .*

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (31) implies

$$\min_{\theta} g_{\theta}(q) \leq \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma 9.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (32). Choose  $\theta_C$  attaining the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

*Remark 9.3.* The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem 3.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

## 10. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [6]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma 10.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-} (L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem 10.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(33) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(34) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma 10.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ , and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being

at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (34).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_{\pm}^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ . Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_{\pm}^n(i, \cdot), \pi_{\pm}) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (34). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (33). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (34) is an observation time at which an external analyst reads the autonomous machine, not a free input clock used by its transitions. The adversarial model of [10] is not covered by the independent-report proof above.

## 11. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary 11.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\overline{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\overline{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\overline{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding's inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition 11.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (5); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem. This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

## 12. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section 9 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section 10 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (25), polynomial identity (27), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: STATISTICAL RESOURCE DUALITY AND TWO-PREPARATION PHYSICAL CERTIFICATION

QIAN QI

**ABSTRACT.** We study the resources needed to distinguish a marked experiment from a family of private causal simulators. We separate the optimization of one finite architecture from the optimization over all admissible architectures. For reset experiments whose feedback rows are garblings of a common row, we express the unrestricted-memory preparation value as a minimum of posterior-predictive total variations. The resulting dual bounds every adaptive finite-memory architecture, without selecting an architecture in advance. For the positive-noise marked collision experiment, a four-point rational dual certificate excludes all auditors with at most one training preparation. A deterministic auditor with two training preparations attains a strictly larger uniform score. Its complete bit-level register profile has peak twelve, proving that two training preparations are necessary and sufficient at every peak budget at least twelve on an explicit interval of score thresholds. For general finite architectures we give subdivided positive-basis certificates of explicitly bounded degree and error, including reused stochastic rows. We also give a fully priced autonomous binary-testing construction, with the stationary bound attributed to Hellman and Cover. The earlier compatible-occupation, noisy-testing, continuation and physical-comparison developments are retained in the accompanying complete mathematical volumes.

## 1. INTRODUCTION

An exact description of finite stochastic controllers does not by itself determine a resource frontier. There are two distinct questions. The first asks for the best controller within a specified architecture. The second asks whether any architecture satisfying a resource budget can perform a specified statistical task. A lower bound for the first question need not answer the second. We develop certificates that respect this distinction.

The principal application is a marked collision experiment. Its ideal all-on law is supported on four atoms, but neither the simulator nor the auditor is restricted to a four-atom transcript. The simulator produces two independent report bits and an independent actual mark; the target has a correlation between its reports and that mark. The auditor may use the original feedback rows, arbitrary stochastic transitions and stopping rules, subject to the reset and validation interface. Our upper certificate for the auditor is valid simultaneously for all such architectures. The matching construction uses the mark during validation and not during training. This distinction permits a much shorter preparation schedule than an audit based on unmarked diagonal events.

Put

$$(1) \quad u_1 = \frac{4035777}{10240000}, \quad m_2 = \frac{12 - 3\sqrt{3}}{16}, \quad \beta_0 = \frac{1}{300}.$$

The main resource conclusion is

$$(2) \quad N_c^{\text{phys}}(W, Q) = 2 \quad \text{if} \quad W \geq 12, \quad \text{TV}(Q, Q_*) \leq \beta, \quad u_1 + \beta \leq c < m_2 - \beta.$$

Here  $N$  counts candidate training preparations; two additional, fresh validation preparations are charged separately. The objective is a strict expected signed score greater than  $c$ . In particular, (2) applies to  $c = 2/5$  and  $\beta = \beta_0$ . The lower bound permits unlimited memory, whereas the construction has peak width twelve. This is an exact preparation boundary on a high-width segment, not a claim that twelve is the least possible peak width.

Three mechanisms organize the proof. First, a dominating experimental row removes the outer choice of feedback schedules from the converse. Second, minimax duality turns a prior on fixed simulator parameters into a posterior-predictive upper certificate. Third, residual continuation functions compile the winning decision into a compatible small-memory machine. The general algebraic encoding is useful for checking that the compiled machine belongs to the intended class, but no generic Positivstellensatz is needed to prove (2).

For finite architectures we also supply quantitative information not contained in eventual sum-of-squares completeness. A partition of the stochastic-row simplices into cells of diameter  $O(m^{-1})$  gives positive-basis certificates with error at most  $HS/m$ , where  $H$  bounds the number of row uses and  $S$  bounds the number of destinations in a row. The block degree is the maximum number of times the corresponding row can be used. The argument works with autonomous row reuse. It gives an effective, generally exponential, certification procedure; it is not a uniform degree bound for the unmodified Putinar hierarchy.

**1.1. Relation to the literature.** Comparison of experiments and minimax theory provide the classical background [1, 2]. Polynomial feasible-frequency formulations for partially observed stochastic control are treated by Müller and Montúfar [3]; the rank-one compatibility constraints below are not presented as a new general conditional-independence device. Likewise, strict positivity certificates use established real algebraic geometry [4]. Our quantitative subdivision theorem is a positive-basis construction with a causal error estimate, rather than a new general Positivstellensatz.

Finite-state testing has a substantial earlier theory. Hellman and Cover [5, 6], Flower and Hellman [7], and Cover, Freedman and Hellman [8] distinguish time-invariant rules, finite horizons

and randomization. We explicitly identify the stationary result in Section 6 as a specialization of that theory. Managoli and Prabhakaran [9], posted in May 2026, study randomized time-invariant finite-state binary testing against adaptive adversarial distribution choices and establish matching state exponents, with exact bounds for a class of problems. Our physical theorem has a different objective: a finite training-validation signed score against a fixed private simulator, with bit-level memory and preparations charged. We make no priority claim for the general phenomenon that randomization can save states.

Norberg’s filtered comparison of experiments [10] is pertinent to the broader causal comparison program. The original proof-level comparison remains incomplete: the accessible publisher record verifies the bibliographic identity but does not justify an assertion that its results exclude the present constructions. None of our proofs uses such an exclusion.

**1.2. The mathematical volumes.** The present article gives the new proof chain. The accompanying *Complete Mathematical Manuscript* contains this article followed by the unaltered 96-page revision 23. The *Complete Development* contains this article followed by the unaltered 649-page development. Thus the earlier general continuation, occupation, noisy binary, physical, Gaussian and operator interfaces remain available with their full hypotheses and proofs [11]. They are not silently replaced by (2). In particular, the independent A2 geometric chain and the unresolved historical B4 and broad C2 obligations remain distinct. The mathematical role of the present first foundation is an experimental and resource-comparison root; a universal derivation of every program branch is not assumed.

## 2. EXPERIMENTS, ARCHITECTURES AND ATTAINABLE RESOURCES

Throughout, total variation is  $\text{TV}(P, Q) = \sup_{0 \leq h \leq 1} (P - Q)h = \frac{1}{2} \sum_x |P(x) - Q(x)|$ . An experimental parameter is unknown and fixed throughout an execution. Controller randomization is independent of that parameter. A reset preparation is a fresh draw, independent of earlier preparations given the parameter. A controller may not recover discarded information from an uncharged tape, clock, selector or calibration table.

**Definition 2.1** (Finite architecture). A finite architecture  $A$  specifies a finite causal execution graph, its legal experimental operations, the observable inputs to each controller row, and a register alphabet at every cut. It also specifies which row occurrences share a stochastic table. A clocked architecture may use different rows at different scheduled times. An autonomous architecture may use time only through a charged state. For a parameter family  $\Theta$  and terminal reward in  $[-1, 1]$ , let

$$V(A) = \sup_{q \in \prod_r \Delta_{sr}} \inf_{\theta \in \Theta} g_\theta(A, q).$$

If  $\mathcal{A}(R)$  is the class of architectures obeying a global resource budget  $R$ , its outer value is

$$V^{\text{out}}(R) = \sup_{A \in \mathcal{A}(R)} V(A).$$

Both the architecture and the simulator parameter are fixed before the controller’s random choices. In particular, a mixture of complete controllers is not automatically an admissible controller at the original register profile.

For a finite hidden execution graph, compatibility can be stated without division. Let  $x_{\theta ir}$  be the incoming mass of hidden history  $i$  at observable row  $r$ , and let  $f_{\theta irj}$  be the outgoing mass through choice  $j$ . Include the usual fixed-kernel flow equations, as well as

$$(3) \quad f_{\theta irj} \geq 0, \quad \sum_j f_{\theta irj} = x_{\theta ir}, \quad f_{\theta irj} x_{\theta' i' r} = f_{\theta' i' rj} x_{\theta ir}.$$

For shared rows, the indices  $i, i'$  include all their occurrences.

**Proposition 2.2** (Compatible realization). *For a specified finite architecture, nonnegative flow arrays satisfying (3) are exactly those realized by a common stochastic row at every declared observable input, including at zero incoming mass.*

*Proof.* Necessity follows from  $f_{\theta irj} = x_{\theta ir} q_r(j)$ . For sufficiency, if some incoming mass at row  $r$  is positive, define  $q_r(j)$  by dividing the corresponding outgoing mass by that incoming mass. Conservation makes  $q_r$  stochastic, and the cross-products force the same ratio at every other positive incoming mass. If an incoming mass vanishes, nonnegativity and conservation force all its outgoing masses to vanish. If the entire row is unreachable, choose any legal stochastic row. Induction through the finite execution graph reconstructs the prescribed flows. The same ratio argument applies to identified occurrences of an autonomous row.  $\square$

This formulation is inherited from the complete companion and is included to fix the controller class. Compact semialgebraic feasibility and an Archimedean positivity theorem provide a complete semialgebraic certificate hierarchy for a *fixed finite architecture*. They do not interchange the two optimizations in the definition. Section 5 gives a quantitative alternative for the inner problem. The next section supplies a different certificate that survives the outer optimization.

### 3. A STATISTICAL DUAL THAT IS UNIFORM OVER ARCHITECTURES

Let  $\Theta$  be compact, let  $\Omega$  be finite, and let  $\theta \mapsto P_\theta \in \mathcal{P}(\Omega)$  be continuous. Fix  $Q \in \mathcal{P}(\Omega)$ . An  $N$ -preparation reset selector observes  $Z = (Z_1, \dots, Z_N) \sim P_\theta^{\otimes N}$  and chooses a response  $h_Z \in [0, 1]^\Omega$ . Its expected validation score is

$$(4) \quad G_\theta(h) = \sum_{z \in \Omega^N} P_\theta^{\otimes N}(z) (Q - P_\theta) h_z.$$

The response is fixed before two independent validation draws. Operationally it can be realized by choosing a random event with those coordinate marginals and retaining that event for both validations. No memory bound is imposed in the definition of  $U_N(P, Q) = \max_h \min_\theta G_\theta(h)$ .

**Theorem 3.1** (Posterior-predictive dual). *Both extrema in the following identity are attained:*

$$(5) \quad U_N(P, Q) = \min_{\mu \in \mathcal{P}(\Theta)} \sum_{z, \omega} \left[ \int P_\theta^{\otimes N}(z) \{Q(\omega) - P_\theta(\omega)\} d\mu(\theta) \right]_+$$

$$(6) \quad = \min_{\mu \in \mathcal{P}(\Theta)} \sum_z m_\mu(z) \text{TV}(Q, \bar{P}_\mu(\cdot | z)).$$

Here  $m_\mu(z) = \int P_\theta^{\otimes N}(z) d\mu(\theta)$  and, when  $m_\mu(z) > 0$ ,

$$\bar{P}_\mu(\omega | z) = \frac{\int P_\theta^{\otimes N}(z) P_\theta(\omega) d\mu(\theta)}{m_\mu(z)}.$$

A zero-mass term in (6) is defined to be zero.

*Proof.* The response space is a finite-dimensional compact convex box. Probability measures on the compact space  $\Theta$  form a weakly compact convex set. The integral of (4) is continuous and affine in each argument. The minimum over parameters equals the minimum over probability measures. The minimax theorem [2] therefore interchanges the maximum and minimum. For fixed  $\mu$ , each response coordinate is independent in the maximization and its contribution is the positive part of its coefficient, proving (5). The coefficient vector at a fixed  $z$  has zero sum. For positive  $m_\mu(z)$  it equals  $m_\mu(z)(Q - \bar{P}_\mu(\cdot | z))$ , proving (6). If  $m_\mu(z) = 0$ , every nonnegative likelihood integrand vanishes  $\mu$ -almost surely and all coefficients are zero. Continuity on the two compact strategy spaces gives attainment.  $\square$

**Theorem 3.2** (Dominating-row converse). *Suppose every permitted training row is a parameter-independent causal garbling of one fresh draw from  $P_\theta$ . Suppose every permitted validation row is the same garbling of the target and candidate laws, and every selected row–event pair is fixed before validation. Then  $U_N(P, Q)$  bounds the worst-case expected score of every auditor using at most  $N$  candidate training preparations, regardless of its register profile, feedback schedule, independent randomization, or stopping rule. Independent target-only calibration, whose law does not depend on  $\theta$ , does not invalidate the bound. If the all-on row and all its events are permitted, the bound is attained in the class with no memory cap and  $N$  training preparations.*

*Proof.* Generate  $N$  independent all-on observations in advance. At the  $t$ th requested preparation, apply the declared garbling to observation  $t$ , using only previously simulated reports and independent randomization. This simulates the adaptive transcript with its exact law. A stopped execution ignores the unused observations; it does not reveal them to the auditor. Pull back its final row–event response to the all-on alphabet. Conditional on the entire generated training word and the independent random seed, this is a function in  $[0, 1]^\Omega$ . Averaging the seed, including any target-only calibration, produces one response  $h_z$  for each full word  $z$ . The score is consequently (4). This proves the upper bound for the union of all architectures. Conversely, retaining the entire word and then a selected event implements any such finite response kernel when memory is unrestricted. Fresh validation gives exactly (4).  $\square$

*Remark 3.3* (What the dual does not convexify). The measure  $\mu$  is an adversarial prior used to bound the minimum over *fixed* parameters. Its likelihood is  $\int P_\theta^{\otimes N} d\mu(\theta)$ , not  $(\int P_\theta d\mu(\theta))^{\otimes N}$ . It neither enlarges the private candidate class to mixtures nor gives the auditor a free persistent selector. Attainment of  $U_N$  without a memory cap does not assert attainment at any specified finite profile.

The state in (6) is generated by the actual preparation law, not by a geometric measure chosen independently of the experiment. For sequential continuation one retains the posterior  $\mu_z$  or its future-test equivalence class; a single predictive marginal need not be closed under further observations. This is the distinction between a one-step response quotient and a future-predictive quotient.

**Corollary 3.4** (Finite moment support for the product family). *For two independent Bernoulli report bits with parameters  $(p, q)$  and an independent fair mark, an optimal prior in (5) can be chosen with at most  $(N + 2)^2$  atoms. The two report counts  $(k, \ell)$  are a causally updatable sufficient statistic for computing the dual.*

*Proof.* Conditional on the two counts, all arrangements of report bits and all mark words have parameter-independent probabilities. Summing their coefficients reduces (5) to the  $(N + 1)^2$  count pairs. Their likelihoods are

$$\binom{N}{k} p^k (1 - p)^{N-k} \binom{N}{\ell} q^\ell (1 - q)^{N-\ell}.$$

After multiplication by  $Q(\omega) - P_{p,q}(\omega)$ , every integrand has degree at most  $N + 1$  in each variable. Thus the objective depends only on the  $(N + 2)^2$  rectangular moments. Their constant coordinate is one. Carathéodory’s theorem in the remaining affine space replaces an optimal moment vector by a convex combination of at most  $(N + 2)^2$  point evaluations. Counts update by addition of the current bits. No claim that this count register is optimal for the decision is made.  $\square$

#### 4. THE PHYSICAL EXPERIMENT AND ITS SHARP PREPARATION BOUNDARY

Take  $\Omega = \{0, 1\}^3$ , with coordinates  $(x_1, x_2, w)$ . The all-on private candidate is

$$b(p, q) = \text{Ber}(p) \otimes \text{Ber}(q) \otimes \text{Ber}(1/2), \quad 0 \leq p, q \leq 1.$$

The mark  $w$  is the actual mark, not an invented simulator bit. Put  $a = (1 - p)(1 - q)$  and  $c = pq$ . On the ordered atoms

$$(7) \quad 000, \quad 001, \quad 110, \quad 111,$$

let  $Q_*$  have masses  $5/16, 3/16, 3/16, 5/16$ , and set it to zero elsewhere. The candidate masses on these atoms are  $a/2, a/2, c/2, c/2$ . A target  $Q$  is allowed whenever  $\text{TV}(Q, Q_*) \leq \beta$ .

The original feedback operation has the form

$$(8) \quad T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w), \quad g : \{0, 1\} \rightarrow \{0, 1\}.$$

The selected gate is observable. It may depend on earlier preparations and on the first current report. The target rows are pushforwards by (8). For the converse, restrict the adversary to the admissible private subfamily whose second emission is  $AX_2$ , where  $A$  is the current gate and  $X_2 \sim \text{Ber}(q)$  is independent of the first emission and of the fair mark. Every row is then a causal garbling of  $b(p, q)$ . For the construction only the all-on row is used, and every private candidate in the original width-one class has the all-on product law just specified. These two facts, proved for the microscopic interface in [11, physical-complexity, feedback-completion lemma], explain why using a subfamily for the lower bound does not narrow the upper construction.

The admissible audit first trains, then selects one row–event pair, then uses one fresh candidate and one fresh target validation. It reports  $D = \mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The event and row cannot be reselected after seeing a validation draw. All bit, mark, decision and validation cuts are charged. Define  $N_c^{\text{phys}}(W, Q)$  to be the minimum number of candidate training preparations among these original-interface auditors, with peak register width at most  $W$ , whose score is uniformly strictly greater than  $c$ . Randomization, feedback and stopping are allowed. If no such audit exists, the value is  $+\infty$ .

**Theorem 4.1** (Two-preparation physical segment). *Let  $u_1, m_2$  be as in (1). For every  $\beta \geq 0$ ,  $\text{TV}(Q, Q_*) \leq \beta$ , and*

$$W \geq 12, \quad u_1 + \beta \leq c < m_2 - \beta,$$

*one has  $N_c^{\text{phys}}(W, Q) = 2$ . The two-preparation audit is deterministic, uses no acquired calibration and no random bits, and has the full profile*

$$(9) \quad (1, 2, 3, 3, 4, 5, 5, 10, 12, 10, 10, 7, 3)$$

*from the initial cut through its twelve bit/mark updates. In particular, its decision alphabet has five labels and its peak has twelve. The lower bound remains valid with no memory cap.*

The proof occupies the next three subsections. The interval in the statement can be empty for large  $\beta$ ; no assertion is then made. For  $\beta = 1/300$ , it contains  $c = 2/5$  strictly between its endpoints.

##### 4.1. An exact rational certificate against one preparation.

**Lemma 4.2.** *Every original-interface auditor using at most one candidate training preparation has worst-case score at most  $u_1 + \beta$ , regardless of memory.*

*Proof.* By Theorem 3.2, it suffices to bound  $U_1(b, Q_*)$  and then perturb the target. In (5) use the four fixed parameters

$$(p, q) = (1/8, 1/8), (1/5, 1/5), (4/5, 4/5), (7/8, 7/8)$$

with weights  $1/16, 7/16, 7/16, 1/16$ , respectively. This measure is not asserted to be least favorable. Since  $p = q$  on its support, the training count  $K = x_1 + x_2$  is sufficient. The independent training mark and the order of unequal bits contain no further information about this prior.

For  $k = 0, 1, 2$  and the four validation atoms in (7), the signed coefficients in (5), after grouping by  $K$ , are the entries of

$$(10) \quad \frac{1}{40960000} \begin{pmatrix} -1977 & -1775177 & 2170423 & 3943623 \\ 1765554 & 191954 & 191954 & 1765554 \\ 3943623 & 2170423 & -1775177 & -1977 \end{pmatrix}.$$

For example, the coefficient in column  $j$  is

$$\sum_{i=1}^4 \mu_i \binom{2}{k} p_i^k (1-p_i)^{2-k} \left( Q_{*,j} - \frac{(1-p_i)^2 \mathbf{1}_{j \leq 2} + p_i^2 \mathbf{1}_{j \geq 3}}{2} \right).$$

This identity proves every entry of (10) by rational arithmetic. All coefficients at off-diagonal validation atoms are nonpositive. The sum of the positive entries in (10) is  $4035777/10240000 = u_1$ . Each response coordinate is in  $[0, 1]$ , so this sum bounds its prior-averaged score and hence its minimum over the four fixed candidates.

Replacing  $Q_*$  by  $Q$  changes the score of any trained response by at most  $\beta$ . The training law is a candidate law and is unchanged. Consequently the same prior bounds every score by  $u_1 + \beta$ . A procedure with no training, or one that stops before taking its permitted sample, is covered by ignoring the generated all-on observation.  $\square$

**4.2. A marked five-event selector.** Take two independent all-on training preparations. Let  $S$  be the total number of ones among their four report bits; discard their marks. Choose the following events, represented by their indicators on (7) and with indicator zero at every off-diagonal atom:

$$(11) \quad \begin{array}{c|cccc} S & 000 & 001 & 110 & 111 \\ \hline 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 & 1 \\ 3 & 1 & 1 & 0 & 1 \\ 4 & 1 & 1 & 0 & 0 \end{array}$$

Denote these indicators by  $h_0, \dots, h_4$  and report  $D = h_S(Y) - h_S(X)$  on independent validation draws.

**Lemma 4.3** (Exact uniform score of the selector). *Against the ideal target, the selector (11) has uniform minimum score  $m_2 = (12 - 3\sqrt{3})/16$ . Against  $Q$ , its score is at least  $m_2 - \beta$ .*

*Proof.* The generating polynomial of  $S$  is

$$((1-p) + pz)^2((1-q) + qz)^2.$$

Writing  $g_s = (Q_* - b(p, q))h_s$ , its expected score is  $G(p, q) = \sum_{s=0}^4 [z^s]((1-p) + pz)^2((1-q) + qz)^2 g_s$ . Substitution of the five rows in (11) and collection of terms with  $x = p + q - 1$ ,  $y = p - q$ ,  $u = x^2$  and  $v = y^2$  gives

$$(12) \quad \begin{aligned} G(p, q) = H(u, v) = & -\frac{u^3}{32} + \frac{3u^2v}{32} + \frac{3u^2}{16} - \frac{3uv^2}{32} - \frac{uv}{4} - \frac{3u}{32} \\ & + \frac{v^3}{32} + \frac{v^2}{16} + \frac{15v}{32} + \frac{7}{16}. \end{aligned}$$

This is a polynomial identity, not an interpolation over a grid. Since  $0 \leq u \leq 1$  and  $v \geq 0$  on the parameter square,

$$\partial_v H(u, v) = \frac{3(u-v)^2 - 8u + 4v + 15}{32} \geq \frac{7}{32}.$$

Thus  $H(u, v) \geq H(u, 0) = (-u^3 + 6u^2 - 3u + 14)/32$ . The derivative of the last expression is  $(-3u^2 + 12u - 3)/32$ . On  $[0, 1]$  it changes sign from negative to positive at  $u = 2 - \sqrt{3}$ . Substitution gives  $(12 - 3\sqrt{3})/16$ . The minimizing values are feasible: take  $p = q = (1 \pm \sqrt{2 - \sqrt{3}})/2$ . This proves exactness of the minimum for this specified selector, not optimality of its score over all selectors with two preparations. Finally, for each  $s$ , the target expectation of  $h_s \in [0, 1]^\Omega$  changes by at most  $\beta$ . Averaging over training proves the claimed robustness.  $\square$

#### 4.3. Causal compilation and the full register profile.

**Lemma 4.4.** *The selector and its two validations admit the deterministic profile (9). No selector, first-bit buffer or validation accumulator is outside the charged register. An autonomous phase-tagged realization uses at most 75 states.*

*Proof.* After each training report bit retain the count accumulated so far. The two marks are read and discarded. The first six updates therefore have widths 2, 3, 3, 4, 5, 5 after the initial singleton. At the decision cut the five count values select the five events.

During candidate validation, after the first bit retain the event and that bit, using at most ten states. After the second bit retain the event and the function of the unread mark that gives its candidate-event indicator. For events 0, 1, 2, 3, 4, respectively, the possible functions are

$$\{0, 1\}, \quad \{0, 1 - w, 1\}, \quad \{0, 1\}, \quad \{0, w, 1\}, \quad \{0, 1\}.$$

There are twelve event–function pairs. After the candidate mark, retain the event and its now known candidate indicator  $c_0 \in \{0, 1\}$ , using at most ten states.

During target validation, after the first bit discard the event name and retain  $c_0$  and its residual function of the second bit and mark. These residual functions belong to

$$\{0, x_2, (1 - x_2)(1 - w), 1 - x_2, x_2 w\}.$$

This uses at most ten states. After the second bit, the residual *difference* as a function of the unread mark belongs to

$$\{-1, 0, 1, w, 1 - w, w - 1, -w\},$$

so seven states suffice. The mark update gives the three possible outputs  $-1, 0, 1$ . Each transition depends only on its retained residual and the current report. Thus it is a legal common observable row, not a family of independently optimized hidden-history maps.

For completeness, equality of two residual functions implies equality of their restrictions after either next bit, so identifying equal residuals is closed under every subsequent update. The supplied transition tables are obtained by these restrictions and can be reconstructed directly from (11). Enumerating residuals is a convenience for reproducing the tables, not the proof of their sufficiency. Finally, disjointly tag the states at the thirteen cuts by their phase and use terminal self-loops. The sum of the displayed widths is 75. This implementation charges the clock; it does not assert that 75 is optimal.  $\square$

*Proof of Theorem 4.1.* Lemma 4.2 excludes  $N \leq 1$  for a strict score greater than  $c \geq u_1 + \beta$ , for every architecture and every memory budget. Lemmas 4.3 and 4.4 supply a two-preparation architecture of peak twelve with score at least  $m_2 - \beta > c$ . Larger width budgets can use the same machine.  $\square$

**Corollary 4.5** (The positive-noise collision family). *For the original marked collision targets with  $9/10 \leq d \leq 11/10$  and  $0 < \sigma \leq 1/24$ , the inherited microscopic estimate  $\text{TV}(Q_{d,\sigma}, Q_*) < 1/300$  implies*

$$N_{2/5}^{\text{phys}}(W, Q_{d,\sigma}) = 2 \quad (W \geq 12).$$

*There are four preparations in the complete audit: two candidate training, one candidate validation, and one target validation.*

*Proof.* Apply Theorem 4.1. The lower-end margin is the exact rational number

$$\frac{2}{5} - u_1 - \frac{1}{300} = \frac{78269}{30720000} > 0.$$

For the other endpoint,  $\sqrt{3} < 7/4$  implies  $m_2 > 27/64$  and  $27/64 - 1/300 > 2/5$ . The physical total-variation estimate, including the actual mark and positive sensor noise, is proved in the retained microscopic-composition and physical-complexity modules [11]; the current deduction does not replace those hypotheses by a zero-noise limit.  $\square$

*Remark 4.6* (The part of the frontier determined here). The theorem evaluates the minimum preparation coordinate for  $W \geq 12$ . It does not determine  $N_c^{\text{phys}}(W, Q)$  for  $3 \leq W \leq 11$ , the maximum score with two preparations, or the least peak width at  $N = 2$ . The earlier exact decision-width result  $\kappa_{2/5}^{\text{rows}} = 3$  is unchanged: it allows longer training, whereas this shortest audit uses five decision states. The older points (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  remain valid constructions with decision width three. They are dominated by (2, 12) in the projection onto training preparations and peak width, but not necessarily in a resource order that also constrains the decision alphabet separately.

## 5. QUANTITATIVE CERTIFICATES FOR A FINITE COMPATIBLE ARCHITECTURE

We return to an arbitrary finite architecture, now with a finite parameter set. It can have hidden states, controlled experiments, more than two hypotheses and registers of any size. Enumerate its distinct stochastic rows by  $r = 1, \dots, R$  and write  $q_r \in \Delta_{s_r}$ . A reused autonomous row appears only once in this product. Assume each execution uses at most  $H$  controller rows, and uses row  $r$  at most  $d_r$  times. Delete unused rows and put  $S = \max_r s_r$ . Fixed environmental kernels are not controller rows.

For an integer  $m \geq 1$ , intersect  $\Delta_{s_r}$  with the coordinate boxes of side  $1/m$ . The resulting nonempty closed polytopes cover the simplex, with overlaps permitted at their boundaries. Write  $C$  for a product of such row cells and choose a vertex  $q_r^C$  in each factor. A row-cell vertex has at most one coordinate not fixed at a box boundary; consequently it has at most  $v_r = s_r 2^{s_r - 1}$  vertices, all on the  $1/m$  grid. There are at most  $m^{\sum_r s_r}$  product cells.

Write the vertices of row cell  $C_r$  as  $v_{r,j}$  and parametrize  $q_r = \sum_j \lambda_{r,j} v_{r,j}$  with  $\lambda_r$  in a simplex. A reward polynomial has degree at most  $d_r$  in block  $\lambda_r$ . Use the homogeneous simplex Bernstein basis of degree  $d_r$  in that block, obtaining

$$(13) \quad g_\theta(q(\lambda)) = \sum_\alpha b_{\theta,C,\alpha} B_\alpha(\lambda), \quad B_\alpha \geq 0, \quad \sum_\alpha B_\alpha = 1.$$

Degree elevation includes the factors  $\sum_j \lambda_{r,j} = 1$ . No independence between different visits of a shared row is imposed on its unknown row vector.

**Lemma 5.1** (Causal interpretation of the coefficients). *Every coefficient in (13) satisfies*

$$|b_{\theta,C,\alpha} - g_\theta(q^C)| \leq HS/m.$$

*Proof.* For each row  $r$ , independently prepare an ordered list of  $d_r$  vertex labels, sampled independently with law  $\lambda_r$ . At its  $k$ th visit, use the stochastic row given by the  $k$ th vertex label in that list. Before conditioning, the next label is independent of the previous execution, so this experiment has exactly the row  $q_r$  at every visit and expected reward  $g_\theta(q(\lambda))$ . Unused labels may be sampled after termination without altering the reward.

Condition on the counts of every vertex label in every list. The probability of those counts is  $B_\alpha(\lambda)$ . Conditional on the counts, each list is a uniformly ordered multiset. Its expected reward is independent of  $\lambda$  and is therefore the corresponding Bernstein coefficient. This also proves (13) directly.

Each row used by this conditioned experiment is a vertex of  $C_r$  or a mixture of its remaining vertices. Every two vectors in  $C_r$  have coordinate differences at most  $1/m$ , hence total variation at most  $s_r/(2m) \leq S/(2m)$ . Couple the conditioned experiment to the one using  $q^C$ , using the same environmental randomness while their executions agree. At each actual controller update the probability of a first row-level disagreement is at most  $S/(2m)$ . There are at most  $H$  such updates on the agreeing path. The terminal laws consequently differ in total variation by at most  $HS/(2m)$ . A reward in  $[-1, 1]$  has expectation difference at most twice that quantity. This proves the estimate. The conditioned urn is used to analyze a coefficient; it is not declared to be an admissible free-memory controller.  $\square$

**Theorem 5.2** (Explicit subdivision certificate). *Define*

$$\ell_C = \min_{\theta} g_{\theta}(q^C), \quad u_C = \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha}, \quad L_m = \max_C \ell_C, \quad U_m = \max_C u_C.$$

*For the exact all-stochastic value of the specified architecture,*

$$(14) \quad L_m \leq V(A) \leq U_m \leq L_m + HS/m.$$

*On each cell, a witnessing parameter  $\theta_C$  supplies the nonnegative coefficient certificate*

$$u_C - g_{\theta_C}(q(\lambda)) = \sum_{\alpha} (u_C - b_{\theta_C, C, \alpha}) B_{\alpha}(\lambda).$$

*Its degree in row block  $r$  is  $d_r$ , and its total degree is at most  $\sum_r d_r$ . At most  $\prod_r \binom{d_r + v_r - 1}{v_r - 1}$  coefficients per parameter and cell are needed. If the primitive data are rational, all coefficients and bounds can be checked by rational arithmetic. Taking  $m \geq HS/\varepsilon$  gives a certified interval of length at most  $\varepsilon$ .*

*Proof.* The point  $q^C$  is feasible, so  $\ell_C$  is a lower bound on the value restricted to  $C$ . For any  $q \in C$ , choose a convex representation of its rows. Equation (13) implies

$$\min_{\theta} g_{\theta}(q) \leq \min_{\theta} \max_{\alpha} b_{\theta, C, \alpha} = u_C.$$

Choose a parameter attaining the minimum defining  $\ell_C$  and apply Lemma 5.1; this gives  $u_C \leq \ell_C + HS/m$ . Taking the maximum over the finite cover proves (14). Choose  $\theta_C$  attaining the definition of  $u_C$ ; all displayed coefficients of its certificate are nonnegative. The degree and count statements follow from the product Bernstein basis. Cell vertices are rational grid points, and a finite execution sums finite products, proving the rational statement.  $\square$

*Remark 5.3.* The number of cells and coefficients can be enormous. Neither polynomial running time nor a uniform degree bound for the original sum-of-squares hierarchy follows. Refinement changes the domain cover, not merely a single global SOS degree. For a finite collection of architectures obeying a specified budget, maxima of these intervals give outer intervals; an unbounded architecture class needs a separate uniform argument such as Theorem 3.2. For compact parameter families, an effective net and a verified modulus for the primitive kernels are additional inputs, not consequences of compactness alone.

The resource estimate also makes row precision explicit. With  $m = 2^b$ , the lower witnesses have dyadic rows and lose at most  $HS2^{-b}$  in value. Thus increasing row precision provides a quantified approximation for a fixed architecture, while its random-bit implementation still has to be charged. The physical theorem avoids this cost altogether because its rows are deterministic.

## 6. AUTONOMOUS NOISY TESTING WITH A PRECISION AND TIME LEDGER

This section supplies a substantive autonomous comparison rather than merely identifying shared rows. The stationary optimum is classical [5]; the proof and explicit finite-time implementation are recorded to make the resource conventions unambiguous. They are not used as novelty evidence for the physical theorem.

Let reports be independent, with law  $\text{Ber}(p)$  under hypothesis  $-$  and  $\text{Ber}(q)$  under hypothesis  $+$ , where  $0 < p < 1/2$ ,  $q = 1 - p$ , and  $r = q/p$ . A  $W$ -state autonomous machine has two time-independent stochastic transition matrices  $T_0, T_1$ . Assume their induced chains  $P_- = qT_0 + pT_1$  and  $P_+ = pT_0 + qT_1$  are irreducible. A final decision uses only the state, with optional fresh terminal randomization.

**Lemma 6.1** (Likelihood-range bound). *If equivalent probability laws  $\nu_+, \nu_-$  on a finite set satisfy*

$$\frac{\max_i \nu_+(i)/\nu_-(i)}{\min_i \nu_+(i)/\nu_-(i)} \leq R,$$

*then  $\text{TV}(\nu_+, \nu_-) \leq (\sqrt{R} - 1)/(\sqrt{R} + 1)$ .*

*Proof.* Write  $L = d\nu_+/d\nu_-$ ,  $a = \min L$  and  $b = \max L$ . Since  $\mathbb{E}_{\nu_-} L = 1$ , one has  $a \leq 1 \leq b$ . The chord bound for  $(L - 1)_+$  gives

$$\text{TV}(\nu_+, \nu_-) = \mathbb{E}_{\nu_-} (L - 1)_+ \leq \frac{(1 - a)(b - 1)}{b - a}.$$

For fixed  $b/a$ , maximizing the last expression gives  $a = 1/\sqrt{b/a}$ ; substitution yields  $(\sqrt{b/a} - 1)/(\sqrt{b/a} + 1)$ . It is increasing in  $b/a$ , proving the assertion. The identical-law case follows directly.  $\square$

**Theorem 6.2** (Autonomous stationary bound and an explicit approximation). *Put  $D = W - 1$ ,  $W \geq 2$ . In the irreducible autonomous class the infimum stationary minimax error is*

$$(15) \quad e_W = \frac{1}{1 + r^D}.$$

*For every  $\epsilon = 2^{-b}$ ,  $b \geq 0$ , there is a machine whose rows have denominator dividing  $2^{b+1}$ , and whose minimax error at report time  $n$  from any initial state is at most*

$$(16) \quad e_W + \epsilon(W - 2) + \exp \left\{ - \left( \frac{p\epsilon}{2} \right)^D \left\lfloor \frac{n}{D} \right\rfloor \right\}.$$

*The stationary lower bound is not a finite-horizon lower bound.*

*Proof.* Every positive induced transition has its likelihood ratio in  $[r^{-1}, r]$ , and the supports of the two induced matrices are identical. The Markov chain tree formula writes each stationary weight as a sum of products over directed spanning trees rooted at that state. Each product has  $D$  transitions; its ratio lies in  $[r^{-D}, r^D]$ . The ratio of the two unnormalized stationary weights lies in the same interval. Normalizing multiplies all state likelihood ratios by a common number, so their maximum-to-minimum ratio is at most  $r^{2D}$ . Lemma 6.1 therefore bounds stationary total variation by  $(r^D - 1)/(r^D + 1)$ . The equal-prior Bayes error is at least  $1/(1 + r^D)$ ,

and a minimax error cannot be smaller than that Bayes error. This is the equal-prior binary specialization of the Hellman–Cover bound.

For the upper approximation, take states  $i = 0, \dots, D$ , weights  $c_0 = c_D = 1$ , and  $c_i = \epsilon$  at interior states. On report 1, move from  $i$  to  $i + 1$  with probability  $a_i = \frac{1}{2} \min(1, c_{i+1}/c_i)$ , if that neighbor exists; otherwise stay. On report 0, move to  $i - 1$  with probability  $b_i = \frac{1}{2} \min(1, c_{i-1}/c_i)$ , if it exists; otherwise stay. All other probability is assigned to staying. Detailed balance gives

$$\pi_+(i) = \frac{c_i r^i}{\sum_j c_j r^j}, \quad \pi_-(i) = \frac{c_i r^{-i}}{\sum_j c_j r^{-j}}.$$

Reflection  $i \mapsto D - i$  exchanges these laws. Decide  $+$  for  $i > D/2$ ,  $-$  for  $i < D/2$ , and use a fair terminal decision at  $i = D/2$  when this state exists. The two errors agree. Conditional on being at an endpoint, the error is exactly  $e_W$ . The total interior stationary mass is at most  $\epsilon(W - 2)$ , since each  $r^i \leq r^D$  and the denominator is at least  $r^D$  under  $+$ , with the reflected argument under  $-$ . This proves the first two terms of (16).

Every existing neighbor transition under either hypothesis has probability at least  $p\epsilon/2$ , and every self-loop has probability at least  $1/2$ . From any state, move down to zero and then stay until  $D$  steps have elapsed. This yields the common minorization  $P_\pm^D(i, \{0\}) \geq \delta = (p\epsilon/2)^D$ . Subtracting that common atom gives contraction in total variation by  $1 - \delta$  every  $D$  steps. Comparison with the stationary law yields  $\text{TV}(P_\pm^n(i, \cdot), \pi_\pm) \leq (1 - \delta)^{\lfloor n/D \rfloor} \leq e^{-\delta \lfloor n/D \rfloor}$ . A bounded decision changes error by at most this amount, proving (16). Finally, letting  $n$  tend to infinity and then  $\epsilon$  to zero proves that the stationary infimum equals (15). All transition probabilities belong to  $\{0, 1, 1/2, \epsilon/2, 1 - 1/2, 1 - \epsilon/2\}$ .  $\square$

The  $W$  states in this theorem refer to an atomic stochastic update after each report. A sequential fair-bit implementation must also retain the report, the current state, a bit counter and a flag. Each nontrivial move probability is  $1/2$  or  $2^{-(b+1)}$ ; test for a string of zero bits of the required length, and pad to  $b + 1$  bits if a uniform report cycle is required. At most  $4W(b + 2)$  states suffice for this implementation, including its bit-phase counter and a ready phase. This conservative bound is an implementation claim, not an optimal precision–state tradeoff. The time index  $n$  in (16) is an observation time at which an external analyst reads the autonomous machine, not a free input clock used by its transitions. The adversarial model of [9] is not covered by the independent-report proof above.

## 7. PHYSICAL CONSUMERS AND THE FIRST-PRINCIPLES CONNECTION

The physical preparation theorem needs no estimate of the target law as a stored input: the five events are fixed and their uniform validity uses a proved neighborhood of  $Q_*$ . This removes calibration memory from this particular consumer without asserting that target acquisition is unnecessary in an arbitrary comparison problem. The general acquired calibration theorem, with its full counter register, remains in the complete companion.

**Corollary 7.1** (A raw-interface confidence construction). *Let  $m = m_2 - \beta > 0$  and  $0 < c < m$ . Repeat the full four-preparation audit independently  $R$  times and write  $\bar{D}_R$  for the mean score. Under every private candidate,*

$$\mathbb{P}(\bar{D}_R \leq c) \leq \exp\{-R(m - c)^2/2\}.$$

*Under the null in which the independent candidate and target validation laws agree, with the same event chosen before both validations,*

$$\mathbb{P}(\bar{D}_R > c) \leq \exp\{-Rc^2/2\}.$$

*A clocked implementation uses  $4R$  preparations and at most  $12(2R + 1)$  persistent states, with no calibration and no random bits.*

*Proof.* The independent block scores lie in  $[-1, 1]$  and have mean at least  $m$  under a private candidate. Hoeffding's inequality gives the first bound. Under the null, conditional on the selected event, the two independent validation indicators have the same mean. Each block therefore has mean zero, and the same inequality gives the second bound. Retain the integer sum in  $\{-R, \dots, R\}$  along with the current twelve-state block. At a block boundary add its terminal score and reset its register. The deterministic external schedule is part of the clocked convention.  $\square$

This is an upper construction on the raw marked interface. Its proof does not transfer a lower bound from a deliberately reduced Bernoulli interface, and no optimal confidence-memory frontier is claimed.

**Proposition 7.2** (Target transport without a training multiplier). *For the two-preparation audit, changing only the target from  $Q$  to  $Q'$  changes its expected score by at most  $\text{TV}(Q, Q')$ . Its candidate training law, register profile and event selector remain unchanged.*

*Proof.* Condition on the candidate training word. The expectation difference is  $(Q - Q')h_S$ , whose absolute value is at most  $\text{TV}(Q, Q')$ . Average over that unchanged training law.  $\square$

In particular, every common-preparation transport estimate verified for the original positive-noise collision family can be inserted here without multiplying it by a long training horizon. If candidate kernels also change, their training and validation defects must be added by a causal coupling; the target-only statement does not remove those terms.

The first-principles route is now concrete. The positive experimental kernels and actual reset preparations give the likelihoods in (5); these generate posterior continuation states. The validation-test quotient gives the positive parts in the statistical dual. A prior then supplies an architecture-uniform impossibility certificate. On the constructive side, the five-event decision is compiled by taking its future residual functions, which are closed under observation shifts. These are compatible causal states and determine the charged profile. Thus the preparation law, predictive continuation and finite-resource realization are used in the same upper/lower theorem. This is not a deduction of geometry or nonlinear operator compactness from the existence of finite stochastic rows.

## 8. DEPENDENCIES, RETAINED RESULTS AND REMAINING DISTINCTIONS

The exact three-report binary noisy frontier, arbitrary-horizon binary-register minimax recursion and compatible Bayesian interval recursion remain as proved in the complete companion. Its exact odd-horizon majority realization is also retained; it is not a new result of this revision. Section 5 applies to registers of any finite width, controlled rows and any finite parameter set, but provides certified intervals rather than a closed minimax recursion for all such classes. The physical theorem supplies a matched preparation segment in a continuous two-parameter family with overlapping stochastic reports; its converse is not a finite parameter-grid check.

The stationary autonomous result in Section 6 has an explicit formula, but its stationary lower bound must not be applied to a finite-horizon clocked machine. Its finite-time upper bound is purposely conservative and exposes the slowing caused by finite transition precision. An arbitrary compact-family presentation still requires additional effective information to construct a kernel net. A subdivided positive-basis degree bound must not be called a degree bound for a global SOS hierarchy.

The physical result is a genuine consumer of the experimental and continuation root. It does not make the independent A2 geometric proofs dependent on this root. The original B4 normalized-resolvent, range, compactness and control-transfer obligations, and the broad C2 strict-dual, form, rigidity and optional-projection obligations, are not proved by our finite-state theorem. Their statements, derivations and current status remain in the retained historical pipeline. No aggregate closure is inferred from preserving their source files.

Finally, the rational certificate (10), polynomial identity (12), and residual transitions are independently reproducible. The program in the accompanying source checks their exact identities and includes deliberately invalid controls. These checks are not substitutes for the proofs above. Neither compilation, preservation of earlier pages nor a successful finite test establishes novelty or an editorial decision.

# GENERAL THETA FOUNDATIONS I: COMPATIBLE STATISTICAL EXPERIMENTS AND RESOURCE FRONTIERS

QIAN QI

**ABSTRACT.** We study statistical experiments subject to a register constraint at each cut of a finite causal protocol. Their feasible occupation arrays are characterized by linear flow equations and quadratic compatibility equations, including at zero-probability histories. This yields constructive realizations and a complete polynomial upper-certificate hierarchy for the full-profile minimax value, without convexifying the class of machines. For binary experiments we obtain an exact posterior partition recursion for Bayesian decisions and an exact receiver-curve recursion for minimax decisions with binary registers. In a three-report experiment with overlapping binary noise, we compute the entire register-profile frontier for both objectives; the resulting strict gap shows that a free mixture of machines changes the minimax value. The characterization is connected to finite-precision response-cover auditors, acquired calibration, and positive-noise physical experiments, with preparations, intermediate registers and clocks explicitly charged. The marked continuation, residual, microscopic and Gaussian comparison results are developed with their proofs and with their distinct hypotheses retained.

## 1. INTRODUCTION

An experiment is used through a causal observer. Information acquired at one time may be lost at a later checkpoint, and a decision rule that is economical after training may be expensive to train. The statistical value of an observer therefore depends on its entire register profile, not only on the dimension of its last statistic. A further difficulty is that two feasible observers need not be mixable at the same profile: the variable that selects an observer has to be retained wherever their future actions differ.

We study this problem from positive experimental kernels, preparations, causal interventions and bounded executable tests. These objects do not presuppose a convex parameter image, an information metric, or a finite-dimensional closure of the underlying dynamics. The present paper develops their finite resource layer and its comparison maps. The word “finite” refers to a declared protocol and its observable alphabets, not to a removal of the microscopic or limiting questions in the larger theory.

**1.1. The full-profile problem.** Fix a finite schedule  $\sigma$ , a register profile  $\mathbf{K}$ , a family of environments  $B$ , and a terminal payoff  $G \in [-1, 1]$ . Let

$$V_{\sigma, \mathbf{K}}^{\text{clk}}(B, G) = \sup_A \inf_{b \in B} \mathbb{E}_b^A G,$$

where every persistent data-dependent variable of  $A$  passes through the specified registers. The clocked model allows a predetermined transition table at each epoch; its clock carries no discarded data. An autonomous controller instead reuses its declared transition rows and must retain any phase variable needed to select a different row. Refining an atomic operation into input-bit or random-bit epochs changes  $\sigma$  and its resource problem. These conventions are part of the theorem statements.

The central object is a compatible occupation array. Its coordinates record the probability mass entering and leaving each observable controller row, under every environment and hidden history. Ordinary flow conservation is necessary but not sufficient. All hidden histories that present the same observable row must use the same stochastic transition. This requirement is a collection of quadratic proportionality equations. Unlike a division-based parametrization, these equations also retain every zero-occupation boundary case.

**Theorem 1.1** (Compatible statistical resource frontiers). *The following statements hold for the indicated finite protocols.*

- (i) *For a finite environment family, compatible occupation arrays are exactly the arrays of all stochastic machines of the full profile. Their minimax value is attained. It equals the decreasing limit of polynomial sum-of-squares upper certificates, and every feasible array reconstructs a machine. Shared-row equations give the corresponding autonomous characterization. Finite-precision controller witnesses and compact-family kernel nets give matching two-sided approximations.*
- (ii) *For binary, conditionally independent finite observations, possibly with a finite controlled choice of experiment, the optimal clocked Bayesian value at any finite register profile is given by a recursion of compatible interval partitions of incoming posterior atoms. For uncontrolled observations with one- or two-state registers, a receiver-curve recursion gives the exact clocked minimax value at every finite horizon. These are optimizations over all stochastic machines, not implementation bounds for a chosen statistic.*
- (iii) *With three independent binary reports of error probability  $p \in (0, 1/2)$ , put  $d = p(1-p)(1-2p)$ . At the atomic profile  $(2, 2, 2)$  the exact fair-prior and minimax successes are respectively  $1 - p + d/2$  and  $1 - p + d/3$ . At profile  $(2, 3, 2)$  both equal  $1 - p + d$ . A free mixture of the two Bayesian optimal machines would raise the first profile's minimax value by  $d/6$ , so that convexification is strictly incorrect for that resource problem.*
- (iv) *A fixed  $K$ -response calibration can be acquired from  $M = 2^s$  target preparations, with uniform error at most  $\rho$  except with probability  $\beta$ , whenever  $M \geq (2\rho^2)^{-1} \log(2K/\beta)$ . Its  $(M + 1)^K$ -state counter vector is retained and priced through the subsequent auditor. The resulting response-cover constructions and their physical consumers belong to the same full-profile classes as the occupation converse.*

*Proof.* Part (i) is Theorems 2.1 and 2.2 and Corollary 2.3. Part (ii) is Theorems 3.2 and 3.3. Part (iii) is Theorem 4.1 and Corollary 4.3. Part (iv) is Theorem 5.2 and Corollary 6.1.  $\square$

The certificate hierarchy in (i) uses a classical positivity theorem. Its role is to give an upper bound on every complete machine, paired with the reverse reconstruction from feasible occupations. It is not an efficiency or finite-termination assertion. The noisy recursions in (ii) and the closed formulas in (iii) supply structural information that a generic polynomial encoding alone would not provide. In particular, the distinction between Bayesian and minimax objectives survives in an experiment whose two laws have common support at every observation.

**1.2. Comparison with existing methods.** Comparison of experiments is classical [1, 2, 13]. Filtered randomization is also an existing subject. Weisshaupt's filtered criterion [10, Lemma 1 and Theorem 5] concerns compact convex classes of positive operators and a risk criterion for filtered randomization. Our feasible object is a specified finite register execution, whose behavior set need not be convex. We also cite Norberg [3]; the original proof text has not been obtained for a definitive theorem-level comparison, and no priority claim rests on that gap in access.

Finite-memory statistical learning and the role of time-dependent transition rules are treated by Cover and by Hellman and Cover [24, 26]. Likelihood-ratio quantizer optimality is a classical mechanism [27, Section III]. We use it both for compatible posterior partitions and for binary-channel domination. The receiver-curve and equal-error arguments are not introduced as new

statistical principles. Their role here is to solve one full-profile optimization, including its stochastic minimax part and the selector cost exposed by the explicit three-report frontier.

Polynomial descriptions of partially observed controller occupations are likewise established. Müller and Montúfar [28, Example 15, Theorem 16 and Remark 19] give semialgebraic feasible-frequency descriptions and polynomial planning for infinite-horizon memoryless POMDPs, with their stated positivity assumptions. The finite-protocol formulation here makes the observable row equivalences, changing register alphabets and zero-mass reconstruction explicit. Its upper-certificate completeness applies Putinar’s theorem and its rational version [29, 30]. The combined contribution is the exact compatible frontier, its noisy evaluations, and its connections to fully priced experimental consumers; neither polynomial optimization nor the vanishing-minor identity is claimed as a new invention.

**1.3. Organization and scope of the applications.** Sections 2–6 contain the principal proof chain. The marked continuation and decision spectra then identify the underlying experimental interfaces. The finite precision, response-cover tournaments, multicut revelation formula, weighted residuals, nonlinear tests and adaptive tests are developed with their proofs. The microscopic moving-collision construction and the bounded Gaussian comparison produce physical consumers of the same interfaces. The original short, polynomial-horizon and long-clock physical resource points are all retained.

Those three points are constructions, not an exact physical Pareto curve. The general converse now applies to each of their fixed protocols, but its numerical evaluation across all physical budgets is a separate task. Likewise a confidence lower bound at a specified retained-coin interface is not automatically a lower bound for an auditor that uses richer raw observations. These distinctions are mathematical typing conditions on the applications, not changes to the physical or operator targets.

The article retains the full development of its supporting results; versioned derivation and review records are kept outside the exposition. The dependency appendix records the namespaced eleven-component program. The primary A2 geometric chain remains independent, while B4 kinetic and broader C2 operator conclusions require their own stated hypotheses and proofs. No artificial dependence on a finite-state theorem is imposed on those branches of the program.

## 2. COMPATIBLE OCCUPATION ARRAYS

A fixed terminal statistic and an optimal statistic under a sequence of memory constraints are different objects. We begin with a characterization of the second object. All the spaces in this section are finite. No strict positivity assumption is imposed on a probability coordinate.

**2.1. The finite protocol and its observable rows.** Fix a finite schedule  $\sigma$  and a register profile  $\mathbf{K} = (K_t)_{t \in \sigma}$ . A cut is part of the specification of  $\sigma$ : subdividing an atomic observation or a randomization operation inserts additional register constraints. The clocked model permits a different transition table at each scheduled operation. It does not permit access to a discarded observation. We write  $\mathcal{M}_\sigma^{\text{clk}}(\mathbf{K})$  for this class. Initial randomization, when allowed, is a transition of the same kind as all other randomizations.

Let  $\Theta$  be a finite set of environments. Under  $\theta$ , all preparation and experimental kernels are specified. One may include the complete physical and public past in a finite hidden index  $i$ . This index is a variable in the analysis, not an observer register. An elementary observer operation has an accessible row  $r$  and chooses  $j$  from a nonempty finite set  $J_r$ . The row contains exactly the current register and the current atomic input, if there is one. The choice  $j$  can specify a new register and a public action. A public action that is subsequently needed by the observer must be

retained in that register. Every permissible transition has the form

$$u(j \mid r), \quad u(j \mid r) \geq 0, \quad \sum_{j \in J_r} u(j \mid r) = 1. \quad (2.1)$$

Neither  $\theta$  nor the unobserved part of  $i$  is an argument of  $u$ .

Known environment operations act linearly on conditional occupation masses. For example, if  $z(\theta, h, m)$  is the mass before an observation, then its incoming mass at the observer is

$$x(\theta, h', (m, y)) = \sum_h z(\theta, h, m) L^\theta(h', y \mid h, m). \quad (2.2)$$

Dependence on a previously issued action is included in  $h$  or in the retained part of  $m$ . After an observer choice, the public history is updated and discarded indices are summed out, again by a known linear map. Alternating these two kinds of operation represents a finite controlled experiment, including feedback, calibration, validation, and a terminal readout. The cut alphabets and the allowed rows are fixed before optimization. In particular, this representation does not silently grant the observer the hidden history used to define the experimental kernels.

For each observer operation introduce outgoing masses  $f(\theta, i, r, j)$ . Impose the conservation and compatibility equations

$$f(\theta, i, r, j) \geq 0, \quad \sum_{j \in J_r} f(\theta, i, r, j) = x(\theta, i, r), \quad (2.3)$$

$$f(\theta, i, r, j)x(\theta', i', r) = f(\theta', i', r, j)x(\theta, i, r) \quad (\theta, i, \theta', i', r, j). \quad (2.4)$$

All incoming masses are nonnegative and are linked to the preceding operation by the known linear maps. Preparations are prescribed and have conditional mass one for each  $\theta$ . We call the resulting set of arrays  $\mathcal{O}_\sigma^{\text{clk}}(\mathbf{K})$ .

**Theorem 2.1** (Exact full-profile realization). *The occupation arrays of  $\mathcal{M}_\sigma^{\text{clk}}(\mathbf{K})$  are exactly  $\mathcal{O}_\sigma^{\text{clk}}(\mathbf{K})$ . This set is compact and is defined by linear equations, nonnegativity, and the quadratic equations (2.4). Every feasible array determines an implementing machine, with arbitrary legal rows only where the incoming mass vanishes under every environment.*

*More generally, suppose specified occurrences of observable rows must use the same transition distribution, with their choices identified. For each such class impose (2.4) also between different occurrences. The resulting arrays are exactly those realized by machines with these shared rows. In particular this gives an exact formulation for an autonomous controller with a fixed state alphabet and a single reused transition table.*

*Proof.* A machine gives  $f(\theta, i, r, j) = x(\theta, i, r)u(j \mid r)$ , so conservation and every minor equation follow. Conversely, fix an occurrence of  $r$ . If some  $x(\theta_0, i_0, r) > 0$ , define

$$u(j \mid r) = \frac{f(\theta_0, i_0, r, j)}{x(\theta_0, i_0, r)}.$$

Conservation makes this a stochastic row. The minor with  $(\theta_0, i_0)$  shows that the same formula reproduces  $f$  at every positive incoming mass. At a zero incoming mass, nonnegativity and conservation force each outgoing mass to be zero. If all incoming masses vanish, choose any legal stochastic row. Thus the recovered row is independent of both the environment and the hidden index.

Perform this construction at every observer operation. Induction along the schedule, using (2.2) and the corresponding linear outgoing maps, proves that the recovered machine has exactly the given occupation arrays. Its registers are the declared alphabets; the proof has not introduced a retained selector. For a shared row class, choose one positive incoming mass anywhere in that class and use the cross-occurrence equations. The same argument reconstructs one common row. A class with no positive incoming mass is treated arbitrarily.

Each coordinate is a conditional probability or a subprobability mass and is therefore at most one. Adding these redundant upper bounds makes boundedness explicit. The equations and inequalities are closed, and there are finitely many coordinates. Compactness follows.  $\square$

The zero-mass provision is essential. Cancelling an occupation coordinate without a case distinction would remove valid boundary machines. Nor would separate low-rank descriptions at successive cuts imply (2.2)–(2.4). The latter equations refer to one execution, not to a list of independently selected encoders. For an autonomous machine, the phase cannot be supplied through a row name unless it is either an actual input or part of the charged state. A clocked machine can be embedded autonomously by retaining  $(t, m)$ ; Theorem 2.1 also permits direct optimization without making that possibly wasteful construction.

**2.2. A complete polynomial converse.** Let  $G \in [-1, 1]$  be a terminal payoff and let  $L_\theta(z)$  denote its expectation as a linear function of the complete occupation array  $z$ . The terminal decision is included among the observer operations. Set

$$V_{\sigma, \mathbf{K}}^{\text{clk}}(\Theta, G) = \max_{A \in \mathcal{M}_\sigma^{\text{clk}}(\mathbf{K})} \min_{\theta \in \Theta} \mathbb{E}_\theta^A G. \quad (2.5)$$

The admissible row sets are assumed nonempty. Introduce  $v \in [-1, 1]$  and impose  $L_\theta(z) - v \geq 0$  for every  $\theta$ . Write  $h_a = 0$  for all the linear and quadratic equalities and  $g_b \geq 0$  for the remaining inequalities. Include the redundant ball inequality

$$R - \|(z, v)\|^2 \geq 0,$$

where the positive integer  $R$  is larger than the number of coordinates. Let  $\mathcal{F}$  be this basic closed feasible set. For  $d \geq 1$ , define  $U_d$  as the infimum of  $u \in \mathbb{R}$  for which the polynomial identity

$$u - v = \sigma_0 + \sum_b \sigma_b g_b + \sum_a q_a h_a \quad (2.6)$$

holds, with each  $\sigma_b$  a sum of squares, each  $q_a$  a polynomial, and every displayed summand of degree at most  $2d$ . An empty certificate class has infimum  $+\infty$ .

**Theorem 2.2** (Complete full-profile certificates). *For the finite protocol above,*

$$V_{\sigma, \mathbf{K}}^{\text{clk}}(\Theta, G) = \max_{(z, v) \in \mathcal{F}} v = \inf_{d \geq 1} U_d, \quad U_{d+1} \leq U_d. \quad (2.7)$$

*A feasible occupation array is a constructive lower certificate. An identity (2.6) is an upper certificate for every stochastic machine of the specified full profile. For rational experimental data, every rational  $u > V_{\sigma, \mathbf{K}}^{\text{clk}}$  admits such a certificate with rational coefficients. The same conclusions hold with shared rows, including the autonomous case.*

*Let  $\ell_r$  be the best worst-case payoff among the actual controller tables whose entries are dyadic with denominator  $2^r$ . If transition  $t$  has at most  $s_t$  choices per row, then*

$$\ell_r \leq V_{\sigma, \mathbf{K}}^{\text{clk}} \leq \min \left\{ U_d, \ell_r + 2 \sum_t (s_t - 1) 2^{-r} \right\}. \quad (2.8)$$

*Here repeated uses of a shared row are counted repeatedly in the sum. Thus there are matching constructive and converse certificates to any positive accuracy, without a minimax interchange or a convexification of fixed-width machines.*

*Proof.* The first equality follows from Theorem 2.1 and the inequalities  $v \leq L_\theta(z)$ . Compactness gives attainment. Evaluating (2.6) at any feasible point gives  $v \leq u$ . Increasing  $d$  only enlarges the certificate class.

For completeness, take  $u > \max_{\mathcal{F}} v$ . The polynomial  $u - v$  is strictly positive on  $\mathcal{F}$ . Apply Putinar's positivity theorem [29] to the inequalities  $g_b \geq 0$  and the pairs  $h_a \geq 0, -h_a \geq 0$ . The explicitly included ball makes the quadratic module Archimedean. The resulting identity has

finite degree. Collecting the two multipliers of  $h_a$  gives (2.6). Letting  $u$  decrease to the maximum proves the second equality. For rational data and rational  $u$ , the rational version with an explicit ball generator [30, Theorem 6] gives rational sums of squares and rational multipliers. This is an application of those positivity theorems, not a new Positivstellensatz.

Finally round each stochastic row to the dyadic simplex, preserving its causal zeros, at total-variation cost at most  $(s_t - 1)2^{-r}$ . Round a shared row once and use that rounded row at every occurrence. Coupling the original and rounded executions until their first discrepancy bounds the probability of a discrepancy by the sum in (2.8), capped at one. The payoff range is at most two. This estimate is uniform in  $\theta$ , so rounding a maximizing machine proves the rightmost bound. The dyadic machines are actual machines, which proves the left bound. Their finite enumeration is a construction, even though its cost may be large.  $\square$

A numerical semidefinite solution is not by itself an identity (2.6); coefficients and nonnegativity must be certified. The theorem proves convergence, not a uniform degree bound, finite termination at  $u = V$ , or an efficient algorithm. Its necessity statement is nevertheless different from a resource upper construction: every machine obeys every certified upper bound. Dropping compatibility constraints produces a relaxation. It does not preserve the exact value in general, as Theorem 4.1 will demonstrate explicitly.

**Corollary 2.3** (Compact families and finite experimental adapters). *Suppose  $B$  is a compact family of finite experimental kernels on a fixed schedule with  $N$  environment calls. Let  $B_j \subset B$  be a finite  $\omega_j$ -net in the maximum conditional total-variation metric, with  $\omega_j \rightarrow 0$ . Use the same bounded terminal payoff throughout. Then*

$$\ell_r(B_j) - 2N\omega_j \leq V_{\sigma, \mathbf{K}}^{\text{clk}}(B, G) \leq U_d(B_j). \quad (2.9)$$

*As  $j, r, d$  tend to infinity in a suitable order, the two sides have common limit  $V_{\sigma, \mathbf{K}}^{\text{clk}}(B, G)$ . A certified adapter changing call  $i$  by at most  $\delta_i$  contributes  $2\sum_i \delta_i$  to a payoff comparison. A simulator with profile  $\mathbf{R}$  is charged by the product profile  $(R_t K_t)$ .*

*Proof.* For any one controller, couple corresponding calls until the first unequal outcome. Its expected payoff varies by at most  $2N\omega_j$  between a kernel and its net representative. Hence  $V(B_j) - 2N\omega_j \leq V(B) \leq V(B_j)$ . Apply Theorem 2.2 to  $B_j$  and choose the dyadic and certificate accuracies after choosing  $j$ . The same coupling with unequal  $\delta_i$  gives the adapter bound. Retaining the ordered pair of simulator and controller states proves the product assertion.  $\square$

An effective net is additional data; abstract compactness is not an algorithm for an arbitrary presentation. The finite-alphabet, compact parameter collision experiments considered below have this interface. Consequently their fixed-schedule, full-profile values admit the same all-auditor certificates. This implication does not evaluate those certificates numerically for every physical sample budget, nor does it identify a minimal autonomous implementation.

### 3. CONTINUATION POLYTOPES AND NOISY POSTERIOR PARTITIONS

We next obtain a finite exact recursion, and then an explicit solution, for noisy experiments. Unlike a revelation channel, these experiments need never disclose the parameter at any time.

**3.1. One common continuation matrix.** Let  $\Theta$  and the terminal action set  $A$  be finite. Conditional on  $\theta$ , report  $t$  has distribution  $p_t^\theta$  on  $Y_t$  and reports are independent. A clocked observer starts in one state, retains at most  $K_t$  states after report  $t$ , and receives payoff  $G(\theta, a)$ . For the moment there are no prescribed zeros in its update tables. For a fixed prior  $\pi$ , denote its optimal Bayesian payoff by  $B_{n, \mathbf{K}}^{\text{clk}}(\pi, G)$ . The terminal readout has no further observation of a discarded report.

Define finite sets of continuation matrices, with one column per retained state, backwards by

$$\mathcal{C}_n = \{(G(\theta, a_s))_{\theta, s} : (a_s)_s \in A^{K_n}\}, \quad (3.1)$$

$$\mathcal{C}_{t-1} = \bigcup_{f: [K_{t-1}] \times Y_t \rightarrow [K_t]} T_{t,f}(\mathcal{C}_t), \quad (3.2)$$

$$(T_{t,f}C)_{\theta, s} = \sum_{y \in Y_t} p_t^\theta(y) C_{\theta, f(s, y)}, \quad K_0 = 1. \quad (3.3)$$

The same matrix  $C$  occurs in every term of (3.3). Different incoming states do not receive independently selected future machines. If there are finitely many controlled experiments, include an action choice  $a_s$  in the union and replace  $p_t^\theta(y)$  by  $p_t^\theta(y \mid a_s)$ .

**Proposition 3.1** (Exact Bayesian continuation recursion). *Every matrix in  $\mathcal{C}_t$  is implemented by one deterministic suffix of the prescribed profile, and every such suffix has a matrix in  $\mathcal{C}_t$ . Moreover,*

$$B_{n, \mathbf{K}}^{\text{clk}}(\pi, G) = \max_{C \in \mathcal{C}_0} \sum_{\theta} \pi_{\theta} C_{\theta, 1}. \quad (3.4)$$

For Bayesian optimization the sets can be replaced by their joint convex hulls  $\mathcal{P}_t = \text{conv } \mathcal{C}_t$ , using  $\mathcal{P}_{t-1} = \text{conv } \bigcup_f T_{t,f}(\mathcal{P}_t)$ . This operation does not authorize a free shared random seed. Replacing  $\mathcal{P}_t$  by the product of its separate column projections is not valid in general.

*Proof.* At the terminal time, each column records the selected terminal action. At an earlier time, a deterministic update  $f$  feeds the new state into one fixed suffix. Conditional expectation gives (3.3). Backward induction proves the realization and converse statements, including recovery of the update tables.

For a fixed prior the payoff is a multiaffine function of the finitely many time-indexed stochastic rows: an execution visits any such row at most once. A maximum exists. Holding all but one row fixed, replace that row by a maximizing vertex of its simplex. Doing this finitely many times gives a deterministic maximum without changing the budget. The same argument includes an experiment-selection row. This proves (3.4) for all stochastic machines. Linearity of  $T_{t,f}$  gives the asserted convex-hull recursion. A maximizing vertex of the final finite hull has a deterministic witness; the hull is used only to calculate a support value.

For the last assertion, consider a suffix with two possible initial states, a compulsory next cut of width one, and no informative subsequent report. Its two continuation columns must be equal. Individually each column may implement either constant binary decision. The product of the two column projections also contains the matrix that makes opposite decisions in the two initial states, which the compulsory one-state cut cannot implement. Under a fair preparation where the two initial states reveal the binary parameter, this false matrix gives success one instead of the true value one half.  $\square$

**3.2. Binary posterior geometry.** For  $\Theta = \{0, 1\}$  write a current occupation list as  $Z = (z_s)_s$ , where

$$z_s = (\mathbb{P}(\theta = 0, M = s), \mathbb{P}(\theta = 1, M = s)) \in \mathbb{R}_+^2.$$

Zero columns can be discarded and unused labels can always be padded. After report  $t$ , its incoming atoms are

$$b_{s,y} = (z_{s,0} p_t^0(y), z_{s,1} p_t^1(y)). \quad (3.5)$$

Order the nonzero atoms by  $q(b) = b_1/(b_0 + b_1) \in [0, 1]$ . An interval partition divides that ordered list into at most  $K_t$  consecutive nonempty blocks; summing the atoms in each block gives a new list  $\mathcal{I}_t(Z)$ . Equal-posterior atoms may first be merged. No nestedness of the partitions at different times is required.

Set

$$\begin{aligned} F_n(Z) &= \sum_s \max_{a \in A} \{z_{s,0}G(0, a) + z_{s,1}G(1, a)\}, \\ F_{t-1}(Z) &= \max_{\mathcal{I}_t} F_t(\mathcal{I}_t(Z)), \quad t = n, \dots, 1. \end{aligned} \tag{3.6}$$

For controlled observations, first maximize over the finite vector of experiment choices  $(a_s)_s$  and then form (3.5) with those choices. Only lists reachable from the initial list are needed in evaluating this recursion.

**Theorem 3.2** (Exact noisy full-profile recursion). *For arbitrary binary finite experiments of the conditionally independent form above, any prior, any bounded terminal payoff, and any finite cardinality profile,*

$$B_{n, \mathbf{K}}^{\text{clk}}(\pi, G) = F_0((\pi_0, \pi_1)). \tag{3.7}$$

*There is an optimal deterministic machine whose update at every time is an interval partition of the current incoming posterior atoms. The recursion produces such a machine and optimizes over all stochastic machines, not just over a preselected statistic. It also holds with a finite choice of controlled experiments at each state.*

*Proof.* Deterministic optimality follows from Proposition 3.1. Fix a deterministic global maximum, and consider one of its update times. Hold its prefix, experiment choices at this time, and entire suffix fixed. If the suffix starting at label  $j$  has continuation rewards  $c_{0j}, c_{1j}$ , assigning incoming atom  $b$  to  $j$  contributes

$$b_0 c_{0j} + b_1 c_{1j} = (b_0 + b_1)((1 - q(b))c_{0j} + q(b)c_{1j}).$$

It is therefore optimal to select a maximizing affine function of  $q$ . The upper envelope of finitely many affine functions on  $[0, 1]$  has interval regions. Choose tied affine functions consistently, ordering active slopes and discarding identical duplicates. Each selected label then occupies an interval. At an identical posterior, all atoms have the same maximizing set, so they can be assigned to the same label. Unused labels cause no difficulty. Relabel the active suffix states in interval order, including their future experiment choices.

Now perform these replacements in chronological order. A replacement does not alter any earlier incoming occupation list or earlier update. It cannot decrease the payoff and thus preserves global optimality. Later incoming lists may change; they are recomputed before their own replacement. Hence the final machine has the interval property at all times simultaneously. This forward argument is why independently optimizing a partition at each cut would not prove the theorem.

Conversely, every sequence of choices in (3.6) defines causal finite update tables and therefore one admissible machine. The terminal formula is exactly its optimal readout. The existence just proved shows that restricting the finite search to these choices loses nothing. This proves (3.7). With controlled observations, first keep the current deterministic experiment choices fixed in the replacement argument; the same affine-envelope reasoning applies to their incoming atoms. Maximizing over those finite choices completes the proof.  $\square$

This theorem uses the likelihood-ratio quantizer principle [27]; the affine-envelope mechanism is not claimed as new. The point of the recursion is the common, changing occupation list and the simultaneous realizability of all its partitions. The posterior pairs are computed by the designer. The implemented machine stores only a finite label and uses a fixed finite lookup table; it does not store a real-valued posterior. The number of reachable lists can be large. No polynomial-time claim is part of the theorem.

The result is Bayesian and clocked. A maximum of a minimum over environments is not multiaffine, and a reused autonomous row can occur several times in one execution. Neither of those cases is covered by the purification argument. They remain covered by Theorems 2.1 and

2.2. The following example solves the minimax problem directly and shows why the distinction is substantive.

**3.3. An exact minimax recursion for binary registers.** There is also a structural recursion that does not purify the minimax objective. In this subsection observations are conditionally independent and uncontrolled, and every retained alphabet has size one or two. Represent a binary prefix experiment by its pair  $r = (r_0, r_1)$ , where  $r_\theta = \mathbb{P}_\theta(M = 1)$ . Its labels may be exchanged at no cost. Say that  $s$  dominates  $r$  if a single stochastic binary channel, independent of  $\theta$ , maps  $s$  to  $r$ .

For a pair  $s$  and the next report law, let  $E_t(s)$  be the experiment on  $\{0, 1\} \times Y_t$  with masses

$$e_\theta(m, y) = s_\theta^m (1 - s_\theta)^{1-m} p_t^\theta(y).$$

At endpoints this formula has its direct Bernoulli meaning. For any finite binary experiment  $E = (e_0, e_1)$  define its upper receiver curve by the finite linear program

$$R_E(a) = \max \left\{ \sum_x e_1(x) \phi(x) : 0 \leq \phi(x) \leq 1, \sum_x e_0(x) \phi(x) = a \right\}, \quad 0 \leq a \leq 1. \quad (3.8)$$

Ordering atoms by likelihood ratio solves this program: accept the largest ratios first, randomizing at at most one ratio level. Atoms with zero  $e_0$  are treated by their direct contribution to the objective; no division by zero is needed.

Starting with  $\mathcal{R}_0 = \{(0, 0)\}$ , define

$$\mathcal{R}_t = \begin{cases} \{(0, 0)\}, & K_t = 1, \\ \{(a, R_{E_t(s)}(a)) : s \in \mathcal{R}_{t-1}, 0 \leq a \leq 1\}, & K_t = 2. \end{cases} \quad (3.9)$$

This is a recursion of attainable channels, not of their convex hulls. Its continuous parameters are design parameters of finite stochastic rows, not stored posterior coordinates. In particular, it need not have a polygonal reachable set after several stages.

**Theorem 3.3** (Binary-register minimax frontier). *Every channel in  $\mathcal{R}_t$  is attainable with the prefix profile, and every stochastic prefix experiment with that profile is dominated by some member of  $\mathcal{R}_t$ . For a bounded payoff  $G$  and finite terminal action set, let  $\Gamma_G(r)$  be the optimal minimum of the two expected payoffs obtained by a terminal stochastic readout of the binary experiment  $r$ . Then*

$$V_{n, \mathbf{K}}^{\text{clk}}(\{0, 1\}, G) = \max_{r \in \mathcal{R}_n} \Gamma_G(r). \quad (3.10)$$

For correct-decision payoff this reduces to

$$V_{n, \mathbf{K}}^{\text{clk}} = \max_{r \in \mathcal{R}_n} \left\{ \frac{1}{2} + \frac{|r_1 - r_0|}{2(1 + |1 - r_0 - r_1|)} \right\}. \quad (3.11)$$

An optimizer can be implemented by likelihood-ratio quantizers with at most one randomized ratio level per update and a terminal readout. These assertions hold at every finite horizon, with overlapping noise and with arbitrary placement of one-state cuts.

*Proof.* First consider a binary summary of any finite binary experiment, with output probabilities  $(r_0, r_1)$ . Exchange its labels if necessary so that  $r_1 \geq r_0$ . The receiver-curve optimizer at  $a = r_0$  has output probabilities  $(r_0, b)$  with  $b \geq r_1$ . It dominates  $(r_0, r_1)$ . Indeed, if  $b > r_0$ , put

$$\lambda = \frac{r_1 - r_0}{b - r_0} \in [0, 1].$$

The postprocessing probabilities  $\mathbb{P}(M = 1 \mid S = 0) = r_0(1 - \lambda)$  and  $\mathbb{P}(M = 1 \mid S = 1) = r_0(1 - \lambda) + \lambda$  are in  $[0, 1]$  and give the required pair. If  $b = r_0$ , the desired summary is uninformative and can be generated by a constant stochastic row. Undoing the exchange of labels covers the original summary. The receiver program is solved by an ordered threshold because moving an equal amount

of  $e_0$ -mass from a smaller likelihood ratio to a larger one cannot decrease its objective. Sorting the finite atoms and filling the prescribed mass  $a$  proves the stated one-level randomization rule, including zero-mass atoms.

Proceed by induction on  $t$ . Each member of (3.9) is attained by an attaining previous channel and a receiver-curve quantizer. Conversely, suppose a previous prefix channel  $r$  is dominated by an attainable  $s$  in  $\mathcal{R}_{t-1}$ . Conditional independence of the next observation implies that  $E_t(s)$  dominates  $E_t(r)$  by applying the same postprocessing to the state coordinate. Composing this postprocessing with any proposed new summary gives a binary quantizer of  $E_t(s)$ . The preceding argument dominates its output by a receiver-curve point, which belongs to  $\mathcal{R}_t$ . This composition can be incorporated in one update table and introduces no retained selector. At a one-state cut every prefix is uninformative and the reset to  $(0, 0)$  is exact. This proves both inductive assertions.

A terminal readout can compose any dominating channel's postprocessing, so  $\Gamma_G$  is monotone under domination. The original finite machine class has a maximizer by compactness of its row simplices. The inductive domination statement supplies an attainable member of  $\mathcal{R}_n$  with at least that value. No attainable member can exceed the optimum. This proves the maximum and attainment in (3.10), without needing a convexity claim about  $\mathcal{R}_n$ .

For the last formula, exchange labels to arrange  $r_1 \geq r_0$ . If  $r_0 + r_1 \leq 1$ , accept hypothesis one on state one and randomize on state zero with probability  $(1 - r_0 - r_1)/(2 - r_0 - r_1)$ . The two successes then equal  $(1 - r_0)/(2 - r_0 - r_1)$ . If  $r_0 + r_1 \geq 1$ , reject on state zero and accept on state one with probability  $1/(r_0 + r_1)$ ; both successes equal  $r_1/(r_0 + r_1)$ . These are likelihood-ratio tests and are minimax by the same equal-error supporting-prior argument as for a finite receiver curve. Both expressions equal (3.11); uninformative endpoints give  $1/2$  directly. Choosing the attaining prefix quantizers proves the final implementation assertion.  $\square$

Equation (3.9) is a genuine minimax whole-schedule characterization for arbitrary finite horizons in this binary-register class. It uses the ordinary comparison order of binary experiments, not a minimax interchange for complete machines. The restriction to uncontrolled, conditionally independent reports is used exactly when the dominating prefix is tensored with the next report. General controlled experiments and larger minimax registers use the occupation theorem instead. The three-report result that follows is a closed-form evaluation, with a strict mixing gap, of this same noisy resource problem.

#### 4. AN EXACT NOISY FRONTIER AND THE COST OF HIDDEN MIXING

Let  $\theta \in \{0, 1\}$ , and let  $Y_1, Y_2, Y_3$  be conditionally independent binary reports with

$$\mathbb{P}_\theta(Y_t \neq \theta) = p, \quad 0 < p < 1/2.$$

Every report has overlapping support under the two hypotheses. A clocked machine has at most  $K_t$  labels after report  $t$  and makes a binary terminal decision. Updates are atomic stochastic operations; additional random-bit cuts are discussed below. Let  $B_{\mathbf{K}}(p)$  be its optimal success under the fair prior, and let  $V_{\mathbf{K}}(p)$  be its optimal minimum of the two conditional success probabilities. Both optimize over all stochastic machines of this profile. Put

$$d(p) = p(1 - p)(1 - 2p) > 0.$$

**Theorem 4.1** (Complete three-report profile frontier). *For every positive integer profile  $(K_1, K_2, K_3)$ ,*

| <i>profile condition</i>         | $B_{\mathbf{K}}(p)$       | $V_{\mathbf{K}}(p)$       | (4.1) |
|----------------------------------|---------------------------|---------------------------|-------|
| $K_3 = 1$                        | $1/2$                     | $1/2$                     |       |
| $K_3 \geq 2, \min(K_1, K_2) = 1$ | $1 - p$                   | $1 - p$                   |       |
| $K_1, K_3 \geq 2, K_2 = 2$       | $1 - p + \frac{1}{2}d(p)$ | $1 - p + \frac{1}{3}d(p)$ |       |
| $K_1, K_3 \geq 2, K_2 \geq 3$    | $1 - p + d(p)$            | $1 - p + d(p)$            |       |

In the third line a minimax optimal machine retains  $Y_1$ , then retains  $Y_1 Y_2$  (the Boolean AND), and after the third report decides one with probability

$$\frac{(M_2, Y_3)}{\mathbb{P}(\hat{\theta} = 1 \mid M_2, Y_3)} \mid \begin{array}{cccc} (0, 0) & (0, 1) & (1, 0) & (1, 1) \\ 0 & 2/3 & 1 & 1. \end{array} \quad (4.2)$$

The two conditional success probabilities are equal. In particular, for  $p = 1/4$  and profile  $(2, 2, 2)$  the exact Bayesian and minimax values are  $51/64$  and  $25/32$ , whereas profile  $(2, 3, 2)$  has value  $27/32$  for both objectives.

We prove the minimax assertion without passing to a convex hull of machines. The following elementary binary-channel domination is useful.

**Lemma 4.2** (Reduction of a two-report binary register). *Every stochastic binary summary of  $(Y_1, Y_2)$  is, up to exchanging its two output labels, a stochastic postprocessing of a summary with*

$$\mathbb{P}(M = 1 \mid 00) = 0, \quad \mathbb{P}(M = 1 \mid 01) = \mathbb{P}(M = 1 \mid 10) = w, \quad \mathbb{P}(M = 1 \mid 11) = 1 \quad (4.3)$$

for some  $w \in [0, 1]$ . This domination holds simultaneously under both hypotheses and continues to hold after appending an independent third report.

*Proof.* Write  $u, v$  for the summary probabilities on  $00, 11$ , and write  $b$  for the average of its probabilities on  $01, 10$ . Those two words have the same probability under either hypothesis, so their average contains all relevant information. Exchange output labels if necessary to arrange  $v \geq u$ , and put  $\alpha = v - u \in [0, 1]$  and  $c = 2p(1 - p) \in (0, 1)$ . Its output-one probabilities satisfy

$$r_0 = u + c(b - u) + p^2\alpha, \quad r_1 - r_0 = (1 - 2p)\alpha.$$

For the summary (4.3) these probabilities are  $s_0 = p^2 + cw$ ,  $s_1 = (1 - p)^2 + cw$ . Seek a postprocessing that sends input zero to one with probability  $a$  and input one to one with probability  $a + \alpha$ . It is stochastic precisely when  $0 \leq a \leq 1 - \alpha$ , and it reproduces  $r_0, r_1$  if

$$a = u + c(b - u) - c\alpha w.$$

As  $w$  ranges over  $[0, 1]$ , the right side ranges from  $u + c(b - v)$  to  $u + c(b - u)$ . The upper endpoint is nonnegative. The lower endpoint is at most  $1 - \alpha$ , since

$$1 - \alpha - u - c(b - v) = (1 - v) + c(v - b) \geq (1 - v)(1 - c) \geq 0.$$

Consequently this interval meets  $[0, 1 - \alpha]$ . This proves the claim, including  $\alpha = 0$ . Applying the postprocessing independently of the third report proves the last statement.  $\square$

*Proof of Theorem 4.1.* If the last register has one state, its terminal decision is independent of the reports. The fair-prior value is one half, and a fair terminal randomization gives minimax value one half. If an earlier register has one state, at most the last two reports remain informative. The unrestricted optimal success from two equally reliable reports is  $1 - p$  under either criterion: use their common value on agreement and a fair decision on disagreement. One report already gives  $1 - p$ . These rules respect the stated profiles and prove the second line.

Suppose henceforth that  $K_1, K_3 \geq 2$ . There is no loss in retaining  $Y_1$  exactly. Indeed any stochastic first update followed by a second update induces one binary channel from  $(Y_1, Y_2)$  to  $M_2$ , and that channel can be implemented directly when  $Y_1$  is retained. Allowing more than two first-stage labels gives no larger set of such channels. At the last stage any randomized binary decision based on  $(M_2, Y_3)$  can be placed directly in a two-label register. Thus, when  $K_2 = 2$ , the unrestricted optimization is exactly over a binary summary of the first two reports and a randomized readout of it together with  $Y_3$ .

For the Bayesian problem, Theorem 3.2 reduces the middle update to intervals of the three distinct likelihood-ratio classes  $00, \{01, 10\}, 11$ . A nonconstant two-interval update isolates  $00$  or

isolates 11. These are the Boolean OR and AND, up to labels. With AND, the Bayesian readout is  $\hat{\theta} = Y_3 \vee (Y_1 \wedge Y_2)$ . Its conditional successes are

$$c_0 = 1 - p - p^2 + p^3, \quad c_1 = 1 - 2p^2 + p^3.$$

Their average is  $1 - p + d(p)/2$ . The complementary rule interchanges  $c_0, c_1$ . A constant middle update gives only  $1 - p$ , proving the Bayesian third line. This also covers updates that split the tied middle words: the theorem permits assigning the entire tied class to one maximizing suffix label without decreasing the Bayesian objective.

For the minimax problem, Lemma 4.2 reduces the search, without loss, to (4.3). Complementing all reports and output labels replaces  $w$  by  $1 - w$  and interchanges the hypotheses, so it suffices to take  $0 \leq w \leq 1/2$ . Write

$$r_0 = p^2 + 2p(1 - p)w, \quad r_1 = (1 - p)^2 + 2p(1 - p)w.$$

In the experiment  $(M_2, Y_3)$  the likelihood ratios are ordered as 00, 01, 10, 11. Only the ordering of the middle two needs verification; after multiplying by their positive denominators it is equivalent to

$$r_1(1 - r_0)p^2 - r_0(1 - r_1)(1 - p)^2 = p^2(1 - p)^2(1 - 2p)(1 - 2w)^2 \geq 0.$$

Consider the test that accepts hypothesis one on 10, 11, rejects it on 00, and accepts it on 01 with probability

$$a(w) = \frac{1 - r_0 - r_1}{(1 - r_0)p + (1 - r_1)(1 - p)} = \frac{2(1 - 2w)}{3 - 2w}. \quad (4.4)$$

This number is in  $[0, 1]$ . Its two conditional success probabilities are equal, with common value

$$R(w) = 1 - r_0 - a(w)(1 - r_0)p. \quad (4.5)$$

It is a likelihood-ratio test, possibly randomized at one threshold. Choose the prior odds equal to that threshold. The test is then Bayesian optimal for those odds. Since its two successes are equal, no test can have a larger minimum: such a test would also have a larger payoff for this prior. Thus  $R(w)$  is the exact minimax success for this summary, not merely an equal-error attainable value.

Direct differentiation gives

$$R'(w) = -\frac{2p(1 - p)(1 - 2p)(5 - 2w)(1 - 2w)}{(3 - 2w)^2} \leq 0. \quad (4.6)$$

Equivalently, an explicit nonnegative gap certificate is

$$R(0) - R(w) = \frac{2p(1 - p)(1 - 2p)w(5 - 6w)}{3(3 - 2w)} \geq 0, \quad 0 \leq w \leq 1/2. \quad (4.7)$$

The denominator is positive and every factor in the numerator is nonnegative on the stated domain. Therefore the best  $w$  is zero. Equations (4.4)–(4.5) give  $a(0) = 2/3$  and

$$R(0) = 1 - \frac{2}{3}p - p^2 + \frac{2}{3}p^3 = 1 - p + \frac{1}{3}d(p).$$

The postprocessing in Lemma 4.2 can be composed with any final readout and does not need a retained selector. It follows that this upper bound applies to every original stochastic machine. The rule (4.2) attains it.

Finally, if  $K_2 \geq 3$ , retain the number of ones in the first two reports and output the majority of all three. Both successes are  $1 - 3p^2 + 2p^3 = 1 - p + d(p)$ . The likelihood-ratio rule for the full three reports is majority under the fair prior, so no machine can have a larger Bayesian value or a larger minimum. This proves the last line and completes all cases.  $\square$

**Corollary 4.3** (A strict fixed-profile mixing gap). *For profile  $(2, 2, 2)$  a free initial selector that mixes the two complementary Bayesian optimal machines would give worst-case success  $1 - p + d(p)/2$ . Without that uncharged selector the exact value is  $1 - p + d(p)/3$ . The excess  $d(p)/6$  is strictly positive.*

*Proof.* Mix the two payoff vectors  $(c_0, c_1)$  and  $(c_1, c_0)$  from the proof with equal weights. Each coordinate becomes their average. Theorem 4.1 gives the smaller all-stochastic value at the original profile. To implement the mixture literally, retain the selector jointly with the machine state; a profile  $(4, 4, 2)$  suffices. The corollary does not claim that this product construction minimizes the expanded profile.  $\square$

The gap identifies a specific failure of a convexified all-machine converse. A terminal output law can be a convex combination of laws while the machines producing those laws cannot be mixed within their original memory profile. In contrast, the quadratic compatibility constraints of Theorem 2.1 retain exactly the required coupling. The noisy loss  $2d(p)/3$  between two and three middle states is also a strict full-schedule minimax loss; it is not an erasure probability or the cost of remembering a label that was already known.

*Remark 4.4* (Atomic randomization and finite precision). The fraction  $2/3$  in (4.2) is an exact rational row of the all-stochastic model. A fixed finite string of fair bits cannot realize this fraction exactly. Replacing it by a dyadic number within  $2^{-r}$  gives a genuine finite-precision rule whose minimum success is at least  $V_{(2,2,2)}(p) - 2^{-r}$ . If each random-bit epoch is a charged cut, retain  $(M_2, Y_3)$  while executing the dyadic sampler; the three-status comparison sampler of Section 10 gives a conservative peak of 12 for this refined execution. The theorem's exact two-state value refers to its stated atomic-update profile, not to this finer profile. The latter has its own exact occupation formulation. Neither an unbounded rejection sampler nor a free fair-bit clock is hidden in the two-state assertion.

## 5. ACQUISITION, CLOCKS, AND THE RESOURCE ORDER

A statistical bound is ambiguous unless the protocol and the resource coordinates being compared are specified. The superscript  $\text{clk}$  in the preceding theorems is therefore part of their notation, not a qualification confined to an implementation paragraph.

**5.1. Comparable resource points.** On one declared schedule, profiles are ordered coordinatewise. Enlarging a register alphabet preserves every previously feasible machine by padding unused states. Inserting observations is comparable only through an explicit embedding that says which new inputs are ignored and which registers survive the inserted cuts. Atomic and bit-serial schedules are different schedules, even when they have the same number of experimental preparations.

For a finite-precision implementation we record

$$\mathbf{r} = (N_B, N_Q, \mathbf{K}, r, D, \mathbf{C}). \quad (5.1)$$

Here  $N_B, N_Q$  count candidate and target preparations,  $r$  bounds fair bits per declared row sampler,  $D$  bounds a specified read-only description, and  $\mathbf{C}$  specifies clocked or autonomous execution. A description is measured in a fixed code, not by an unspecified notion of compressibility. For example, with a known table layout, store the first  $s - 1$  numerators of a  $2^{-r}$  stochastic row in  $(s - 1)(r + 1)$  bits; its last numerator is the remainder. The layout, response dictionary and any program used to expand repeated phases have their own fixed-code costs. Sample-dependent calibration is not part of that read-only description.

For the same code and schedule, increasing numerical resource caps or register alphabets gives an inclusion of machine classes. Changing  $\mathbf{C}$  does not mean increasing one numerical coordinate. A clocked execution with  $T$  update epochs and profile  $\mathbf{K}$  has an autonomous realization on the

disjoint union of its phase registers, using at most  $\sum_{t=0}^T K_t$  states. This is an attainable conversion, not an equality of optimal frontiers. Shared-row optimization in Theorem 2.1 can be strictly smaller than that conversion.

**Proposition 5.1** (Joint finite resource optimization). *Fix a finite experimental protocol and a finite table code. With finite caps on description and precision, the feasible machines form a finite set and their optimal worst-case payoff is exactly the maximum over that set. If the precision restriction is removed on a fixed table architecture, Theorems 2.1 and 2.2 characterize its exact value. A finite collection of permitted architectures is handled by taking the maximum of their values. Calibration calls can be included as an initial part of the same protocol, with all their retained information passed through the same profile constraints.*

*Proof.* There are finitely many descriptions of bounded length and finitely many allowed dyadic rows. Retain exactly the descriptions that decode to legal tables of the specified finite schedule and budgets. Each has a well-defined payoff. For unrestricted stochastic rows on a fixed architecture, use its observable row sets in the occupation formulation. Optimizing over a finite union is a maximum over its components. A calibration prefix uses known experimental kernels at the unknown environment in exactly the same way as any other prefix; its sample-dependent state is an ordinary retained register. Thus it introduces neither a parameter oracle nor a new exception to the compatibility constraints.  $\square$

The proposition supplies a joint optimization model rather than merely a post hoc resource ledger. It does not claim a short closed formula for arbitrary description budgets. For compact continuous families the net condition in Corollary 2.3 is still required for effective finite certificates.

**5.2. Acquiring a calibration rather than assuming it.** The next result gives a fully priced constructive calibration prefix. Let  $h_1, \dots, h_K : \Omega \rightarrow [0, 1]$  be a fixed known response list, chosen independently of the calibration observations, and suppose its values have denominator  $2^r$ . Write  $d = |\Omega|$  and  $q_i = Qh_i$ . The target  $Q$  need not be given as a table: independent preparations from  $Q$  are available. Let  $M = 2^s$  and  $0 < \beta < 1$ .

**Theorem 5.2** (Sampled calibration with persistent-register pricing). *For every  $\rho > 0$  with*

$$M \geq \frac{1}{2\rho^2} \log \frac{2K}{\beta}, \quad (5.2)$$

*there is a clocked finite-precision calibration protocol using  $M$  target preparations and  $MKr$  fair bits. It returns  $\hat{q}_i \in \{0, 1/M, \dots, 1\}$  with*

$$\mathbb{P} \left( \max_i |\hat{q}_i - q_i| \leq \rho \right) \geq 1 - \beta.$$

*The complete counter register has at most  $C = (M + 1)^K$  states; a word buffer and the three-status dyadic sampler give peak at most  $3dC$ . If a subsequent auditor has peak at most  $W$  for any exogenously fixed calibration vector, retaining the acquired calibration gives the bound  $C \max(3d, W)$  for the combined execution.*

*Let  $v \in [-1, 1]$  and  $\epsilon \geq 0$ . Suppose, uniformly for calibration vectors  $\tilde{q}$ , the auditor's true expected score is at least  $v - \epsilon - 2\|\tilde{q} - q\|_\infty$ , and its score is in  $[-1, 1]$ . With fresh training and validation after this prefix, the combined expected score is at least*

$$v - \epsilon - 2\rho - 2\beta. \quad (5.3)$$

*Proof.* On target trial  $j$ , retain its word  $Y_j$ . For each  $i$ , generate a Bernoulli variable  $B_{ij}$  of parameter  $h_i(Y_j)$  with an independent  $r$ -bit dyadic sampler, and increment counter  $i$ . After all

$K$  updates, discard  $Y_j$ . For fixed  $i$ , the variables  $B_{ij}$  over different trials are independent, lie in  $\{0, 1\}$ , and have mean  $q_i$ . Their averages  $\hat{q}_i$  therefore satisfy

$$\mathbb{P}(|\hat{q}_i - q_i| > \rho) \leq 2e^{-2M\rho^2}.$$

This bounded-variable exponential estimate follows from the exponential moment bound used in Theorem 9.2. A union bound proves the probability assertion. Independence between different counters is not required.

The  $K$  counters each have  $M + 1$  possible values. The word buffer has  $d$  values, and the running comparison of a uniform  $r$ -bit word with a fixed dyadic threshold has three comparison statuses. These yield the stated state counts at every sampler cut. Trial, response and bit indices are in the declared clocked schedule, not in an unmentioned work tape. The persistent counter vector remains in the register of the subsequent auditor and multiplies its width by at most  $C$ . All its values are dyadic because  $M = 2^s$ .

Conditional on the calibration vector, later observations have their original independent laws. On the good calibration event the score bound is  $v - \epsilon - 2\rho$ . On the complementary event the score is at least  $-1$ . Since  $v \leq 1$  and  $\epsilon, \rho \geq 0$ , a loss of at most two times that event's probability suffices. This proves (5.3).  $\square$

For the response-cover tournament of Theorem 13.2, one may take

$$N_B = n(K - 1), \quad W = 3dK(2m + 1), \quad \epsilon = 4(K - 1)\theta + 2(K - 1)(e^{-4\theta m} + e^{-2n\theta^2})$$

when  $v$  is the envelope of the already dyadic response list. Starting with an arbitrary list and rounding it to  $r$  bits incurs the additional  $2^{1-r}$  term of that theorem. The new prefix prices target acquisition and its persistent calibration state. It is an explicit construction, not an optimal calibration-memory claim. Joint optimality at fixed finite budgets is the distinct problem in Proposition 5.1.

## 6. CONSUMERS OF THE COMPATIBLE FRONTIER

The preceding characterizations and the constructive continuation results below have the same object of optimization: one experiment, one schedule and one whole register profile. This section records the connections before developing the underlying marked and physical experiments in detail.

**6.1. Reset scores and physical protocols.** In the reset interface of Section 9, a fixed candidate supplies the training and candidate-validation kernels. The target supplies its own preparation and validation kernels. The final score is a function of the two retained validation bits. Include the response selection, all input-bit buffers, and all randomization cuts in  $\sigma$ . This produces precisely the finite protocol of Section 2. The image of the candidate family is not replaced by its convex hull.

**Corollary 6.1** (Common constructive and converse interface). *At any fixed finite reset protocol and full profile, the best worst-case score has the occupation characterization of Theorem 2.1; for a finite family it has the complete dual of Theorem 2.2. For a compact family with effective finite kernel nets it has the converging upper and lower certificates of Corollary 2.3. The response-cover machines of Theorems 12.2 and 13.2 supply feasible lower certificates in these very classes. Any certified dual bound applies to those machines and to every other stochastic machine with the same protocol and profile.*

*Proof.* Augment the hidden index by the fixed candidate parameter and the finite public trial history. Selection and memory updates are parameter-independent observer rows. Experimental draws are the known linear environment operations. Terminal scoring is linear in the terminal

occupation array. Thus the realization theorem applies in both directions. The constructive machines specify legal rows at every cut and hence feasible occupation arrays. Compact-family and dual assertions are exactly the corresponding general theorems.  $\square$

For the positive-noise marked collision experiment, the finite row-report alphabet is fixed and the private row family is compact. On compact subfamilies with the stated continuous kernel data, finite kernel nets give the preceding certificates. The microscopic and Gaussian comparison theorems below then transfer a certified payoff with their stated common-preparation error. If training kernels differ, their errors must also be charged; equality of the training source cannot be inferred from equality of the terminal validation task. The active-state estimate in Section 15 can replace a worst-case telescoping estimate for a fixed retained execution, but is not a bound on a full discarded transcript.

Thus the physical resource constructions (399, 40602), (320000, 1604) and  $(12800 \cdot 2^{400}, 12)$  are now accompanied by a general all-auditor converse procedure on each fixed full profile. They remain attainable resource points, not a list of proved Pareto optima. In particular, the numerical statement  $3 \leq W_{2/5}^{\text{phys}} \leq 12$  is not changed into an equality without an additional certificate or construction.

**6.2. An exact confidence consumer.** Let a reset audit return  $D \in \{-1, 0, 1\}$ . Suppose its null mean is zero and its alternative mean is at least  $g$ , where  $0 < g \leq 1$  is known. On each independent repetition, use a fresh coin with

$$\mathbb{P}(Z = 1 \mid D) = \frac{1}{2} + \frac{D - g/2}{4}. \quad (6.1)$$

Under the null its success probability is  $p = 1/2 - g/8$ , and under the alternative it is at least  $1 - p$ . Consider the declared coin interface consisting of the null Bernoulli law  $p$  and all alternative Bernoulli laws with parameter in  $[1 - p, 1]$ , independently repeated.

**Corollary 6.2** (Exact three-repetition confidence frontier). *At the atomic retained-coin profile (2, 2, 2), the minimum possible maximum of type-I and type-II error over this coin interface is*

$$p - \frac{1}{3}p(1 - p)(1 - 2p). \quad (6.2)$$

*The rule (4.2) attains it. Increasing only the middle retained-coin alphabet to three changes this value to  $p - p(1 - p)(1 - 2p)$ . If one underlying audit uses  $b$  candidate training trials, two validation trials, and peak  $W$ , the three-repetition construction uses  $3(b + 2)$  preparations. Its inner audit, coin sampler, and outer state are charged jointly, rather than identifying an outer two-state register with the entire physical register.*

*Proof.* The alternative family contains the endpoint  $1 - p$ , so Theorem 4.1 gives the lower bound on the maximum error. For the attaining test, its probability of deciding one, as a function of the three input bits, is coordinatewise nondecreasing: the middle state is AND, and the four final probabilities are 0, 2/3, 1, 1. Couple Bernoulli inputs with common independent uniforms. The power is then nondecreasing in their parameter, so the largest type-II error occurs at the endpoint. This proves attainment for the whole declared alternative interval. The majority test proves the assertion with three middle states in the same way. Preparation counts follow by repeating the base experiment independently three times. Product registers implement the outer transitions together with each inner repetition.  $\square$

If  $g$  is dyadic, the coin in (6.1) has a finite dyadic sampler. At its internal cuts an explicit conservative bound is  $2 \max(W, 9)$  for the outer state and inner audit/coin sampler; the additional 2/3 terminal row is either an atomic rational operation or is replaced by the finite-precision realization

in Remark 4.4. A fully fair-bit-serial realization has the conservative peak  $\max\{2\max(W, 9), 12\}$  and the indicated  $2^{-r}$  error allowance. This does not erase its clock or its bits from the schedule.

The exact lower bound concerns the declared coin interface. A physical subfamily inherits that lower bound only if it contains its endpoint experiment (or an appropriate certified limiting experiment). A raw physical auditor that uses more of  $D$  or of the original report is not restricted to this interface. For such auditors the general occupation converse, with those richer inputs retained, is the relevant statement. The confidence result is therefore a proved consumer, not a relabeling of an expected-score lower bound as a hypothesis-testing lower bound.

**6.3. The foundation and the longer program.** The initial objects remain positive experimental kernels, preparations, causal interventions and executable continuations. Finite protocols are a resource-controlled subcategory, not a replacement for the standard Borel formulation or its limiting targets. The new occupation and continuation results supply a precise G3-type finite resource layer. The marked deficiency and Gaussian transport results supply the comparison maps used above. The finite resource theorems do not supply a missing kinetic generator domain, a compactness theorem for collision measures, or an optional-projection theorem on a general operator domain.

The full historical dependency graph is retained in Appendix B. The geometric A2 chain has its own premises. The B4 state-dependent control-transfer, range and compactness targets, and the broader C2 operator and rigidity targets, retain their original scope. Their relation to this paper is through explicit experiment and simulator interfaces when those have been established, not through a declaration that every manuscript is a consequence of a finite-state comparison theorem.

## 7. INTRINSIC CAUSAL DEFICIENCY

**7.1. Experiments and executable signatures.** Fix a finite parameter set  $\Theta$ , a horizon  $T$ , and finite control alphabets  $A_0, \dots, A_{T-1}$ . An experiment has a report at checkpoints  $0, \dots, T$  and an unobserved terminal mark  $W$  in a common finite set. It is specified by finite causal instruments: for each parameter and control history they give the joint law of the report path and the actual mark. Equivalently, a finite latent-state realization may be expanded into its history tree. The parameter and mark are unavailable to the encoder. The mark may depend on the physical controlled path. We compare experiments with the same control interface and mark space.

Write  $Y_t$  for the source report and  $Z_t$  for the target report. A private simulator of width  $K$  has stochastic rows

$$\begin{aligned} q_0(z, m \mid y), \quad m \in [K_0], \\ q_t(z, m \mid m', a, y), \quad m' \in [K_{t-1}], \quad m \in [K_t], \quad 1 \leq t \leq T. \end{aligned} \tag{7.1}$$

A row consumes the current source report, emits the target report, and retains the new state. The previous target reports are not available to that row unless encoded in  $m'$ . The clock and current control are part of the declared interface. Fresh private randomness is permitted, but no other persistent random variable is free. The product of all row simplexes is denoted  $\mathcal{K}_K$ .

A deterministic feedback tree  $g$  chooses  $a_t$  from  $z_{0:t}$  and its own previous controls. It is the same controller on both sides of a comparison. Let  $\Omega_g$  be the finite marked transcript space, including reports, controls, and  $W$ . Put

$$P_{\theta,g}^q = \text{Law}_\theta(E \xrightarrow{q} g), \quad Q_{\theta,g} = \text{Law}_\theta(F \rightarrow g).$$

Here  $W$  on the left is the source's actual mark. The total variation convention is  $\|P - Q\|_{\text{TV}} = \sup_B |P(B) - Q(B)|$ . Private deficiency is

$$\delta_K^p(E, F) = \min_{q \in \mathcal{K}_K} \max_{\theta, g} \|P_{\theta,g}^q - Q_{\theta,g}\|_{\text{TV}}. \tag{7.2}$$

The minimum will be justified below. Randomized feedback need not be added to the maximum: conditioning on its independent random table expresses its law as a mixture of deterministic feedback laws. The same argument permits arbitrary independent side randomness in the tester.

A *hidden selector*  $U \in [r]$ , independent of the source, chooses one simulator  $q^u$ . It is not visible to the feedback controller or the final test. A *visible selector* is revealed before feedback begins. The two costs are

$$\delta_{K,r}^h(E, F) = \min_{\lambda, q^1, \dots, q^r} \max_{\theta, g} \left\| \sum_u \lambda_u P_{\theta, g}^{q^u} - Q_{\theta, g} \right\|_{\text{TV}}, \quad (7.3)$$

$$\delta_{K,r}^v(E, F) = \min_{\lambda, q^1, \dots, q^r} \max_{\theta, (g_u)} \left\| \sum_u \lambda_u \delta_u \otimes P_{\theta, g_u}^{q^u} - \sum_u \lambda_u \delta_u \otimes Q_{\theta, g_u} \right\|_{\text{TV}}. \quad (7.4)$$

In both expressions  $\lambda \in \Delta_r$  and  $q^u \in \mathcal{K}_K$ . The second formula compares the joint seed–marked interface. Its target seed has the same distribution and is independent of the target experiment. A hidden selector can be stored privately by retaining  $(u, m)$ , at width  $rK_t$ . A visible selector is separate side information and is charged by its own alphabet size. Neither interpretation identifies an arbitrary real-valued design with a free finite register.

**Definition 7.1** (Deficiency spectrum). The private resource spectrum of  $E$  relative to  $F$  is the upward-closed set of pairs  $(K, \varepsilon)$  satisfying  $\delta_K^p(E, F) \leq \varepsilon$ . The hidden spectrum consists of triples  $(K, r, \varepsilon)$  satisfying  $\delta_{K,r}^h(E, F) \leq \varepsilon$ , and the visible spectrum uses  $\delta_{K,r}^v$ . Width profiles are ordered coordinatewise; in the seeded spectra the seed bound and error are ordered as well. Unused states or selector values may be adjoined. The hidden convexification is  $\delta_K^{\text{mix}} = \inf_{r \geq 1} \delta_{K,r}^h$ .

The spectrum, not a presumed unique coordinatewise minimum profile, is the intrinsic object. For example one may minimize  $\max_t K_t$ , with a specified seed signature and tolerance, over its feasible profiles. Different checkpoints can have incomparable optimal tradeoffs.

**7.2. The finite comparison theorem.** Concatenate all probabilities  $P_{\theta, g}^q(\omega)$  into  $b(q) \in \mathbb{R}^N$ , retaining their row indices; put  $b_F = (Q_{\theta, g}(\omega))$ . Let  $\mathcal{D}_K$  be the finite set of deterministic choices of all rows in (7.1). Empty or unreachable rows remain harmless coordinates. Set

$$a_K = \dim \text{aff} \{b(q) : q \in \mathcal{K}_K\}, \quad \mathcal{I} = \{(\theta, g, B) : B \subseteq \Omega_g\}.$$

For  $i = (\theta, g, B)$  and  $d \in \mathcal{D}_K$ , define

$$A_{i,d} = Q_{\theta, g}(B) - P_{\theta, g}^d(B). \quad (7.5)$$

Including both an event and its complement includes both signs.

**Theorem 7.2** (Intrinsic deficiency, priced converse, and visibility). *For the finite marked causal experiments above the following assertions hold.*

(i) *Private deficiency and both fixed- $r$  deficiencies are attained. The private problem has the exact polynomial formulation*

$$\min \{ \varepsilon : q \in \mathcal{K}_K, 0 \leq \varepsilon \leq 1, Q_{\theta, g}(B) - P_{\theta, g}^q(B) \leq \varepsilon \text{ for all } (\theta, g, B) \in \mathcal{I} \}. \quad (7.6)$$

*In particular its zero set is exactly the nonnegative causal factorization of the target marked behavior by the rows (7.1). At  $K_t = 1$  for every  $t$ , this is precisely the same factorization with rows  $q_t(z \mid a, y)$  and  $q_0(z \mid y)$ .*

(ii) *Hidden convexification has the attained dual*

$$\delta_K^{\text{mix}}(E, F) = \min_{\lambda \in \Delta(\mathcal{D}_K)} \max_{i \in \mathcal{I}} \sum_d \lambda_d A_{i,d} = \max_{w \in \Delta(\mathcal{I})} \min_{d \in \mathcal{D}_K} \sum_i w_i A_{i,d}. \quad (7.7)$$

An optimal simulation uses at most  $a_K + 1$  selector values. Thus every weighted causal test has optimal discrepancy at most  $\varepsilon$  if and only if a hidden mixture of  $K$ -state simulators has error at most  $\varepsilon$ ; it has a private realization of width at most  $(a_K + 1)K$ . More specifically,

$$\delta_{rK}^p \leq \delta_{K,r}^h, \quad \delta_K^{\text{mix}} = \delta_{K,a_K+1}^h \leq \delta_K^p. \quad (7.8)$$

(iii) Put  $e_\theta(q) = \max_g \|P_{\theta,g}^q - Q_{\theta,g}\|_{\text{TV}}$ . Then

$$\delta_{K,r}^v = \min_{\lambda, q^1, \dots, q^r} \max_{\theta} \sum_u \lambda_u e_\theta(q^u). \quad (7.9)$$

Writing  $a_K^v = \dim \text{aff}\{(e_\theta(q))_\theta : q \in \mathcal{K}_K\}$ , the infimum over all finite visible selectors is attained using  $a_K^v + 1 \leq |\Theta| + 1$  values and equals

$$\max_{v \in \Delta(\Theta)} \min_{q \in \mathcal{K}_K} \sum_{\theta} v_\theta e_\theta(q). \quad (7.10)$$

For every  $r \geq 1$ , and also after optimizing over all  $r$ ,

$$\delta_{K,r}^v(E, F) = 0 \iff \delta_K^p(E, F) = 0. \quad (7.11)$$

No corresponding equivalence with  $\delta_K^{\text{mix}} = 0$  holds in general.

(iv) For compatible experiments  $E, F, G$  and profiles  $K, L$ ,

$$\begin{aligned} \delta_{KL}^p(E, G) &\leq \delta_K^p(E, F) + \delta_L^p(F, G), \\ \delta_{KL,rs}^s(E, G) &\leq \delta_{K,r}^s(E, F) + \delta_{L,s}^s(F, G), \quad s \in \{h, v\}. \end{aligned} \quad (7.12)$$

Here  $KL$  is the pointwise product, and the second line uses independent selectors. If an  $F$ -consumer has widths  $S_t$ , composing it with a private simulator gives widths  $K_t S_t$  and changes every  $[0, 1]$  marked risk by at most  $\delta_K^p(E, F)$ . A hidden selector is stored at the additional price  $r$ , whereas visible selector alphabets multiply. The same bounds hold for optimized upper risk sets and their lower support functions with the indicated costs.

*Proof.* Expand a probability of a complete source path, simulator state path, and transcript. It is a product of fixed experiment probabilities and one chosen row entry per time. Summing latent and state paths gives a polynomial in the finitely many row entries. No row belonging to a fixed time can occur twice along one path. Consequently the polynomial is multiaffine in the groups of stochastic rows. Continuity and compactness of the product of closed finite simplexes prove attainment in (7.2); the same proof includes  $\lambda$  and the  $r$  policies in (7.3). For the visible problem there are only finitely many collections  $(g_u)$  and transcript events, so its objective is again continuous on a compact set. The finite-event formula for total variation proves (7.6). Setting  $\varepsilon = 0$  forces equality of every transcript probability, in both directions of each event inequality. This proves the factorization and stateless claims, including their necessity.

For each stochastic row of  $q$ , sample its deterministic output once, independently of all other rows, before the experiment. This constructs a probability  $\Lambda_q$  on  $\mathcal{D}_K$ . On any fixed path the row variables encountered have different time indices, so the expectation of their product is the product of the row probabilities. Summing paths shows, simultaneously for every  $\theta, g$ , that

$$b(q) = \sum_{d \in \mathcal{D}_K} \Lambda_q(d) b(d). \quad (7.13)$$

This is a behavior identity, not a same-width deterministic purification of minimax error. It implies  $\text{conv } b(\mathcal{K}_K) = \text{conv}\{b(d) : d \in \mathcal{D}_K\}$ . The latter is a compact polytope. Minimizing the continuous convex maximum of event discrepancies over this polytope gives the first expression in (7.7). Finite-dimensional minimax gives the second, with both optima attained. A point of this polytope is a convex combination of at most  $a_K + 1$  of its generating points by Carathéodory's theorem. For completeness, if a representation uses more points, their affine dependence gives

coefficients  $c_d$  with  $\sum c_d = 0$  and  $\sum c_d b(d) = 0$ . Subtract the largest permissible multiple of  $c$  from the positive mixing weights; a weight becomes zero without changing the represented point. Repeating gives the stated bound. Store its selector together with the machine state to obtain (7.8). The dual inequality for every  $w$  is equivalent to the maximum over  $w$  being at most  $\varepsilon$ , which proves the priced testing converse.

For disjoint seed fibers, total variation is the sum of the fiber total variations weighted by  $\lambda_u$ . For a fixed  $\theta$ , the tester can choose a separate maximizing tree on each revealed fiber. Therefore its maximum is  $\sum_u \lambda_u e_\theta(q^u)$ , proving (7.9). The map  $q \mapsto e(q)$  is continuous, being a finite maximum of continuous functions. Its image is compact. Convexifying it in  $\mathbb{R}^{|\Theta|}$  and applying the preceding finite-dimensional separation and affine-dependence argument proves (7.10) and its selector bound. Notice that the inner minimum is over stochastic  $q$ , not over deterministic tables: the nonlinear function  $e_\theta$  does not commute with (7.13). If the attained visible optimum is zero, then for every  $u$  of positive weight and every  $\theta$  one has  $e_\theta(q^u) = 0$ , since every summand is nonnegative. Any such  $q^u$  is a private exact simulator. The converse uses a selector of one value. This also proves the assertion for the optimized visible selector, whose support is finite by the bound just established.

Finally, cascade a  $K$ -state  $E$ -to- $F$  transducer and an  $L$ -state  $F$ -to- $G$  transducer. Within a step, consume the intermediate report before discarding it. The retained pair has at most  $K_t L_t$  values. For any terminal tester on  $G$ , the second transducer together with that tester is an admissible randomized feedback system on  $F$ . The first error bound applies to this system, and total variation contracts under the remaining channel. The second error bound applies to the genuine  $F$  system. The triangle inequality gives (7.12). With selectors, condition on the independent selectors in the appropriate places; in the visible case keep both selectors in the compared transcript. The same argument is valid because the target reference selectors are independent. Storing a hidden selector or exposing both visible selectors gives the stated costs. The minima established above may be used; equivalently one can use nearly optimal simulators and let the extra tolerance decrease.

A consumer is another causal transducer with task-specific readout and, where allowed, task-specific control, but with its required common encoder. The simulator is task blind, so its product with that encoder is still common. Condition on the consumer's independent random table to apply the feedback bound. Integration of any  $[0, 1]$  marked loss changes by at most the total variation error. Taking the same paired consumer for every row proves the risk-set assertion, rather than a separate choice of simulator for each row. Infima of nonnegative weighted risks give the lower support inequalities.  $\square$

*Remark 7.3* (What the converse says). The dual (7.7) uses mixtures of indexed causal tests and optimizes over the entire common transducer. It is not a task-by-task choice of encoder. Its conclusion is an explicit hidden-selector simulation, with the selector subsequently charged if private storage is required. It does not replace the nonconvex private set by its convex hull at unchanged resource. The next example shows why that replacement would change the zero set.

**7.3. A delayed channel and a strict signature separation.** Let the source reveal  $i \in [n]$  at checkpoint zero and reveal only a constant at checkpoint one. There is no control and the mark is constant. The target reports a constant at checkpoint zero and at checkpoint one draws  $j \in [m]$  from a specified row-stochastic matrix  $V = (V_{ij})$ . The unknown parameter is  $i$ . The first target alphabet has one element: the simulator cannot use an early public output as unpriced storage. Only the intermediate register of size  $K$  matters.

**Proposition 7.4** (The nonnegative-rank slice). *For this experiment,*

$$\delta_K^p(E, F_V) = \min_{A, B} \max_i \frac{1}{2} \sum_j |V_{ij} - (AB)_{ij}|, \quad (7.14)$$

where  $A$  is an  $n$ -by- $K$  row-stochastic matrix and  $B$  is a  $K$ -by- $m$  row-stochastic matrix. In particular

$$\delta_K^p(E, F_V) = 0 \iff \text{rank}_+(V) \leq K, \quad \delta_1^p(E, F_V) = 0 \iff V \text{ has identical rows.}$$

For  $1 \leq K \leq n$  the identity channel has the sharp laws

$$\delta_K^p(E, F_{I_n}) = 1 - \frac{1}{\lceil n/K \rceil}, \quad \delta_K^{\text{mix}}(E, F_{I_n}) = 1 - \frac{K}{n}. \quad (7.15)$$

Thus, at tolerance  $0 \leq \varepsilon < 1$ , the least private width is  $\lceil n/(1-\varepsilon)^{-1} \rceil$ , whereas the least within-mode width with optimized hidden selection is  $\max\{1, \lceil n(1-\varepsilon) \rceil\}$ . The latter still pays for its selector. In particular, for  $n = m = 3$  and  $K = 2$ ,

$$\delta_2^p(E, F_{I_3}) = \frac{1}{2}, \quad \delta_2^{\text{mix}}(E, F_{I_3}) = \frac{1}{3}. \quad (7.16)$$

For  $V_* = (1/2)I_3 + (1/6)\mathbf{1}\mathbf{1}^\top$ ,

$$\delta_{2,3}^h(E, F_{V_*}) = 0, \quad \delta_2^p(E, F_{V_*}) \geq \frac{1}{4\sqrt{3}} > 0, \quad \inf_r \delta_{2,r}^v(E, F_{V_*}) > 0. \quad (7.17)$$

*Proof.* The encoder maps the consumed  $i$  into its retained label by  $A$ ; the terminal decoder maps that label into  $j$  by  $B$ . This proves (7.14) including its converse implementation. If  $V = CD$  is any nonnegative factorization, let  $s_k = \sum_j D_{kj}$ . Delete zero rows of  $D$ , define  $B_{kj} = D_{kj}/s_k$  and  $A_{ik} = C_{ik}s_k$ . Since  $V$  is stochastic, the rows of  $A$  sum to one. Padding with unused states gives the claimed equivalence with nonnegative rank. The one-state statement follows immediately.

For  $V = I_n$ , row error is  $1 - (AB)_{ii}$ . If the least correct probability is  $c$ , for each  $i$  select a row  $k(i)$  of  $B$  with  $B_{k(i),i} \geq c$ . Some row is selected at least  $\lceil n/K \rceil$  times, so stochasticity gives  $c \leq 1/\lceil n/K \rceil$ . A partition into  $K$  groups of sizes at most  $\lceil n/K \rceil$ , each decoded uniformly, attains that bound. Also  $\sum_i (AB)_{ii} \leq K$ , by the calculation below with  $K$  in place of two. It remains valid under mixing, giving hidden error at least  $1 - K/n$ . Start with a deterministic channel that reproduces  $K$  input symbols exactly and sends all others to those  $K$  outputs. Average all simultaneous permutations of its input and output labels. Every diagonal entry is then  $K/n$ , proving the second formula. Inverting the two monotone formulas gives the stated least widths.

For  $V = I_3$ , total variation in row  $i$  is  $1 - (AB)_{ii}$ . If all three diagonal entries of  $AB$  were greater than  $1/2$ , then for each  $i$  some row of  $B$  would have its  $i$ th entry greater than  $1/2$ . A stochastic row has at most one such entry, so two rows cannot serve three indices. This proves the private lower bound  $1/2$ . Merge two input symbols into a retained label that decodes uniformly to that pair, and retain the third symbol exactly. This attains it. For every stochastic factorization with two intermediate states,

$$\sum_{i=1}^3 (AB)_{ii} = \sum_{k=1}^2 \sum_{i=1}^3 A_{ik} B_{ki} \leq \sum_{k=1}^2 \sum_{i=1}^3 B_{ki} = 2.$$

The same inequality holds under hidden mixtures, giving maximal row error at least  $1/3$ . Mix uniformly the three preceding pair-merge channels. The resulting diagonal entries are  $2/3$  and the off-diagonal entries are  $1/6$ . This is exactly  $V_*$  and has error  $1/3$  from  $I_3$ . It proves the hidden claims in both displays.

The smallest singular value of  $V_*$  is  $1/2$ . Any  $AB$  with two intermediate states has a unit vector  $x$  in its right null space, so  $\|V_* - AB\|_F \geq \|(V_* - AB)x\|_2 \geq 1/2$ . If the maximal row total variation error is  $\varepsilon$ , each row has Euclidean error at most  $2\varepsilon$ , and hence the Frobenius error is at most  $2\sqrt{3}\varepsilon$ . This proves the explicit private bound. The optimized visible value is attained by Theorem 7.2; if it were zero, its zero-set assertion would contradict that bound. This proves its strict positivity.  $\square$

**7.4. Optimal resource sets and decision certificates.** For a class  $\mathcal{C}_{S,q}(F)$  of common consumers, with all other information conventions fixed, let  $\mathcal{R}_{S,q}(F)$  be its vector of attainable  $[0, 1]$  risks. For a nonnegative row weight  $w$  summing to one, write

$$h_F(S, q; w) = \inf_{r \in \mathcal{R}_{S,q}(F)} \langle w, r \rangle.$$

If  $E$  privately simulates  $F$  with cost  $K$  and error  $\varepsilon$ , then

$$\mathcal{R}_{S,q}(F) \subseteq \mathcal{R}_{KS,q}(E) + [-\varepsilon, \varepsilon]^J, \quad h_E(KS, q; w) \leq h_F(S, q; w) + \varepsilon. \quad (7.18)$$

For nonfinite row sets the first expression means pointwise paired risk functions within uniform distance  $\varepsilon$ ; no finite coordinate box is needed. Upper sets give the equivalent one-sided order formulation. Hidden selectors multiply private width by  $r$ ; visible selectors multiply the separate public alphabet by  $r$ . These are direct consequences of the final part of Theorem 7.2, with the optimal intrinsic error in place of an externally estimated simulator error.

When two stateless comparison directions have error at most  $\varepsilon$ , paired risk sets and their support values at unchanged width are within  $\varepsilon$ . If each is centered by a paired unrestricted benchmark whose error is also at most  $\varepsilon$ , the centered values are within  $2\varepsilon$ . Therefore a gap  $g > 0$  between zero excess and infeasible widths is stable under  $\varepsilon < g/4$ : a value below  $g/2$  in the approximation certifies feasibility in the exact finite problem, and a value above  $g/2$  certifies infeasibility. The benchmark and the class being optimized must be specified; this assertion does not identify different information signatures.

**Proposition 7.5** (Intrinsic finite-dimensional selector approximation). *Let  $\mathcal{R}$  be a compact risk image in  $C(J)$ , where  $J$  is compact. Suppose a bounded linear operator  $L : C(J) \rightarrow C(J)$  has rank at most  $m$  and  $\sup_{r \in \mathcal{R}} \|r - Lr\|_\infty \leq \eta$ . Every barycenter  $\bar{r}$  of a probability on  $\mathcal{R}$  has a barycenter  $r_*$  of at most  $m + 1$  members of  $\mathcal{R}$  with  $\|\bar{r} - r_*\|_\infty \leq 2\eta$ . If  $\mathcal{R}$  lies in a finite affine space of dimension  $m$ , the error is zero with at most  $m + 1$  members. Thus the selector price can be controlled by the dimension of attainable risks, rather than by a covering number of the row space.*

*Proof.* The compact set  $L\mathcal{R}$  lies in an  $m$ -dimensional space. Its convex hull is compact, and  $L\bar{r}$  belongs to it. The finite-dimensional affine-dependence argument in the proof of Theorem 7.2 gives  $r_1, \dots, r_{m+1} \in \mathcal{R}$  and weights  $\lambda$  such that  $L\bar{r} = \sum_i \lambda_i Lr_i$ . Put  $r_* = \sum_i \lambda_i r_i$ . The two residual terms  $\bar{r} - L\bar{r}$  and  $r_* - Lr_*$  have norms at most  $\eta$ , proving the estimate. Apply the same argument after translation in the exact affine case. The implementation stores the selected design index whenever it is not provided as visible side information.  $\square$

**Remark 7.6** (Finite computation and general carriers). For rational finite instruments, (7.6) and the fixed- $r$  formulations are finite polynomial feasibility problems; (7.7) is a finite linear program. These are exact variational characterizations, not assertions of polynomial running time in a succinct history description. The number of feedback trees, events, or deterministic tables can be large. On standard Borel carriers the same definitions use suprema over measurable feedback and tests and infima over executable kernels. Their product-state composition and decision transport remain valid by the same channel argument. Attainment and the finite testing dual are asserted here only for the stated finite class. The average-risk and physical results below give separate nonfinite theorems with their own hypotheses.

## 8. CONTINUATION GEOMETRY AND AN EXACT MEMORY OBSTRUCTION

**8.1. Normalized continuation laws.** We first separate the transducer from the source to which it is attached. There are  $L$  epochs with finite input alphabets  $X_t$  and output alphabets  $Z_t$ . A causal kernel  $p(z_{1:L} \mid x_{1:L})$  is nonnegative, normalized for every input word, and has output-prefix marginals independent of later inputs. The current input can include both a source report and the

current control. It never includes an unavailable parameter, a terminal mark, or an earlier output not retained by the machine.

Let  $\mathcal{C}_t$ ,  $0 \leq t \leq L$ , be the finite-dimensional polytope of normalized causal kernels from  $x_{t+1:L}$  to  $z_{t+1:L}$ ; put  $\mathcal{C}_L = \{1\}$ . For  $v \in \mathcal{C}_t$  define the shift

$$(S_{x,z}v)(z_{t+2:L} \mid x_{t+2:L}) = v(z, z_{t+2:L} \mid x, x_{t+2:L}).$$

Its total mass  $v(z \mid x)$  is independent of the future input word. A zero shift is allowed.

**Definition 8.1** (Compatible continuation polytopes). A continuation cover of width  $K = (K_0, \dots, K_L)$  consists of lists  $V_t = (v_{t,m})_{m \leq K_t}$  in  $\mathcal{C}_t$  such that, for every  $m, x, z$ ,

$$S_{x,z}v_{t,m} \in \text{cone } V_{t+1}. \quad (8.1)$$

It covers  $p$  when  $p \in \text{conv } V_0$ . Lists may repeat generators and may contain unreachable generators. Thus unused states can be adjoined.

**Theorem 8.2** (Continuation realization with a width profile). *A causal kernel  $p$  has a stochastic transducer realization with an initial  $K_0$ -valued register and  $K_t$  retained states after epoch  $t$  if and only if it has a compatible continuation cover of width  $K$ . Initial randomization is part of the charged initial register. With a deterministic initial state the condition is  $p = v_{0,1}$  and  $K_0 = 1$ .*

*Consequently the set of feasible width profiles depends only on the causal kernel and its declared input interface, not on a row presentation or a labeling of the hidden states. Every matrix of conditional continuation probabilities at cut  $t$  has nonnegative rank at most  $K_t$ . Individual rank bounds do not replace the simultaneous shift conditions (8.1).*

*Proof.* Given a transducer, let  $v_{t,m}$  be the suffix response when its register at time  $t$  equals  $m$ . The remaining rows define this response even for an unreachable state. If the next row is  $q_{t+1}(z, m' \mid m, x)$ , conditioning on its output and new state gives

$$S_{x,z}v_{t,m} = \sum_{m'} q_{t+1}(z, m' \mid m, x) v_{t+1,m'}.$$

The initial state distribution expresses  $p$  as a convex combination of  $V_0$ .

Conversely choose nonnegative coefficients in every cone membership in (8.1). There are only finitely many choices to make. Since every generator on the right has mass one for each future input word, the sum of the coefficients for a fixed  $m, x, z$  is  $v_{t,m}(z \mid x)$ . Summing over  $z$  gives one. The coefficients are therefore stochastic rows  $q_{t+1}(z, m' \mid m, x)$ . Choose an initial distribution representing  $p$  in  $\text{conv } V_0$ . Backward induction from  $\mathcal{C}_L = \{1\}$  proves that the constructed machine has exactly the response  $v_{t,m}$  from each register state. In particular its initial response is  $p$ . Equality for open-loop input words implies equality under adaptive input selection: at each node of an input–output history tree, the same causal conditional probability is used on the two sides.

For the rank assertion, condition on any positive-probability observed history at the cut. Its continuation response is a convex combination of  $v_{t,m}$  with weights equal to the posterior register distribution. Stack these responses as rows, and use all future input–output pairs as columns. This is a nonnegative factorization through  $K_t$  generators. The converse construction required the same generator families at adjacent cuts and all their shifts; an unrelated factorization of each cut matrix provides no such compatibility. The characterization, being stated entirely in terms of these response polytopes, also proves the asserted invariance.  $\square$

Attach such a causal kernel to a marked source experiment. The output law is obtained by contraction with the source’s causal instruments, while its actual mark is retained. Hence zero private deficiency is equivalently the existence of a compatible continuation cover whose contraction equals the target marked behavior in every parameter and feedback row. This is the geometric form of the factorization in Theorem 7.2; no conditional dependence on the mark is introduced.

A hidden selector chooses one such cover independently of the source. It is a convex combination of complete realizations, not a convexification inside every retained-state simplex at the original width. Its private implementation uses the disjoint union of the covers and keeps the selector in the state. A visible selector keeps those fibers in the compared law. The nonnegative fiber argument in Theorem 7.2 therefore continues to give equality of the visible and private zero sets.

**8.2. An erasure cut.** A simple family makes the width obstruction exact, including its error. Let  $X$  take values in  $[N]$  with law  $\pi$ . Before a specified cut the source reveals  $X$ . After the cut it has no reports correlated with  $X$ . The controller has no feedback channel carrying  $X$  across the cut, and all earlier emitted reports are prescribed constants. The only permitted cross-cut information of the simulator is its  $K$ -valued register and any independent selector explicitly included in its signature. The terminal mark is the actual  $W = X$ . The target's terminal report is  $X$ . All memory at other checkpoints is unrestricted.

**Theorem 8.3** (Exact cut spectrum). *For this experiment, for private, hidden and visible signatures alike,*

$$\delta_K = 1 - \sum_{i=1}^{\min(K,N)} \pi_{(i)}. \quad (8.2)$$

For uniform  $X$ ,  $\delta_K = (1 - K/N)_+$ . Thus an erasure cut for  $m$  unbiased bits requires  $K \geq (1 - \epsilon)2^m$  whenever its error is at most  $\epsilon$ . The bound holds for every surrounding width profile; equality is attained when the other checkpoints are unrestricted. If every  $\pi_x > 0$ , exact transmission has nonnegative cut rank  $N$ .

*Proof.* With all post-cut randomness averaged into the decoder, any private machine gives kernels  $e(m | x)$  and  $d(z | m)$ . Its joint terminal law is  $\pi_x \sum_m e(m | x) d(z | m)$ . Since the target law is  $\pi_x \mathbf{1}_{z=x}$ , total variation is exactly one minus the correct-decoding probability. Put  $u_x = \max_m d(x | m)$ . Then

$$0 \leq u_x \leq 1, \quad \sum_x u_x \leq K, \quad \mathbb{P}(Z = X) \leq \sum_x \pi_x u_x \leq \sum_{i=1}^{\min(K,N)} \pi_{(i)}.$$

The last inequality follows by moving mass in  $u$  from a smaller weight to a larger one until the  $K$  largest weights are filled. To attain it, retain distinct labels for those letters and decode them deterministically; all other letters are mapped to any retained label. Before the cut one may use the unrestricted memory to compute this encoding.

For a hidden selector, condition on its value. It is independent of  $X$ , so every conditional correct-decoding probability obeys the same bound; averaging cannot improve it. For a visible selector, variation is the average of the fiber variations, with the same conclusion. The private construction works for both signatures. Finally, the exact joint cut matrix is diagonal with its  $N$  positive diagonal entries  $\pi_x$ . Its ordinary rank is  $N$ , so its nonnegative rank is at least  $N$  and its diagonal factorization attains  $N$ .  $\square$

The absence of an auxiliary cross-cut feedback channel is essential. An unpriced controller storing  $X$  and returning it as a later control would change the experiment, not disprove the cut bound. Likewise a selector correlated with  $X$  is not an independent hidden selector. These distinctions are the same ones needed in the collision certificate below.

## 9. DECISION CONTINUATION SPECTRA

The memory at an experimental cut has a different role from the memory needed to reach that cut. We first identify its exact asymptotic value. This will give both an obstruction and

a construction for the same physical audit, rather than a lower bound for an auxiliary binary problem.

**9.1. A charged training-validation interface.** Let  $\Omega$  be a finite marked alphabet,  $d = |\Omega|$ , let  $B \subset \Delta(\Omega)$  be nonempty and compact, and fix  $Q \in \Delta(\Omega)$ . A candidate  $b \in B$  is fixed throughout the experiment. Training consists of  $n$  independent observations from  $b$ . At the end of training the auditor retains a register  $M \in [K]$ . Everything depending on the training observations or on an earlier random seed must pass through this register. In particular, there is no external copy of the training history and no uncharged persistent selector.

After this cut, fresh independent randomness may select an event  $A$  using  $M$ . The event is chosen before independent candidate and target validation observations  $X \sim b$  and  $Y \sim Q$  are drawn. The score is  $\mathbf{1}_A(Y) - \mathbf{1}_A(X)$ . The downstream register needed to keep  $A$  and to compute this score is distinct from the register at the specified cut. The upstream and downstream widths will be stated separately in concrete implementations. This is the reset interface of Section 18, with one additional charged checkpoint. The actual mark is part of a completed observation; it is not an input to the private candidate's online transition rows.

Write  $\mathcal{H} = [0, 1]^\Omega$  and

$$f_h(b) = \sum_{w \in \Omega} (Q(w) - b(w))h(w), \quad h \in \mathcal{H}.$$

Every randomized event has a response  $h(w) = \Pr(w \in A)$ . Conversely, every  $h \in \mathcal{H}$  is the response of a random event: include each atom independently with its specified probability. This is a finite probability distribution on  $2^\Omega$ . Only its mean response matters for expected signed score. The event itself must still be retained during validation.

**Definition 9.1** (Decision continuation spectrum). The  $K$ -state decision continuation value is

$$\mathfrak{V}_K(B, Q) = \max_{h_1, \dots, h_K \in \mathcal{H}} \min_{b \in B} \max_{m \leq K} f_{h_m}(b). \quad (9.1)$$

Let  $v_{n,K}(B, Q)$  be the supremum of the worst-case expected score of  $n$ -sample auditors at the preceding interface. Only the designated cut has width  $K$  in this definition; all other widths are finite but unrestricted. For  $c \in \mathbb{R}$ , let  $\kappa_c(B, Q)$  be the least  $K$  for which  $\mathfrak{V}_K(B, Q) > c$ , with value  $+\infty$  when no such  $K$  exists.

The definition uses only the marked behavior image and its target, not a parameterization of  $B$  or a labeling of candidate states. No convex hull of  $B$  is taken. A response list is a list of conditional validation continuations; it is not a mixture of feasible private candidates.

**Theorem 9.2** (Operational classification at a decision cut). *All extrema in (9.1) are attained. For every  $n \geq 1$ ,*

$$0 \leq \mathfrak{V}_K(B, Q) - v_{n,K}(B, Q) \leq \min \left\{ \sqrt{\frac{d-1}{n}}, \sqrt{\frac{2 \log(2K)}{n}} \right\}. \quad (9.2)$$

Consequently  $v_{n,K} \rightarrow \mathfrak{V}_K$ . Every auditor with  $K$  states at the designated cut, at any finite training length, has worst-case score at most  $\mathfrak{V}_K$ . If  $\mathfrak{V}_K > c$ , some finite-sample auditor with  $K$  states at that cut has worst-case score greater than  $c$ . Thus  $\kappa_c$  is exactly the minimum cut width permitting such a strict certificate with sufficiently many training samples.

Equivalently,  $\kappa_c$  is the least number of response half-spaces

$$\{b \in B : f_h(b) > c\}, \quad h \in \mathcal{H}, \quad (9.3)$$

that cover  $B$ . If two parameterized behavior families satisfy, uniformly in their common parameter  $q$ ,

$$\|b(q) - \tilde{b}(q)\|_{\text{TV}} \leq \alpha, \quad \|Q - \tilde{Q}\|_{\text{TV}} \leq \beta,$$

then

$$|\mathfrak{V}_K(B, Q) - \mathfrak{V}_K(\tilde{B}, \tilde{Q})| \leq \alpha + \beta. \quad (9.4)$$

*Proof.* For a fixed response list, the inner objective is continuous in  $b$ . Its variation when the list changes is bounded uniformly over  $b$  by  $2 \max_m \|h_m - \tilde{h}_m\|_\infty$ . Its minimum over compact  $B$  is therefore continuous in the list. Compactness of  $\mathcal{H}^K$  proves attainment.

Condition on the retained state of any admissible auditor. Its conditional post-cut event law depends only on that state and fresh randomness, and has a response  $h_m$ . Independence of validation from training gives

$$g(b) = \sum_{m=1}^K \Pr_b(M = m) f_{h_m}(b) \leq \max_m f_{h_m}(b).$$

Taking the minimum over  $b$ , and then the supremum over auditors, proves the upper bound. This argument permits arbitrary stochastic training and arbitrary finite upstream memory. An extra training-dependent decoder would invalidate its first conditioning step and is excluded by the interface, not silently supplied.

For the reverse bound fix an optimal list. Let  $\hat{b}$  be the empirical measure and choose the first index maximizing  $f_{h_m}(\hat{b})$ . Retain that index and discard the empirical table. If  $m_*$  maximizes the true score, then pointwise

$$\max_m f_{h_m}(b) - f_{h_{m_*}}(b) \leq 2 \max_{m \leq K} |(\hat{b} - b)h_m|. \quad (9.5)$$

The maximum is at most  $\|\hat{b} - b\|_{\text{TV}}$ , since  $0 \leq h_m \leq 1$ . Cauchy–Schwarz and the multinomial variances give

$$\mathbb{E} \|\hat{b} - b\|_{\text{TV}}^2 \leq \frac{d}{4n} \left( 1 - \sum_w b(w)^2 \right) \leq \frac{d-1}{4n}.$$

This proves the first rate.

For completeness, if  $V$  takes values in an interval of length one, then  $\log \mathbb{E} e^{s(V - \mathbb{E}V)} \leq s^2/8$ . Indeed the second derivative of the logarithmic moment generating function is the variance under the exponentially tilted law, at most  $1/4$ ; its value and first derivative vanish at zero. Integrating twice proves the inequality for both signs of  $s$ . Independence consequently gives  $\mathbb{E} e^{s(b-b)h_m} \leq e^{s^2/(8n)}$ . For  $s > 0$ ,

$$\mathbb{E} \max_m |(\hat{b} - b)h_m| \leq \frac{\log(2K)}{s} + \frac{s}{8n}.$$

Minimizing in  $s$  gives  $\sqrt{\log(2K)/(2n)}$  and proves the second rate in (9.2). The empirical table has finitely many values; the construction is therefore a finite-state auditor, with only the chosen index surviving the specified cut. Real response coefficients are allowed here; the physical construction below has deterministic rational transitions.

A finite cover in (9.3) says that the continuous function  $b \mapsto \max_m f_{h_m}(b)$  is greater than  $c$  everywhere on compact  $B$ . Its attained minimum is then greater than  $c$ . This proves the covering characterization in both directions. It also proves the strict-threshold assertion; no claim about finite-sample attainment at the boundary  $c = \mathfrak{V}_K$  is needed.

Finally  $|(Q - b)h - (\tilde{Q} - \tilde{b})h| \leq \alpha + \beta$  for every response. Taking maxima, minima over the common parameter set, and maxima over lists preserves this uniform bound, proving (9.4).  $\square$

**Corollary 9.3** (Compression by a finite decision dictionary). *Suppose responses  $h_1, \dots, h_K$  satisfy  $\min_{b \in B} \max_m f_{h_m}(b) \geq c + \eta$  for  $\eta > 0$ . An empirical selector with  $n > 2 \log(2K)/\eta^2$  achieves score greater than  $c$  and retains only  $K$  states at the decision cut. If these responses depend on a finite statistic  $T : \Omega \rightarrow \Xi$ , the training selector can count  $T(X)$  instead of  $X$ . A sufficient*

upstream register has at most  $\binom{n+|\Xi|-1}{|\Xi|-1}$  states at the last training checkpoint, and the corresponding time-dependent count registers suffice at earlier checkpoints.

*Proof.* Use the second bound in (9.2). Empirical expectations of  $h_m$  depend only on the histogram of  $T(X)$ . At time  $t$ , that histogram has  $\binom{t+|\Xi|-1}{|\Xi|-1}$  possibilities. Its update and the final maximization are deterministic. No statistical sufficiency for estimating all of  $b$  is required; sufficiency for the specified responses is enough.  $\square$

This corollary supplies an intermediate principle between a full marked histogram and a problem-specific compressed counter. The invariant is the number and geometry of validation continuations needed to cover the original candidate image at the desired score. It is not the algebraic dimension of a chosen parameterization. The empirical upper bound need not be sample-optimal, and a minimum decision-cut width is not a minimum of the largest width over the entire acquisition schedule.

**9.2. Several feedback rows.** The classification does not require that the declared experiment have only one feedback row. For the row-indexed interface of Section 18, let  $\mathcal{I} = \{(j, A) : A \subseteq \Omega_j\}$  and define

$$f_\lambda(b) = \sum_{i \in \mathcal{I}} \lambda_i f_i(b), \quad \lambda \in \Delta(\mathcal{I}).$$

A post-cut continuation is now a probability distribution on row–event pairs; it is not an arbitrary test on a joint product of validation rows. Put

$$\mathfrak{V}_K^{\text{rows}}(B, Q) = \max_{\lambda_1, \dots, \lambda_K \in \Delta(\mathcal{I})} \min_{b \in B} \max_m f_{\lambda_m}(b).$$

**Corollary 9.4** (Row-indexed classification). *With  $n$  training samples per row, the row-indexed decision-cut value converges to  $\mathfrak{V}_K^{\text{rows}}$ , and its deficit is at most*

$$\min\{\sqrt{D/n}, \sqrt{2 \log(2K)/n}\}, \quad D = \sum_j (|\Omega_j| - 1).$$

*The strict half-space cover characterization holds with  $f_\lambda$ . The upper bound by  $\mathfrak{V}_K^{\text{rows}}$  applies also to any other finite training schedule, including adaptive row selection.*

*Proof.* Conditioning on the cut state gives the same convex-mixture upper bound as before; its proof places no restriction on how that state was reached. For empirical selection among an optimal list,  $|(\hat{b} - b)\lambda_m| \leq \max_j \|\hat{b}_j - b_j\|_{\text{TV}}$ . Sum the rowwise second moments to obtain the first rate. To obtain the second, align the  $r$ th independent training sample from each row into a tuple and write its response as  $\sum_{j,A} \lambda_{m,j,A} \mathbf{1}_A(X_{j,r})$ . This random variable belongs to  $[0, 1]$ , and its sample mean is the empirical candidate mean for that continuation. The logarithmic moment-generating argument in Theorem 9.2 therefore gives the same finite-list rate. Each chosen row–event distribution can be drawn using fresh randomness after the cut. Compactness and the covering argument are unchanged.  $\square$

## 10. FINITE PRECISION AND CHARGED RANDOMIZATION

We distinguish the number of persistent labels from the description of a transition and from the clock that selects it. An observation in a finite alphabet is initially an atomic input. Every random bit used after that input is a separate, charged epoch. Section 11 gives the additional cost of splitting the observation itself.

**Lemma 10.1** (Dyadic rows and finite randomizers). *A probability vector on  $s$  points has a dyadic approximation with denominator  $2^r$  at total variation distance at most  $(s-1)2^{-r}$ . It can be sampled using exactly  $r$  independent fair bits and at most  $2s-1$  persistent labels at each intermediate bit*

*epoch. The label count uses the bit position supplied by the schedule. No partial random integer is retained outside these labels.*

*Proof.* Round down the first  $s - 1$  coordinates and assign the remaining mass to the last coordinate. The positive and negative parts of the change have equal mass, at most  $(s - 1)2^{-r}$ . For sampling, partition  $\{0, \dots, 2^r - 1\}$  into consecutive intervals of the prescribed integer lengths. A binary prefix describes a dyadic interval. If that interval is contained in one output interval, keep the output label and ignore the remaining bits. Otherwise keep the prefix interval. At a fixed depth, every unresolved interval contains a partition boundary in its interior; there are at most  $s - 1$  such intervals. Together with at most  $s$  resolved outputs this gives  $2s - 1$  labels. The children and their resolved labels are fixed by the read-only partition and the depth. Thus the construction is an actual finite transition table, not a real-valued random seed. Zero-length intervals cause no difficulty.  $\square$

**Proposition 10.2** (Rational decision continuations). *Let  $d = |\Omega|$ . A list of  $K$  responses in  $[0, 1]^\Omega$  can be replaced by dyadic responses of denominator  $2^r$ , losing at most  $2^{1-r}$  in its uniform score envelope. After a decision cut retaining  $K$  labels, the randomized event for the chosen dyadic response can be drawn using  $r$  fair bits, at most  $K(2d + 1)$  labels during this draw, and at most  $K(d + 1)$  labels afterwards. Keeping the event through one candidate and one target validation requires at most  $2K(d + 1)$  labels at the intervening atomic-observation cuts. Its final signed score has three values.*

*Proof.* Round every coordinate down. The sup-norm error is at most  $2^{-r}$ , and  $\sum_w |Q(w) - b(w)| \leq 2$ . This proves the envelope estimate. For a fixed rounded response  $h$ , draw a uniform dyadic integer  $U$  and choose  $A_U = \{w : U < 2^r h(w)\}$ . These events are nested and have at most  $d + 1$  distinct values. Their mean response is exactly  $h$ . Apply Lemma 10.1 to their interval lengths, retaining the chosen response index during sampling. Afterwards the event label and the candidate-event indicator suffice; the target indicator emits their difference. All event masks are read-only data fixed before observing the candidate.  $\square$

For  $K$  responses, their rounded coordinates require  $Kd(r + 1)$  bits in a direct read-only representation. These bits are not charged as persistent sample-dependent labels, but are not declared costless precision. A construction using them records both quantities. In particular, the proposition turns every strict response-cover margin into a finite-randomness implementation; it says nothing about exact attainment of an irrational boundary value.

## 11. APPROXIMATE CONTINUATION PROFILES AND RESOURCE TRANSFER

A cut profile records the whole causal schedule, rather than its final compression. We give both a realization certificate and an operational value. These notions keep the compatibility condition of Theorem 8.2; separate nonnegative factorizations at individual cuts are not a substitute for that condition.

**11.1. A causal comparison norm.** For two normalized finite causal suffix kernels  $p, q$  at cut  $t$ , put

$$d_t^{\text{ca}}(p, q) = \sup_{\pi} \|P_p^\pi - P_q^\pi\|_{\text{TV}},$$

where  $\pi$  ranges over deterministic causal input policies on the remaining schedule and  $P_p^\pi$  is the law of its complete output transcript. Randomized policies give the same supremum, by conditioning on their independent random tables. In particular this distance includes feedback; the supremum over open-loop input words alone is not used.

For stochastic coefficients  $q_t(z, j \mid m, x)$  and suffix kernels  $v_{t+1,j}$ , denote by  $\mathcal{Q}_{t+1,m}$  the suffix kernel which, upon input  $x$ , emits  $z$  and chooses  $j$  with these coefficients, then uses  $v_{t+1,j}$ . The notation denotes one first-step operation, not a conditioning on an event of zero probability.

**Theorem 11.1** (Approximate compatible realization). *Let  $K_0, \dots, K_L$  be positive integers. Suppose normalized causal kernels  $v_{t,m}$ ,  $m \leq K_t$ , and stochastic rows  $q_t$  satisfy*

$$d_t^{\text{ca}}(v_{t,m}, \mathcal{Q}_t v_{t+1,m}) \leq \eta_t \quad (t < L, m \leq K_t). \quad (11.1)$$

*At the terminal cut the suffix kernels are the unit empty kernel. If  $\rho \in \Delta_{K_0}$  and  $d_0^{\text{ca}}(\rho, \sum_m \rho_m v_{0,m}) \leq \eta_{-1}$ , then the machine with initial law  $\rho$  and transition rows  $q_t$  has the whole profile  $(K_t)$  and realizes a kernel  $\hat{p}$  satisfying*

$$d_0^{\text{ca}}(\rho, \hat{p}) \leq \min\{1, \eta_{-1} + \sum_{t=0}^{L-1} \eta_t\}. \quad (11.2)$$

*Conversely, a machine with this profile within distance  $\varepsilon$  of  $p$  supplies such a certificate with  $\eta_{-1} = \varepsilon$  and all local errors zero. If a deterministic initial state is required, use  $K_0 = 1$  throughout both statements.*

*Proof.* Let  $\hat{v}_{t,m}$  be the actual continuation of the rows  $q$  from state  $m$ . Fix a future policy. Conditional on the first output and next state, its remaining actions form an admissible suffix policy. Replacing  $v_{t+1,j}$  by  $\hat{v}_{t+1,j}$  therefore changes its transcript law by at most  $\max_j d_{t+1}^{\text{ca}}(v_{t+1,j}, \hat{v}_{t+1,j})$ . Mixtures and pushforwards contract total variation. The triangle inequality and (11.1) imply, backwards from  $L$ ,

$$\max_m d_t^{\text{ca}}(v_{t,m}, \hat{v}_{t,m}) \leq \sum_{s=t}^{L-1} \eta_s.$$

Mixing with  $\rho$  proves (11.2). The converse takes the actual normalized continuations of the given machine, including arbitrary valid continuations for unreachable states. Their one-step equations are identities. There is no assertion that independently optimal approximate lists at successive cuts have compatible updates.  $\square$

**11.2. The full value and its effective approximation.** Fix a finite schedule with finitely many observation and action symbols,  $N$  calls to an experiment, and a bounded terminal payoff  $G \in [-1, 1]$ . An environment  $b \in B$  specifies the conditional observation kernels at all possible visible histories and actions. Assume  $B$  is a nonempty compact subset of the resulting finite product of probability simplexes. A controller  $A$  has a specified persistent profile  $\mathbf{K}$ ; the clock has no access to sample history. All action choices and all retained randomness factor through the current register. Define

$$V_{N,\mathbf{K}}(B, G) = \max_{A \in \mathcal{M}(\mathbf{K})} \min_{b \in B} \mathbb{E}_b^A G. \quad (11.3)$$

Unused states pad smaller machines, so  $\mathcal{M}(\mathbf{K})$  is a finite product of stochastic-row simplexes, with any prescribed causal zeros imposed. The terminal readout is included among its rows.

**Theorem 11.2** (Full-profile resource transfer). *The maximum in (11.3) is attained. Its value is nondecreasing in each  $K_t$ . Removing a charged intermediate cut gives a relaxation, whereas inserting identity-holding cuts preserves every implementation with the same held register.*

*Suppose two environments at each of their  $N$  calls differ in conditional total variation by at most  $\delta_i$ , uniformly over corresponding histories, actions and parameters. Replace the controller rows at its  $L$  transitions by dyadic rows of denominator  $2^r$ , with at most  $s_t$  possible next-state/output pairs at transition  $t$ . Any fixed controller loses at most*

$$2 \min \left\{ 1, \sum_{i=1}^N \delta_i + \sum_{t=1}^L (s_t - 1) 2^{-r} \right\} \quad (11.4)$$

*in expected payoff. The same bound compares optimal values on the same profile, with the appropriate dyadic approximation on one side. More generally an approximate continuation certificate contributes its error in (11.2) inside the braces.*

If  $B_0 \subset B$  is a finite  $\omega$ -net in the maximum conditional-TV metric and  $v_0$  is the maximum over the dyadic controller grid of the minimum over  $B_0$ , then

$$v_0 - 2N\omega \leq V_{N,\mathbf{K}}(B, G) \leq v_0 + 2 \sum_{t=1}^L (s_t - 1) 2^{-r}. \quad (11.5)$$

The bounds are certificates whenever the net and the finite evaluations are certified. Compactness alone supplies existence of nets, not an algorithm for an arbitrary presentation of  $B$ .

*Proof.* For fixed  $b$ , each path probability is a finite product of controller and environment coordinates. Summing the finitely many paths gives a jointly continuous payoff. Its minimum over compact  $B$  is continuous in the controller rows; the controller space is compact. This proves attainment. Padding proves monotonicity. Removing a constraint enlarges the feasible set, and identity transitions prove the insertion assertion.

For the perturbation bound, couple two executions until their first mismatch. On equal histories the conditional observation laws can be maximally coupled, with mismatch probability at most  $\delta_i$ . Couple the controller transitions similarly, using Lemma 10.1. The probability of any mismatch is at most the sum in (11.4), capped at one. The payoff changes by at most two on that event. This coupling is recursive on finite histories and remains valid for feedback controls. Alternatively, approximate continuation kernels are compared in the causal distance and then composed, as in Theorem 11.1.

For a fixed grid controller, a minimizing point of  $B$  has a point of  $B_0$  within  $\omega$ ; the corresponding payoffs differ by at most  $2N\omega$ . Thus the grid optimum on all of  $B$  is at least  $v_0 - 2N\omega$ . Conversely approximate a maximizing unrestricted controller row by row. Its minimum over  $B$  decreases by at most the row-rounding bound, and its minimum over  $B_0$  is no smaller. Taking the grid maximum proves the upper bound. No minimax interchange or convexification of the fixed-width behavior image occurs.  $\square$

The formula records preparation count, persistent labels, calibration error, causal simulation error and transition precision in one execution. The training-count factor is present when training kernels change. It is absent only when those kernels are identical. Failure probabilities are also transported, with factor one rather than two, since their indicators have range  $[0, 1]$ .

**Proposition 11.3** (Composition and schedule refinement). *A causal simulator of profile  $\mathbf{R}$  followed on the same synchronized schedule by a controller of profile  $\mathbf{K}$  has a realization with profile  $(R_t K_t)$ . Causal simulation errors add under successive composition. Two disjoint phases with a genuine reset and no retained bridge use the maximum of their peak widths. If a bridge with  $H$  labels must survive the second phase, its direct width bound is  $H$  times the second-phase width.*

*If one atomic input  $x$  is encoded by  $\ell$  symbols, let  $D_j$  be the number of possible length- $j$  prefixes. Holding the pre-input state and the prefix realizes the refined acquisition cuts with widths  $K_{\text{before}} D_j$ , followed by the original update. A time-dependent machine running for  $T$  scheduled epochs becomes autonomous by retaining its clock, with at most  $(T + 1) \max_t K_t$  states. These are implementation bounds, not claims of optimality for every refinement.*

*Proof.* Keep the ordered pair of simulator and controller registers and compose their transition kernels. The simulator's emitted observation is the controller's current input. Conditional coupling until the first simulation discrepancy gives the error statement. A genuine reset permits reusing the alphabet, whereas a surviving bridge is another register. A partial encoded input is determined by its prefix, giving the stated refinement construction. Finally the augmented state  $(t, m)$  implements the time-indexed transition without an external clock. These constructions also show why neither hidden selectors nor an external transcript may be omitted from the register being counted.  $\square$

## 12. FROM A DECISION COVER TO AN END-TO-END MACHINE

The unrestricted empirical table in Theorem 9.2 can be replaced by a bounded-state training procedure. This replacement trades preparation count against memory, rather than assuming that the training computation has already been performed. The elementary block mechanism belongs to the classical finite-statistics theory of Cover [24]; the result below tracks a finite horizon, a uniform indifference band, rational precision, the whole validation phase, and a compact nonconvex candidate image.

**Lemma 12.1** (A finite-horizon four-state comparison). *Let  $Z_i$  be independent Bernoulli observations of unknown mean  $u$ . For  $0 < \theta < 1/2$  and  $0 < \delta < 1$ , put*

$$L = \left\lceil \frac{\log(2/\delta)}{4\theta} \right\rceil, \quad R = \left\lceil 2^L \log(2/\delta) \right\rceil. \quad (12.1)$$

*There is a deterministic clocked machine with four states at every observation cut, using exactly  $2LR$  observations, that decides the sign of  $u - 1/2$  with error at most  $\delta$  whenever  $|u - 1/2| \geq \theta$ . No assertion is imposed within the indifference band.*

*Proof.* Partition the observations into  $R$  pairs of blocks, each block of length  $L$ . A positive block succeeds when all its observations are one; the following negative block succeeds when all are zero. Stop updating the decision at the first successful block and retain its sign. If none succeeds, decide negative at the end. The prescribed remaining observations are still consumed, but ignored.

Two states are absorbing positive and negative decisions. The other two mean undecided with the current block still alive or already failed. At a block boundary the clock resets the undecided flag to alive. Its polarity and position are supplied by the clock; they are not inferred from an unrecorded sample. The last observation of each block either latches the sign or starts the next block. Thus four states suffice even at the block boundaries.

Write  $x = u^L$ ,  $y = (1 - u)^L$  and  $s = x + (1 - x)y$ . The probability of a positive decision is exactly

$$H_{L,R}(u) = \frac{x}{s} \{1 - (1 - s)^R\}. \quad (12.2)$$

Here  $s > 0$ , including at  $u = 0, 1$ . For  $u \geq 1/2 + \theta$ , the error is at most  $y/x + (1 - s)^R$ . For  $u \leq 1/2 - \theta$ , it is at most  $x/y$ ; the default negative decision is then correct. Since

$$\log \frac{1/2 + \theta}{1/2 - \theta} \geq 4\theta, \quad s \geq \max(x, y) \geq 2^{-L},$$

both errors are bounded by  $e^{-4\theta L} + e^{-R2^{-L}} \leq \delta$ . The logarithmic inequality follows by differentiation from its equality at zero. This also proves uniformity over the two composite hypotheses.  $\square$

**12.1. The whole-schedule continuation value.** In the one-row reset interface of Section 9, let  $W_c(B, Q)$  be the least peak width over all finite training lengths and all auditors whose worst-case expected signed score is strictly greater than  $c$ . Every training-observation cut, the decision cut, every fresh random-bit cut, and both validation cuts are charged. Observations in  $\Omega$  are atomic for this definition. The event is selected before the two validations, exactly as in that interface. The schedule clock and read-only constants are recorded as separate resources. The class includes randomized machines; its rational subclass uses only finite fair-bit randomizers. Write  $W_c^{\text{rat}}$  for the corresponding minimum in the latter class. Empty feasible sets have value  $+\infty$ .

**Theorem 12.2** (Uniform end-to-end realization of a decision cover). *Let  $B \subset \Delta(\Omega)$  be nonempty and compact,  $Q$  fixed, and  $d = |\Omega|$ . For every strict threshold  $c$ ,*

$$\kappa_c(B, Q) \leq W_c(B, Q) \leq W_c^{\text{rat}}(B, Q) \leq 12d \kappa_c(B, Q). \quad (12.3)$$

*The last inequality is interpreted only for finite  $\kappa_c$ ; when  $\kappa_c = +\infty$  all three quantities are infinite.*

More explicitly, fix  $K \geq 2$  and a response list with uniform envelope at least  $v$ . Round its coordinates to denominator  $2^r$ , and choose  $q_i \in [0, 1] \cap 2^{-r}\mathbb{Z}$  with  $|q_i - Qh_i^{(r)}| \leq \rho$ . For  $\theta, \delta$  as in Lemma 12.1, a rational auditor uses

$$N = 2LR(K - 1) \quad (12.4)$$

candidate training observations and two validation observations. Its expected score is at least

$$v - 2^{1-r} - 2\rho - 4(K - 1)\theta - 2(K - 1)\delta. \quad (12.5)$$

Its completed-training-observation cuts have width at most  $4K$ , its decision cut has width  $K$ , and its entire random-bit-refined schedule has width at most  $12Kd$ . No empirical histogram is constructed. The response and comparison thresholds have a direct read-only representation of size  $O(K^2d(r + 3) + \log L + \log R + \log K)$  bits.

*Proof.* Use a sequential tournament. Initially response 1 is incumbent. At stage  $j = 2, \dots, K$ , compare incumbent  $i$  with challenger  $j$  using fresh candidate observations. For one observation  $w \sim b$ , generate a Bernoulli variable with conditional success probability

$$\frac{1}{2} + \frac{q_j - q_i - h_j^{(r)}(w) + h_i^{(r)}(w)}{4}. \quad (12.6)$$

This lies in  $[0, 1]$  and is dyadic of denominator  $2^{r+2}$ . Its unconditional mean is  $1/2 + (\tilde{f}_j(b) - \tilde{f}_i(b))/4$ , where  $\tilde{f}_i(b) = q_i - bh_i^{(r)}$ . Conditional on the incumbent at the start of this stage, all these variables are independent and have this mean. The fixed candidate  $b$  is not changed by the comparison. Run Lemma 12.1 and replace  $i$  by  $j$  exactly when its decision is positive.

At each comparison, conditionally on all earlier stages, the probability of choosing the inferior response when their  $\tilde{f}$  values differ by at least  $4\theta$  is at most  $\delta$ . With probability at least  $1 - (K - 1)\delta$ , no such error occurs. On this event each stage loses at most  $4\theta$  relative to the better of its two responses. Induction on  $j$  gives

$$\tilde{f}_i(b) \geq \max_i \tilde{f}_i(b) - 4(K - 1)\theta.$$

Replacing the calibrated means by their true means loses at most  $2\rho$ . Rounding the original list loses at most  $2^{1-r}$  in its envelope, by Proposition 10.2. Any response payoff belongs to  $[-1, 1]$ , so failure of the good event loses at most  $2(K - 1)\delta$  in expectation. This proves (12.5), uniformly over  $b$ .

During a comparison keep the incumbent index and one of the four block states. The challenger and block positions are fixed by the schedule. At the end of a comparison the sign updates the incumbent and is forgotten. This gives the  $4K$  bound at completed-observation cuts. While drawing the coin in (12.6), keep this register and the current observation, and use the three-label binary sampler of Lemma 10.1. Thus at most  $12Kd$  labels occur at any intervening random-bit cut. At the final decision cut only the incumbent remains. Proposition 10.2 gives at most  $K(2d + 1)$  labels during event selection and  $2K(d + 1)$  during validation; both are bounded by  $12Kd$ . The three-valued terminal output fits this bound as well. These are compatible transitions over the entire schedule.

The coin thresholds can be precomputed for all triples  $(i, j, w)$  and stored as  $r + 3$ -bit integers. The event thresholds and  $L, R, K$  give the stated description bound; no arbitrary real coefficient is used by the executed machine. Formula (12.4) counts every training observation, including ignored observations after a block decision has been latched.

For (12.3), a width- $W$  auditor has at most  $W$  labels at its decision cut. The operational upper bound of Theorem 9.2 implies  $\kappa_c \leq W$ . If  $K = \kappa_c < \infty$ , its optimal list has a positive margin over  $c$ . Take  $r$  large,  $\rho \leq 2^{-r}$ , and then  $\theta, \delta$  small enough that the loss in (12.5) is smaller than that margin. If  $K = 1$ , no training is needed: round the single response and use Proposition 10.2.

Rational auditors are a subclass of all auditors, proving the remaining inequality. Finally a finite-width successful machine would give finite  $\kappa_c$ , proving the assertion at infinity.  $\square$

The dependence on the schedule is essential. The theorem is a constant-factor classification for fixed observation alphabet, not an optimal sample-complexity theorem. In particular  $R$  is exponential in  $L$ . For an autonomous implementation, a coarse bound on the number of epochs is  $T \leq N(r+3) + r + 4$ ; Proposition 11.3 then gives at most  $12Kd(T+1)$  states. The free-clock and autonomous statements are different resource bounds. Cover's theorem already exhibits the importance of this distinction [24, Theorem 2 and Section 4]; bounded-state learning itself is not a novelty claim of the present theorem.

**Corollary 12.3** (Finite-precision, calibrated certificates). *Suppose the true training kernels differ from those used in an ideal auditor by at most  $\alpha$  per training call, and the candidate and target validation laws differ by at most  $\beta_c$  and  $\beta_t$ . The right side of (12.5) is decreased by at most*

$$2 \min\{1, N\alpha\} + \beta_c + \beta_t$$

*for the same implemented machine. A calibration error  $\rho$  in the known response means is already accounted for separately in that formula. When the training source is unchanged,  $\alpha = 0$ , regardless of how large  $N$  is.*

*Proof.* Couple the training executions until their first mismatch, as in Theorem 11.2. The selected-event payoff has range  $[-1, 1]$ , giving the factor two. Conditional on a common selected event, its two validation means change by at most the two total variation errors. This uses no independence between a failed coupling and its terminal event.  $\square$

### 13. FINITE-HORIZON SAMPLE-MEMORY BOUNDS

The minimum  $W_c$  in Theorem 12.2 permits arbitrarily long finite training. To retain the preparation constraint, let  $V_{N,K}(B, Q)$  denote the supremum of the worst-case expected score over the same reset auditors, using at most  $N$  training trials and satisfying the specified register bound at each acquisition, random-bit, decision and validation cut. The observation order and the external clock are fixed parts of this interface. Write  $V_{N,W}$  when every bound equals  $W$ . Padding an audit with ignored trials shows monotonicity in  $N$ . This value does not identify machines having only the same terminal dictionary.

A second realization of a response cover gives a polynomial preparation bound. Its counter is larger than the four-state block counter, and both constructions remain useful. The elementary random-walk argument below is classical; the purpose of retaining its proof is to price its use in the complete, calibrated continuation machine.

**Lemma 13.1** (A truncated absorbing comparison). *Let  $Z_i$  be independent Bernoulli variables with mean  $u$ . Fix integers  $m, n \geq 1$  and  $0 < \theta < 1/2$ . Start at  $S_0 = 0$ , add  $2Z_i - 1$  while  $|S_{i-1}| < m$ , and retain the state forever after either boundary is reached. At time  $n$  declare positive exactly when  $S_n \geq 0$ . The machine has  $2m + 1$  states. Whenever  $|u - 1/2| \geq \theta$ , its error probability is at most*

$$e_{m,n}(\theta) = e^{-4\theta m} + e^{-2n\theta^2}. \quad (13.1)$$

*If  $\tau$  is the boundary hitting time without truncation, then, with  $x = 2u - 1$ ,*

$$\mathbb{E}_u \tau = \begin{cases} m \tanh(m \operatorname{arctanh} x) / x, & 0 < |x| < 1, \\ m^2, & x = 0, \\ m, & |x| = 1. \end{cases} \quad (13.2)$$

*In particular  $\mathbb{E}_u(\tau \wedge n) \leq \min(n, m^2)$ , and outside the indifference band it is at most  $\min(n, m^2, m/(2\theta))$ .*

*Proof.* First suppose  $1/2 < u < 1$  and put  $r = (1 - u)/u$ . For the unabsorbed walk  $T_j = \sum_{i \leq j} (2Z_i - 1)$ , the process  $r^{T_j}$  is a nonnegative martingale. Stopping on  $\{-m, m\}$  gives

$$\mathbb{P}_u(T_\tau = -m) = \frac{r^m}{1 + r^m} \leq r^m.$$

For completeness, absorption has finite mean: in each block of  $2m$  steps, a run of  $2m$  positive increments has probability  $u^{2m} > 0$  and forces absorption from every interior state. Thus the unabsorbed survival time is bounded by a geometric number of such blocks. Stopping first at  $\tau \wedge j$ , then using bounded convergence on the stopped exponential martingale, justifies the displayed identity. The estimate  $\log((1 + 2\theta)/(1 - 2\theta)) \geq 4\theta$  gives  $r^m \leq e^{-4\theta m}$  when  $u \geq 1/2 + \theta$ .

If the walk has not been absorbed, a negative final answer requires  $T_n < 0$ . Hoeffding's inequality [25] for variables in  $[-1, 1]$  gives

$$\mathbb{P}_u(T_n \leq 0) \leq e^{-2n(u-1/2)^2} \leq e^{-2n\theta^2}.$$

Partitioning a wrong answer according to absorption proves (13.1). Reflection proves the lower-mean case; its nonabsorbed error includes  $T_n = 0$  and satisfies the same bound. At  $u = 0, 1$  the assertion follows directly.

The drift martingale  $T_j - xj$  stopped at  $\tau \wedge j$  gives  $\mathbb{E}_u T_\tau = x\mathbb{E}_u \tau$ , by integrability of  $\tau$  and boundedness of the stopped walk. The hitting probabilities yield  $\mathbb{E}_u T_\tau = m(1 - r^m)/(1 + r^m)$ . Since  $r = \exp(-2 \operatorname{arctanh} x)$ , this is (13.2) when  $x \neq 0$ . For  $x = 0$ , stop  $T_j^2 - j$  to obtain  $\mathbb{E} \tau = m^2$ . The endpoint formula is deterministic. Finally  $\tanh(my) \leq m \tanh y$  for integer  $m \geq 1$  and  $y \geq 0$ : induction follows from the addition formula for  $\tanh$ . This proves  $\mathbb{E} \tau \leq m^2$ ; the bound  $m/|x|$  follows from  $|T_\tau| \leq m$ . Truncation can only decrease the mean.  $\square$

**Theorem 13.2** (A preparation-width family of realizations). *Let  $B \subset \Delta(\Omega)$  be compact,  $d = |\Omega|$ , and let  $h_1, \dots, h_K \in [0, 1]^\Omega$ ,  $K \geq 2$ , have envelope  $v = \min_{b \in B} \max_i (Q - b)h_i$ . Round their coordinates to dyadic precision  $r$ , obtaining  $h_i^{(r)}$ , and choose known dyadic numbers  $q_i \in [0, 1]$  with  $|q_i - Qh_i^{(r)}| \leq \rho$ . Suppose  $q_i$  also have denominator  $2^r$ ; enlarging  $r$  accommodates any specified dyadic calibration. For  $m, n \geq 1$  and  $0 < \theta < 1/2$ , an explicitly clocked fair-bit audit satisfies*

$$N = n(K - 1), \quad W \leq 3dK(2m + 1), \quad (13.3)$$

$$\inf_{b \in B} \mathbb{E}_b D \geq v - 2^{1-r} - 2\rho - 4(K - 1)\theta - 2(K - 1)e_{m,n}(\theta). \quad (13.4)$$

*At completed training-trial cuts its width is at most  $K(2m + 1)$ ; at the decision cut it is at most  $K$ . Every random-bit cut, the selected event, and both validations are included in  $W$ . In particular one can replace  $e_{m,n}(\theta)$  by  $\delta$  by taking*

$$m = \left\lceil \frac{\log(2/\delta)}{4\theta} \right\rceil, \quad n = \left\lceil \frac{\log(2/\delta)}{2\theta^2} \right\rceil. \quad (13.5)$$

*Proof.* For a fixed unknown  $b$ , set  $g_i(b) = q_i - bh_i^{(r)}$ . Compare the current incumbent  $i$  with the next index  $j$  on fresh observations. Conditional on the observation  $w$ , generate a coin with probability

$$\frac{1}{2} + \frac{q_j - q_i - h_j^{(r)}(w) + h_i^{(r)}(w)}{4}. \quad (13.6)$$

This is in  $[0, 1]$ , is dyadic with denominator  $2^{r+2}$ , and has mean  $1/2 + (g_j(b) - g_i(b))/4$ . Apply Lemma 13.1, selecting  $j$  for a positive answer and  $i$  otherwise. Conditional on all earlier stages, the observations and fair bits for this comparison are fresh. The probability of selecting the worse index when  $|g_j - g_i| \geq 4\theta$  is at most  $e_{m,n}(\theta)$ .

Outside these exceptional comparisons each tournament stage loses at most  $4\theta$  relative to the better of its two contestants. Induction shows a total loss at most  $4(K - 1)\theta$  relative to  $\max_i g_i$ .

The union probability of exceptional comparisons is at most  $(K-1)e_{m,n}(\theta)$  even though the incumbent is random. All  $g_i$  lie in  $[-1, 1]$ , so their range is at most two. Consequently

$$\mathbb{E}_b g_i(b) \geq \max_i g_i(b) - 4(K-1)\theta - 2(K-1)e_{m,n}(\theta).$$

The calibration changes selection and evaluation by at most  $2\rho$ . For each coordinate rounding,  $\|h_i - h_i^{(r)}\|_\infty \leq 2^{-r}$ , so  $|(Q-b)(h_i - h_i^{(r)})| \leq 2^{1-r}$ . A nested random event with mean  $h_i^{(r)}$  has exactly that rounded payoff; hence (13.4).

At a completed trial retain the incumbent and the absorbing walk state. The stage number  $j$  is supplied by the predetermined clock, not by a sample-dependent register. During coin generation additionally retain  $w$  and at most three sampler labels, by Proposition 10.2. This gives  $3dK(2m+1)$  labels. The terminal event sampler, held event, and validation storage use at most  $K(2d+1)$ ,  $K(d+1)$ , and  $2K(d+1)$  labels, respectively, as in Theorem 12.2; all are bounded by the stated  $W$ . The stage boundary discards the walk and initializes the next one. After absorption, remaining observations and bits in that stage are ignored, but are still charged to the fixed schedule. Thus the count  $N$  includes padding. Each active coin uses  $r+2$  fair bits. A coarse bound for the full number of epochs is  $T \leq N(r+3) + r + 4$ .

The finite transition description consists of the dyadic coin table, the boundary and horizon integers, and the nested-event thresholds. It has  $O(K^2d(r+3) + \log m + \log n + \log K)$  bits under binary encoding; the constants depend on a fixed encoding convention. No unknown  $b$  occurs in that description. The autonomous conversion stores the clock and has width at most  $(T+1)W$ , rather than  $W$ . Substitution of (13.5) proves the last assertion.  $\square$

**Corollary 13.3** (Two general preparation regimes). *For a strict  $K$ -response cover and a prescribed positive score margin, there are whole-schedule rational realizations of that margin with width at most  $12dK$  and exponential block preparation count, and with width at most  $3dK(2m+1)$  and preparation count  $n(K-1)$  as in (13.5). Both constrain every training cut. Their resource pairs are upper bounds for  $\mathbb{V}_{N,W}$ , not a claim of an optimal frontier for every compact image.*

*Proof.* Choose rounding, calibration, band and error budgets whose sum is smaller than the strict margin. Apply Theorem 12.2 or Theorem 13.2. A one-response cover needs no training and is implemented directly by the rational event sampler.  $\square$

#### 14. AN EXACT STATISTICAL FRONTIER AT ALL CUTS

The preceding realizations are uniform upper bounds. A family with an exact answer illustrates what an all-algorithm statistical lower bound requires. Unlike exact computation of a prescribed word function, the objective here is the best decision risk among all rules, including stochastic rules, under a fixed preparation schedule and full profile.

Let  $\Theta = \{1, \dots, M\}$  and fix a known prior  $\pi_1 \geq \dots \geq \pi_M \geq 0$ ,  $\sum_j \pi_j = 1$ . At time  $t$ , an independent indicator  $E_t$  has known mean  $q_t \in [0, 1]$ . The report is  $Y_t = \vartheta$  if  $E_t = 1$ , and  $Y_t = *$  otherwise. All indicators are independent of the parameter and the machine's private randomization. The unknown parameter  $\vartheta$  is fixed during the  $n$  observations. The machine starts in a parameter-independent state, has at most  $K_t$  labels after report  $t$ , and finally guesses  $\vartheta$ . Its initial and final randomization is part of the same finite causal machine. The objective is Bayesian probability of a correct answer under  $\pi$ . Parameter-dependent loss is specified here and is not identified with the one-row physical signed-score problem.

Write  $P_k = \sum_{j=1}^k \pi_j$  and put

$$k_t = \min\{M, K_t, K_{t+1}, \dots, K_n\}, \quad a = \prod_{s=1}^n (1 - q_s), \quad w_t = q_t \prod_{s=t+1}^n (1 - q_s). \quad (14.1)$$

Thus  $a + \sum_t w_t = 1$  and  $k_t$  is nondecreasing in  $t$ .

**Theorem 14.1** (Exact all-cut revelation frontier). *Over all stochastic causal machines satisfying the specified profile, the optimal Bayesian success probability is*

$$S_{\mathbf{q}, \mathbf{K}}(\pi) = a\pi_1 + \sum_{t=1}^n w_t P_{k_t}. \quad (14.2)$$

*A single deterministic machine attains this value simultaneously for all  $\mathbf{q} \in [0, 1]^n$ . The upper bound therefore applies to all approximate statistical decision rules, not just to machines implementing a chosen selector exactly.*

*Proof.* Let  $L$  be the last time with  $E_L = 1$ , with  $L = 0$  when no revelation occurs. Then  $\mathbb{P}(L = 0) = a$  and  $\mathbb{P}(L = t) = w_t$ . These events, and every particular pattern of indicators, are independent of  $\vartheta$ .

First consider any stochastic machine. Realize all of its transition and output kernels by independent random variables indexed by time, state and input, and also realize its initial randomization. This is possible on a product space independent of  $\vartheta$  and the indicators. Conditional on the entire random table the machine is deterministic. This conditioning is an analysis device, not a free persistent random seed in an implementation.

Fix that table and an indicator pattern with last revelation  $t > 0$ . The map from  $\vartheta$  to the terminal guess factors through the state at every time  $s \geq t$ : all reports after  $t$  are the same symbol  $*$ , so the remaining transitions and output are fixed maps. The set of possible terminal guesses therefore has cardinality at most  $\min_{s \geq t} K_s$ , and at most  $M$  guesses can be correct. Its prior success probability is bounded by the mass of the  $k_t$  largest prior atoms, namely  $P_{k_t}$ . Earlier revelations and any parameter information encoded before  $t$  do not evade this future bottleneck. On the no-revelation pattern, the output is independent of  $\vartheta$  and its success probability is at most  $\pi_1$ . Integrate these bounds over the random table and indicator patterns to obtain the upper bound in (14.2). In particular no extremality claim about a nonconvex minimax set has been used.

For attainment, use the labels  $\{1, \dots, k_t\}$  at time  $t$ , start with label one, and use the following deterministic updates. On  $*$ , hold the label. On a revelation  $j \leq k_t$ , replace it by  $j$ ; on a revelation  $j > k_t$ , replace it by one. The holding update is legal because  $k_{t-1} \leq k_t$ . At termination output the label. Conditional on  $L = t > 0$ , exactly the parameters  $1, \dots, k_t$  are correct; on  $L = 0$ , exactly parameter one is correct. This proves equality. The updates use only the prescribed profile and prior ordering, not the probabilities  $q_t$ , establishing simultaneous attainment.  $\square$

**Corollary 14.2** (Sharp preparation–peak tradeoff). *For the uniform prior, a constant reveal probability  $0 < q < 1$ , and constant width  $1 \leq K \leq M$ , write  $a_n = (1 - q)^n$ . Then*

$$S_{n, K} = \frac{a_n + K(1 - a_n)}{M}. \quad (14.3)$$

*For  $n \geq 1$  and target success  $s \in [1/M, 1]$ , the least feasible width is*

$$K_{n, s} = \max \left\{ 1, \left\lceil \frac{Ms - a_n}{1 - a_n} \right\rceil \right\}, \quad (14.4)$$

*provided this integer is at most  $M$ ; otherwise the target is infeasible at that preparation count. If  $s > 1/M$  and  $K > Ms$ , the least preparation count for width  $K$  is*

$$n_{K, s} = \left\lceil \frac{\log((K - 1)/(K - Ms))}{-\log(1 - q)} \right\rceil. \quad (14.5)$$

*If  $K \leq Ms$  and  $s > 1/M$ , no finite  $n$  attains the target, except that equality can be attained when revelations are certain, a case excluded by  $q < 1$ . Width one gives success exactly  $1/M$  for all  $n$ .*

*Proof.* Here  $P_k = k/M$  and  $k_t = K$ . Since  $\sum_t w_t = 1 - a_n$ , Theorem 14.1 gives (14.3). Solving  $a_n + K(1 - a_n) \geq Ms$  first for  $K$  and then for  $n$  proves the formulas. For  $K > 1$ , the limiting value  $K/M$  is approached strictly from below when  $0 < q < 1$ , which proves the boundary assertion.  $\square$

**Corollary 14.3** (Exact cost of a changed checkpoint). *Replacing a profile  $\mathbf{K}$  by a tighter profile  $\widetilde{\mathbf{K}}$  loses exactly*

$$\sum_{t=1}^n w_t (P_{k_t} - P_{\widetilde{k}_t}).$$

*Inserting a charged holding cut of width  $H$  immediately after time  $s$  replaces  $k_t$  by  $\min(k_t, H)$  for  $t \leq s$ , and leaves the later terms unchanged. In particular a single narrow early cut does not constrain information acquired after that cut.*

*Proof.* Subtract (14.2) for the two profiles. A holding cut is a further bottleneck exactly for revelations that precede it. The same deterministic construction realizes the refined schedule.  $\square$

For example, with  $M = 4$ ,  $q_1 = q_2 = q_3 = 1/2$ , and  $(K_1, K_2, K_3) = (4, 1, 4)$ , the effective profile is  $(1, 1, 4)$  and the optimal uniform-prior success is  $5/8$ . Four labels at the terminal cut alone would instead give  $29/32$ . These are risks of complete experiments, not counts of residual classes of one word function. For a nonuniform prior the same theorem weights every surviving label by its actual mass. The nested optimal label sets are what makes all cut bounds jointly attainable. For a general loss or observation channel such nesting need not hold; compatible continuation updates, not independently optimized dictionaries, remain necessary.

The exact formula is Bayesian. Its upper bound also obstructs any uniform worst-case guarantee exceeding that Bayesian value, but the attaining prior-ordered machine is not asserted to be minimax. In particular an uncharged persistent random permutation cannot be used to turn its Bayesian success into a minimax statement. The prior, observation channel and all register cuts have been declared explicitly.

## 15. TRANSPORT PRICED BY ACTIVE UPDATES

A changed training source need not affect a latched computation at every subsequent scheduled preparation. The relevant quantity is the defect of its induced retained-state transition, not the number of raw reports that happen to be present. This distinction gives a sharper transfer bound without assuming equality of the training laws.

**Theorem 15.1** (Occupation-weighted retained-law transfer). *Consider a fixed finite execution with common initial state law  $\mu$  and retained-state transition kernels  $P_t, Q_t$  on the same finite state spaces,  $1 \leq t \leq T$ . The kernels may depend on a fixed unknown parameter; all inequalities below hold separately for each parameter. Let*

$$d_t(x) = \|P_t(x, \cdot) - Q_t(x, \cdot)\|_{\text{TV}}, \quad \mu_{t-1} = \mu P_1 \cdots P_{t-1}.$$

*For the same terminal readout kernel  $F$ ,*

$$\|\mu P_1 \cdots P_T F - \mu Q_1 \cdots Q_T F\|_{\text{TV}} \leq \min \left\{ 1, \sum_{t=1}^T \int d_t d\mu_{t-1} \right\}. \quad (15.1)$$

*If  $d_t(x) \leq \alpha_t \mathbf{1}_{A_t}(x) + \zeta_t(x)$ , the right side can be replaced by the truncated sum  $\sum_t \alpha_t \mathbb{P}_P(X_{t-1} \in A_t) + \sum_t \mathbb{E}_P \zeta_t(X_{t-1})$ . For a readout in  $[-1, 1]$  multiply the bound by two; for an indicator no factor two is needed. The reverse bound with  $P, Q$  exchanged is also valid.*

*Proof.* For signed measures, expand the product difference in the order

$$\mu P_1 \cdots P_T - \mu Q_1 \cdots Q_T = \sum_{t=1}^T \mu P_1 \cdots P_{t-1} (P_t - Q_t) Q_{t+1} \cdots Q_T.$$

Integration of a row difference against  $\mu_{t-1}$  has total variation at most  $\int d_t d\mu_{t-1}$ . All suffix kernels and  $F$  contract total variation. The triangle inequality and the bound one for probability-law

distance prove (15.1). Substitute the rowwise estimate for its occupation version. The expectation bounds follow from the oscillation of the readout.  $\square$

Here the retained state must support the displayed transition kernels. For independent reset observations and a time-inhomogeneous finite machine this is automatic, even when the selected row depends on the state. For a non-reset physical process one must include the necessary analysis state or use its history kernels; ignoring a report need not remove its influence on subsequent physical dynamics. No Markov closure of an arbitrary compressed physical state is assumed.

**Corollary 15.2** (Calibrated training with absorption). *Run the audit of Theorem 13.2 under an ideal reset source and a perturbed reset source whose row laws differ by at most  $\alpha$  per active call. Use the same implemented coin and event randomizers. If  $A$  is the number of active comparison updates under the ideal execution, the change in its selected-response score is at most*

$$2 \min(1, \alpha \mathbb{E}A) + \beta_c + \beta_t, \quad \mathbb{E}A \leq (K - 1) \min(n, m^2), \quad (15.2)$$

where  $\beta_c, \beta_t$  bound candidate and target validation-law changes. A comparison with conditional coin mean  $u$  has the sharper active expectation  $\mathbb{E}_u(\tau \wedge n)$  in (13.2). Uniform gaps  $|u - 1/2| \geq \eta$  give the bound  $\min(n, m^2, m/(2\eta))$  for that comparison.

*Proof.* At a completed comparison trial, marginalize the fresh coin bits into its transition kernel. Before absorption, data processing bounds its row defect by the source defect  $\alpha$ . After absorption its retained transition is the same identity under both sources; its defect is zero. At predetermined stage boundaries the common reset of the walk is also defect-free. Theorem 15.1 therefore bounds the terminal incumbent-law distance by  $\alpha \mathbb{E}A$ . The score associated with an incumbent lies in  $[-1, 1]$ . Conditional on a common incumbent and common nested event, the two validation expectations change by at most  $\beta_c + \beta_t$ . This proves the score estimate. Condition on the incumbent at each stage and apply Lemma 13.1; summing proves the active-count bound. Marginalizing the coin here is a proof of a law estimate, not a waiver of its implementation states, which remain charged in (13.3).  $\square$

The estimate is for the output or retained computation, not for the complete raw-observation transcript. A padded sequence of  $N$  changed reports can still have total variation of order  $N\alpha$  even after the machine has stopped using them. Conversely, all  $N$  preparations remain in the resource ledger even when only  $A$  updates influence the answer. Finite row-rounding defects can be inserted as the terms  $\zeta_t$  in Theorem 15.1; a changed initial law adds its total variation separately. Thus source-preserving transport is the case  $\alpha = 0$ , while the active bound also has content for  $\alpha > 0$  and does not assert generic sample-count-free stability.

## 16. WEIGHTED CONTINUATION OBSTRUCTIONS

We next give a distribution-sensitive version of the wordwise obstruction. It applies to finite-valued terminal decisions and is useful even when a word of small probability should not be assigned the same weight as a likely one.

Let  $f : \Sigma_1 \times \cdots \times \Sigma_L \rightarrow \mathcal{A}$  have finite range. The residual of a prefix  $x$  at cut  $t$  is the function  $v \mapsto f(xv)$  on the suffix alphabet. Write  $r_t(f)$  for the number of distinct residuals. A stochastic machine has a charged register at every cut; all persistent randomness is included in this register. Its wordwise error is  $e(w) = \Pr(\hat{f}(w) \neq f(w))$ .

**Theorem 16.1** (Finite-valued realization and weighted cut bound). *Exact stochastic computation of  $f$  requires  $K_t \geq r_t(f)$  at every cut. The whole residual profile is simultaneously attained by a deterministic machine.*

Fix a cut, prefixes  $x_1, \dots, x_r$ , and a graph on  $[r]$ . For each edge  $ij$  choose a suffix  $v_{ij}$  such that  $f(x_i v_{ij}) \neq f(x_j v_{ij})$ . Let  $\mu(w) \geq 0$  be arbitrary word weights. Choose edge weights  $\lambda_{ij} \geq 0$  satisfying the word capacity constraints

$$\sum_{ij: w=x_i v_{ij} \text{ or } w=x_j v_{ij}} \lambda_{ij} \leq \mu(w) \quad \text{for every word } w. \quad (16.1)$$

Every machine with  $K$  states at this cut satisfies

$$\sum_w \mu(w) e(w) \geq \min_{\phi: [r] \rightarrow [K]} \sum_{ij: \phi(i)=\phi(j)} \lambda_{ij}. \quad (16.2)$$

The right side is a weighted monochromatic-edge obstruction. Maximizing it over admissible witnesses and weights gives a finite, distribution-sensitive lower bound. The bound can be an equality with positive error.

*Proof.* Let  $a_i(m)$  be the state distribution after prefix  $x_i$ . For a fixed edge and a common state  $m$ , the future output distribution on suffix  $v_{ij}$  is the same for both prefixes. Since their correct outputs are different, the sum of their two conditional error probabilities is at least one. Multiplying by the smaller state mass and summing gives

$$e(x_i v_{ij}) + e(x_j v_{ij}) \geq \sum_{m=1}^K \min\{a_i(m), a_j(m)\}. \quad (16.3)$$

Weight the inequalities by  $\lambda_{ij}$  and use (16.1). The resulting lower bound is

$$F(a_1, \dots, a_r) = \sum_{ij} \lambda_{ij} \sum_m \min\{a_i(m), a_j(m)\}.$$

This is a concave continuous function on  $(\Delta_K)^r$ . Every point of that product is a convex combination of its deterministic vertices; concavity implies that its value is at least the minimum over those vertices. A vertex is a labeling  $\phi: [r] \rightarrow [K]$ , and its value is exactly the right side of (16.2). This proves the bound without treating stochastic encodings as deterministic encodings.

For zero error, choose one distinguishing suffix for every two different residuals. Equation (16.3) forces the corresponding state supports to be disjoint. Hence at least  $r_t(f)$  states are needed. For the converse, keep the residual class of the observed prefix. Equal residuals have equal shifts after every next input, so the next class is well defined. At the last epoch the residual is the output label itself. These quotient transitions realize all widths simultaneously.

For a positive-error equality, let the only relevant words be two one-letter prefixes with different required labels, weighted  $p$  and  $1 - p$ , where  $0 < p < 1$ . Put  $K = 1$  and  $\lambda_{12} = \min(p, 1 - p)$ . The cut obstruction is  $\min(p, 1 - p)$ , attained by always emitting the more likely label. Thus the weighted constant is sometimes exact; universal sharpness for all graphs or input distributions is not asserted. With unit weights on the same two words the total-error lower bound is one, also attained by a constant output; this is equality in the earlier  $(r - K)/(r - 1)$  bound at  $r = 2$ ,  $K = 1$ .  $\square$

**Corollary 16.2** (A Bayes-regret obstruction for constrained audits). *Fix a finite action set  $\mathcal{A}$ , candidate class  $B$ , and a probability measure  $\nu$  on  $B$ . For a training word  $w$ , let  $p_w(b)$  be its likelihood and let  $f_a(b)$  be the expected validation payoff. Put*

$$R_w(a) = \int_B p_w(b) f_a(b) d\nu(b), \quad S_\nu = \sum_w \max_a R_w(a).$$

*Choose a maximizing label  $f(w)$ . Set  $\mu(w) = R_w(f(w)) - \max_{a \neq f(w)} R_w(a)$ , taking zero when a maximum is tied. Let  $\Gamma_{t,K}(f, \mu)$  be any lower bound supplied by (16.2). Then every width- $K$  audit*

at cut  $t$  has worst-case expected payoff at most

$$S_\nu - \Gamma_{t,K}(f, \mu). \quad (16.4)$$

*Proof.* The conditional distribution of the auditor's output for a fixed word is independent of the unknown candidate. Its Bayes payoff is therefore  $\sum_{w,a} R_w(a) \Pr(\hat{f}(w) = a)$ . Subtracting this from  $S_\nu$  gives at least  $\sum_w \mu(w)e(w)$ . Apply the theorem, and use that a minimum over candidates is at most the average under  $\nu$ .  $\square$

The corollary does not exchange a maximum and minimum over a nonconvex fixed-width machine class. The prior is a lower-bound device, not a randomization resource supplied to the candidate. With a unique maximizing label and strictly positive margins at every word, equality with  $S_\nu$  forces exact wordwise computation. This makes explicit the uniqueness step used in the odd-sample binary theorem below. For even sample size, the balanced-count words have zero likelihood gap. A rule can differ on those ties without losing value; equality of values then does not force one prescribed total Boolean rule, and the odd-sample width profile cannot simply be asserted for that case.

## 17. JOINT RESIDUAL BUDGETS AND GROWING FAMILIES

We now put lower bounds on several cuts into one statistical budget. Summing separate cut bounds without controlling their common words would count the same regret more than once.

**Theorem 17.1** (A shared-capacity multicut obstruction). *Let  $f : \prod_{i=1}^L \Sigma_i \rightarrow \mathcal{A}$  and  $\mu(w) \geq 0$  be as in Theorem 16.1. At each chosen cut  $t$ , choose a finite prefix graph with an edge  $e = (u, v)$  carrying a distinguishing suffix  $s_e$ , and a weight  $\lambda_{t,e} \geq 0$ . Impose the single family of constraints*

$$\sum_{t,e: w=us_e \text{ or } w=vs_e} \lambda_{t,e} \leq \mu(w) \quad \text{for every complete word } w. \quad (17.1)$$

For a graph at cut  $t$ , write

$$\Gamma_{t,K_t}(\lambda) = \min_{\phi: \text{prefixes} \rightarrow [K_t]} \sum_{e=(u,v): \phi(u)=\phi(v)} \lambda_{t,e}.$$

Every stochastic machine of profile  $\mathbf{K}$  satisfies

$$\sum_w \mu(w) \Pr(\hat{f}(w) \neq f(w)) \geq \sum_t \Gamma_{t,K_t}(\lambda). \quad (17.2)$$

Consequently, with  $R_w, S_\nu, \mu$  defined in Corollary 16.2, every audit of this profile and the fixed training schedule has worst-case payoff at most

$$S_\nu - \sup_{\lambda \text{ satisfying (17.1)}} \sum_t \Gamma_{t,K_t}(\lambda). \quad (17.3)$$

For fixed graphs the supremum is the value of a finite linear program.

*Proof.* For each edge use the overlap inequality (16.3). Multiply it by  $\lambda_{t,e}$  and sum over all cuts and edges. The left side is bounded above by the left side of (17.2), by the shared capacity constraint. At each cut the resulting overlap expression is concave in its prefix state distributions, hence at least its minimum over deterministic labelings, as proved in Theorem 16.1. Adding these bounds proves (17.2). Although prefix distributions at different cuts are compatible, minimizing them separately only weakens the bound; it does not assume independent realizability. The Bayes-regret argument of Corollary 16.2 proves (17.3).

For the last assertion introduce variables  $z_t$  and impose, for each labeling  $\phi$  of each finite graph,

$$z_t \leq \sum_{e=(u,v): \phi(u)=\phi(v)} \lambda_{t,e}.$$

Maximize  $\sum_t z_t$  subject to these inequalities, nonnegative edge weights, and (17.1). There are finitely many constraints. This is a computable obstruction, not a claim that every multicut statistical optimum equals this relaxation.  $\square$

**17.1. Actual physical word weights.** For  $n$  all-on trials of the private marked collision subfamily, a complete training word  $w$  specifies the two report bits and the mark of each trial. With  $N_{ab}$  its report-pair counts,

$$p_w(p, q) = 2^{-n} p^{N_{10}+N_{11}} (1-p)^{N_{00}+N_{01}} q^{N_{01}+N_{11}} (1-q)^{N_{00}+N_{10}}. \quad (17.4)$$

The formula has the continuous endpoint interpretation  $0^0 = 1$ . For any finitely supported prior on actual pairs  $(p, q) \in [0, 1]^2$ , use this likelihood in  $R_w(A) = \int p_w(p, q)(Q - b(p, q))\mathbf{1}_A d\nu$ , with all marked events  $A \subseteq \Omega$  as actions. Randomized events are included by linearity. Equations (17.1) and (17.3) then give a finite all-algorithm obstruction for that full training profile, with the true physical word probabilities. Changing only  $Q$  by total variation  $\beta$  changes every audit's payoff by at most  $\beta$ .

This specialization bounds all stochastic selectors on the fixed all-on training schedule, not merely exact implementations of a majority rule. It does not assert a new numerical lower bound above three for every adaptive physical audit. Adaptive training has controller-dependent word likelihoods and must instead be included in the full experiment of (11.3); using (17.4) unchanged for such a likelihood would be incorrect. The feedback-uniform lower bound used below remains Lemma 29.2.

## 17.2. A family with matching end-to-end growth.

**Theorem 17.2** (Point-source decision spectra). *Let  $d \geq 2$ ,  $B_d = \{\delta_1, \dots, \delta_d\}$  on  $[d]$ , and let  $Q_d$  be uniform. For every  $K \geq 1$ ,*

$$\mathfrak{V}_K(B_d, Q_d) = 1 - \frac{\lceil d/K \rceil}{d}. \quad (17.5)$$

*For  $1 - 2/d < c < 1 - 1/d$ , the decision complexity is exactly  $d$ , and the whole-schedule peak satisfies*

$$d \leq W_c(B_d, Q_d) \leq W_c^{\text{rat}}(B_d, Q_d) \leq 2d.$$

*The upper bound uses one training observation and two validations, with no randomization. Thus the end-to-end width grows linearly in this nontrivial sequence of compact behavior images.*

*Proof.* Assign each point source to a response that maximizes its score. Some response is assigned a set  $S$  of at least  $\lceil d/K \rceil$  indices. For  $s = |S| < d$ , the mean of its scores on  $S$  equals

$$\frac{d-s}{d} \left( \frac{1}{d-s} \sum_{i \notin S} h_i - \frac{1}{s} \sum_{i \in S} h_i \right) \leq 1 - \frac{s}{d}.$$

For  $s = d$  the mean is zero. At least one assigned source has score no larger than this mean, proving the upper bound. Partition  $[d]$  into at most  $K$  groups of size at most  $\lceil d/K \rceil$  and use their complements as events. This attains the lower bound.

In the stated interval the formula forces  $K \geq d$ . A single training observation identifies the point source  $i$  exactly. Keep  $i$  and choose the complement of  $\{i\}$ . During validation retain  $i$  and the candidate indicator, at most  $2d$  states, then emit the target indicator minus it. This computes the prescribed signed score on every input word, including words that have zero probability under the point-source family. Its expected score is  $1 - 1/d$ . The lower bound follows from the necessary decision-cut width.  $\square$

**17.3. A sharp simultaneous storage profile.** A second class separates overlapping retention obligations. Independent uniform labels  $X_j \in [q_j]$  are revealed at scheduled epochs  $a_j$  and must be reported at epochs  $b_j > a_j$ . No later input reveals an active label, and previous outputs cannot be read as external memory. Let  $A_t = \{j : a_j \leq t < b_j\}$  and  $D_t = \prod_{j \in A_t} q_j$ .

**Theorem 17.3** (Overlapping retention intervals). *Every stochastic machine whose probability of correctly reporting all labels is at least  $1 - \varepsilon$  has*

$$K_t \geq (1 - \varepsilon)D_t \quad \text{at every cut } t. \quad (17.6)$$

*The exact profile  $K_t = D_t$  is attained simultaneously by a deterministic machine. Thus the minimum peak number of bits lies between  $\log_2 \max_t D_t + \log_2(1 - \varepsilon)$  and  $\lceil \log_2 \max_t D_t \rceil$  for  $\varepsilon < 1$ .*

*Proof.* Fix a cut and give the decoder, as additional information, all labels outside  $A_t$ , whether past or future. They are independent of the uniform active vector. Conditional on them, every future prediction of that vector factors through the  $K_t$ -valued retained state and fresh randomness. If  $a(m | x)$  is its conditional encoder and  $d(x | m)$  the induced joint prediction law, its success probability is at most

$$\frac{1}{D_t} \sum_m \sum_x a(m | x) d(x | m) \leq \frac{1}{D_t} \sum_m \sum_x d(x | m) = \frac{K_t}{D_t}.$$

Correctness of all reports implies correctness of the active reports, so averaging over the independent additional information proves (17.6). For the upper bound, keep precisely the vector of active labels, append a label when revealed, and delete it when reported. Every update is deterministic and respects the schedule. The bit bounds follow by taking logarithms and rounding for an actual binary register. The lower bound is a counting argument, not an independence assumption about labels after conditioning on a compressed state.  $\square$

## 18. FINITE-DATA TESTING ON THE ORIGINAL BEHAVIOR IMAGE

**18.1. The reset interface.** Let  $B \subset \prod_{j=1}^J \Delta(\Omega_j)$  be compact, and let  $Q = (Q_j)$  be fixed. Set  $d_j = |\Omega_j|$ ,  $D = \sum_j (d_j - 1)$ ,  $\mathcal{I} = \{(j, A) : A \subseteq \Omega_j\}$ , and  $f_{j,A}(b) = Q_j(A) - b_j(A)$ . Include the empty event. No convexity of  $B$  is assumed.

A candidate  $b$  is fixed for the whole audit. The auditor obtains  $n$  independent samples of each  $b_j$ , with independence between rows. In a causal experiment, row  $j$  means a specified parameter and deterministic feedback tree; the reset interface supplies that row. It is an additional experimental interface, not information available to the online simulator. A complete sample contains the terminal mark. Private randomness and any per-run hidden selector are reset between runs. The design of the candidate is not resampled.

Write  $C_{j,w}$  for the counts, and  $\mathcal{N}_n$  for all count arrays with  $\sum_w C_{j,w} = n$ . Their probability is the polynomial

$$p_C(b) = \prod_j \frac{n!}{\prod_w C_{j,w}!} \prod_w b_j(w)^{C_{j,w}}.$$

A randomized audit is an array  $c = (c_{C,i})$  with  $c_C \in \Delta(\mathcal{I})$ . After training it chooses  $i = (j, A)$  according to  $c_C$ . Independent candidate and target validation runs give the signed score  $\mathbf{1}_A(\text{target}) - \mathbf{1}_A(\text{candidate})$ . Its expected value is

$$g_c(b) = \sum_{C,i} p_C(b) c_{C,i} f_i(b), \quad v_n^{\text{aud}}(B, Q) = \max_c \min_{b \in B} g_c(b). \quad (18.1)$$

Thus every audit payoff is polynomial of total degree at most  $Jn + 1$  in the behavior coordinates. The probability of a large observed score in a single audit is not asserted to equal its expectation; additional independent validation would be required for a specified confidence level.

**Theorem 18.1** (Reset-audit duality and finite-sample approximation). *Let  $\delta = \min_{b \in B} \max_i f_i(b)$ . Then all the extrema below are attained, and*

$$v_n^{\text{aud}}(B, Q) = \min_{\mu \in \mathcal{P}(B)} \sum_{C \in \mathcal{N}_n} \max_{i \in \mathcal{I}} \int_B p_C(b) f_i(b) d\mu(b), \quad (18.2)$$

$$0 \leq \delta - v_n^{\text{aud}}(B, Q) \leq \sqrt{D/n}. \quad (18.3)$$

The values are nondecreasing in  $n$ . If  $a = \dim \text{aff } B$ , a minimizing measure in (18.2) can be supported on at most  $\binom{a+Jn+1}{a}$  points.

An explicit feasible audit attaining the lower bound  $\delta - \sqrt{D/n}$  chooses an event maximizing  $Q_j(A) - C_j(A)/n$ , with a fixed deterministic tie rule. If the rational target probabilities are given, this is a rationally specified finite rule. With a free schedule clock, a conservative retained-state bound is

$$H(|\mathcal{I}| + 1)(n + 1) \sum_j d_j,$$

where  $H$  is the number of states needed to execute and record one causal transcript. This budget is charged to the auditor, not to the simulator.

*Proof.* The coefficient arrays form a compact convex product of finite simplexes. The integrand is continuous in  $b$  and affine in  $c$ . The probability measures on compact  $B$  form a compact convex set for weak convergence. The minimum over  $b$  equals the minimum over such measures for fixed  $c$ . Finite-dimensional minimax (or its compact measure version) therefore exchanges the two extrema. Maximization over each independent coefficient simplex selects its largest coordinate integral, giving (18.2). Continuity and compactness give attainment. This step uses measures on the original  $B$ , not feasible private realizations of their barycenters.

For any audit,  $g_c(b) \leq F(b) = \max_i f_i(b)$ . At a minimizer of  $F$  this gives  $v_n^{\text{aud}} \leq \delta$ . The zero event gives  $v_n^{\text{aud}} \geq 0$ . For the stated explicit rule put  $\hat{b}_j = C_j/n$  and  $\rho = \max_j \|\hat{b}_j - b_j\|_{\text{TV}}$ . Comparing the empirical maximizer with a true maximizing event gives the pointwise regret bound

$$F(b) - f_{i(C)}(b) \leq 2\rho.$$

For a multinomial empirical measure,

$$\mathbb{E} \|\hat{b}_j - b_j\|_{\text{TV}}^2 \leq \frac{d_j}{4} \sum_w \mathbb{E} (\hat{b}_j(w) - b_j(w))^2 = \frac{d_j(1 - \sum_w b_j(w)^2)}{4n} \leq \frac{d_j - 1}{4n}.$$

Consequently  $\mathbb{E} \rho \leq (\sum_j \mathbb{E} \|\hat{b}_j - b_j\|_{\text{TV}}^2)^{1/2} \leq \sqrt{D/n}/2$ . Averaging the regret uniformly over  $B$  proves (18.3).

From  $n + 1$  unordered samples in each row, discard one uniformly at random. The remaining counts have exactly the  $n$ -sample law, independently across rows. This realizes every  $n$ -sample audit as a randomized  $(n + 1)$ -sample audit and proves monotonicity.

Choose affine coordinates on  $\text{aff } B$ . All the functions  $p_C f_i$  lie in the span of monomials of total degree at most  $Jn + 1$ , a space of dimension at most  $s = \binom{a+Jn+1}{a}$  including the constant. The moment vector of a probability measure is in the convex hull of the evaluation vectors; their constant coordinate is one, so their affine dimension is at most  $s - 1$ . Eliminating affine dependencies gives a representation by at most  $s$  points. It preserves every integral in (18.2), and hence preserves the objective.

Finally, each count is in  $\{0, \dots, n\}$ . The indicated product register stores all counts, the within-run state, and the selected event for validation. Only the latter event and the within-run buffer need survive once training ends, so the product bound is conservative. Randomizing an event uses fresh randomness. The schedule, reset access and terminal mark readout were declared before the theorem. No private simulator state is read by this implementation.  $\square$

The dual measure chooses a candidate once, after which its samples are independent conditional on that candidate. Replacing it by  $\bar{b} = \int b d\mu$  would replace  $\int p_C(b) f_i(b) d\mu$  by  $p_C(\bar{b}) f_i(\bar{b})$ , generally a different quantity. It would also replace the joint replicated law by a product of its marginals. Neither operation is part of the theorem. This is the operational meaning of the moment side, rather than a same-budget convexification theorem.

**Proposition 18.2** (Both sides sampled). *Suppose the target reference  $Q^b$  varies with the candidate, as it does when visible-selector weights are design variables. Supply independent training samples from both  $b$  and  $Q^b$ , and use their empirical difference. If their row dimensions are  $D_P, D_Q$ , the same construction has regret at most  $\sqrt{D_P/n} + \sqrt{D_Q/n}$ . Minimax and attainment hold on the compact image of pairs  $(b, Q^b)$ . In particular a variable reference law must not be treated as known fixed input to Theorem 18.1.*

*Proof.* The error in any event discrepancy is at most the sum of the maximal row variations of the two empirical tables. Apply the preceding second moment bound separately and then the empirical-maximizer regret inequality. Count probabilities are products for the two tables. They are continuous polynomials on the compact image of pairs, so the same minimax argument applies without changing the simulator signature.  $\square$

## 18.2. A matching uniform sampling obstruction.

**Theorem 18.3** (Binary reset lower bound). *Take one binary row with target  $\text{Ber}(1/2)$  and candidate class  $B_h = \{\text{Ber}(1/2 - h), \text{Ber}(1/2 + h)\}$ , where  $0 < h < 1/2$ . Then*

$$\delta = h, \quad v_n^{\text{aud}} = h \|\text{Ber}(1/2 + h)^{\otimes n} - \text{Ber}(1/2 - h)^{\otimes n}\|_{\text{TV}}. \quad (18.4)$$

For every  $n \geq 1$ , choosing  $h = 1/(8\sqrt{n})$  gives

$$\delta - v_n^{\text{aud}} \geq \frac{1}{16\sqrt{n}}.$$

Thus the exponent in (18.3) is sharp uniformly over compact candidate classes, already at affine dimension one. This does not assert a degree lower bound for revealed-behavior polynomials, nor that this two-point class equals an unrestricted private-row image.

*Proof.* Only the two complementary singleton events and the zero event matter. A randomized choice is a statistic  $d$  in  $[-1, 1]$ . The two expected payoffs are  $h\mathbb{E}_+d$  and  $-h\mathbb{E}_-d$ . Their minimum is at most half their sum, which is at most  $h\|P_+^n - P_-^n\|_{\text{TV}}$ . Conversely take the sign of the likelihood difference, assigning zero at a tie. Complementing every sample interchanges  $P_+^n$  and  $P_-^n$  and changes that sign. The two payoffs are equal, and their average attains the variation bound. The statistic depends only on the count, so it is an admissible audit. The symmetric measure on the two candidates attains the dual value. Every Dirac measure has dual objective  $h$ , whereas for finite  $n$  the two product laws are equivalent and their variation is strictly less than one. Thus no dual minimizer is a Dirac measure. Their barycenter is the target law, but replacing the dual by that barycenter would incorrectly give value zero instead of the strictly positive value in (18.4).

For  $h \leq 1/8$ , elementary integration of  $(1 - u^2)^{-1}$  gives

$$\text{KL}(\text{Ber}(1/2 + h) \parallel \text{Ber}(1/2 - h)) = 2h \log \frac{1 + 2h}{1 - 2h} \leq 16h^2.$$

The product relative entropy is at most  $16nh^2$ . Pinsker's inequality bounds its total variation by  $\sqrt{8nh^2}$ . At the specified  $h$  this is less than  $1/2$ . Substituting in (18.4) proves the claim. The inequality uses the classical two-point testing mechanism; the restriction being measured is the reset budget of the present game.  $\square$

### 18.3. Transport of one fixed audit.

**Proposition 18.4** (Reset cost under model perturbation). *Let  $q$  range over the same compact set of executable row designs in two models. Suppose uniformly in  $q, j$  that*

$$\|P_j^q - \tilde{P}_j^q\|_{\text{TV}} \leq \alpha, \quad \|Q_j - \tilde{Q}_j\|_{\text{TV}} \leq \beta.$$

*For the same coefficient rule  $c$ , evaluated with each model's own target validation,*

$$|g_c(q) - \tilde{g}_c(q)| \leq (2Jn + 1)\alpha + \beta. \quad (18.5)$$

*The deficiencies themselves differ by at most  $\alpha + \beta$ , at the same resource budget. If the source behavior is unchanged, a fixed audit loses at most  $\beta$ , independently of its reset count.*

*Proof.* A product coupling of the  $Jn$  training runs fails with probability at most  $Jn\alpha$ . Taking counts and choosing the event are contractions. A score with fixed target discrepancies lies in  $[-1, 1]$ , so the change in its expectation from this training-law perturbation is at most  $2Jn\alpha$ . At each event the discrepancy changes by at most  $\alpha + \beta$ . This proves (18.5). For deficiency, every row variation changes by at most  $\alpha + \beta$ ; taking the maximum and then the minimum preserves that bound. No new simulator is inserted.  $\square$

For a rational polynomial image, a rational rule and a rational threshold, strict positivity of  $g_c(q)$  above that threshold is a first-order formula over the original row simplexes. Real quantifier elimination decides it. The same is true of an existential rule followed by this universal condition. This is an exact finite verification statement, not an efficient algorithm. The explicit empirical rule below will be verified by a uniform analytic inequality, rather than by storing its enormous complete table.

## 19. CONTINUATION COMPLEXITY OF A FINITE-DATA TEST

The reset budget does not by itself bound the auditor's retained memory. We now impose both constraints. At scheduled epoch  $t$  a streaming auditor reads one letter  $x_t$  from a finite alphabet  $X_t$ , updates a register, and emits no information to any auxiliary store. It makes its decision on reading the last letter. Transition rows may depend on the epoch; the clock is free. All other information crossing a cut belongs to the register. Fresh randomization is allowed. An independent persistent selector, when allowed, selects a complete auditor before any letters are read.

For a Boolean decision  $\psi : X_1 \times \cdots \times X_n \rightarrow \{-1, 1\}$ , let  $u \sim_t v$  mean that

$$\psi(us) = \psi(vs) \quad \text{for every } s \in X_{t+1} \times \cdots \times X_n.$$

Write  $r_t(\psi)$  for the number of equivalence classes of prefixes of length  $t$ , for  $0 \leq t < n$ . These are the deterministic continuation responses. The terminal decision is emitted on the last transition, so no terminal register is needed. In particular,  $r_0 = 1$ . The equivalence is a finite-horizon version of the classical residual-state construction [16]. The following quantitative statement will also measure the loss when a statistical auditor has fewer states than this construction.

**Theorem 19.1** (Exact continuation width and a quantitative cut obstruction). *A stochastic streaming auditor computes  $\psi$  exactly on every word with width profile  $(K_t)_{0 \leq t < n}$  if and only if  $K_t \geq r_t(\psi)$  at every cut. The profiles are attained simultaneously by a deterministic auditor. Independent persistent randomization does not reduce these widths for exact computation.*

*More generally, at a cut with  $r = r_t(\psi) \geq 2$ , every stochastic auditor of width  $K$  satisfies*

$$\sum_{w \in X_1 \times \cdots \times X_n} e_\psi(w) \geq \frac{(r - K)_+}{r - 1}, \quad (19.1)$$

where  $e_\psi(w)$  is its probability of an incorrect Boolean decision on input  $w$ . The inequality also holds after averaging over an independent selector whose conditional auditors each have width at most  $K$ .

*Proof.* From a prefix  $u$  let  $e_u(m)$  be the distribution of the retained state. From state  $m$  and suffix  $s$  let  $a_m(s)$  be the probability of terminal answer  $+1$ . Exact computation says

$$\sum_m e_u(m) a_m(s) = \frac{1 + \psi(us)}{2}.$$

The right side is zero or one. Every state of positive  $e_u$ -mass must therefore have precisely that zero-one continuation response for all  $s$ . Distinct prefix classes have disjoint positive supports. Hence  $K_t \geq r_t$ . Conversely, retain the prefix class. Appending the same letter to two equivalent prefixes gives equivalent new prefixes; thus every transition is well defined. At the last transition the class and the last letter determine  $\psi$ . This realizes every width  $r_t$  simultaneously. For a persistent independent selector, a zero average error on each of the finitely many words implies zero conditional error on all words outside a single null set of selector values. The preceding bound applies there.

For the quantitative claim choose representative prefixes  $u_1, \dots, u_r$ , one per class, and put  $e_i(m) = e_{u_i}(m)$ . Define

$$o_{ij} = \sum_{m=1}^K \min\{e_i(m), e_j(m)\}.$$

For nonnegative numbers  $a_1, \dots, a_r$ , ordering them shows that  $\sum_{i < j} \min(a_i, a_j) \geq \sum_i a_i - \max_i a_i$ . Apply this at each state. Since every  $e_i$  has mass one and each  $\max_i e_i(m) \leq 1$ , it follows that

$$\sum_{i < j} o_{ij} \geq r - K. \quad (19.2)$$

Choose a suffix  $s_{ij}$  distinguishing  $u_i, u_j$ . Conditional on a common state and this suffix, the two desired answers are opposite. Their error probabilities, weighted by  $e_i(m), e_j(m)$ , have sum at least  $\min\{e_i(m), e_j(m)\}$ . Thus

$$e_\psi(u_i s_{ij}) + e_\psi(u_j s_{ij}) \geq o_{ij}.$$

On summing, each complete word on the left occurs at most  $r - 1$  times: its prefix identifies a single representative, which participates in  $r - 1$  pairs. Nonnegativity of all other word errors and (19.2) prove (19.1). When  $r \leq K$  the claim is just nonnegativity. Finally apply the bound conditional on a selector and integrate. Independence ensures that conditioning has not changed the input experiment.  $\square$

The exact part is also the extremal zero-one case of Theorem 8.2. Its content is a simultaneous width profile, rather than separate unrelated factorizations at different cuts. The error bound does not assert that its constant is optimal for every Boolean function. Its use below is to convert a continuation obstruction into a strict loss of the attainable statistical value.

**19.1. The width required to attain the binary reset value.** Fix  $0 < h < 1/2$  and the binary candidate class  $B_h$  of Theorem 18.3. A terminal decision  $+1$  chooses the singleton event appropriate to the  $+$  candidate, and  $-1$  the complementary event. A zero-score event can equivalently be replaced by an independent fair choice of these decisions. The expected payoffs are therefore  $h\mathbb{E}_+d$  and  $-h\mathbb{E}_-d$ , where  $d \in [-1, 1]$  is the conditional mean decision and  $P_\pm = \text{Ber}(1/2 \pm h)^{\otimes n}$ . Let  $v_{n,K}$  be the supremum of the smaller of these two payoffs over streaming auditors with the declared width profile. The final validation interface is unchanged; the widths here count training and selection only.

**Theorem 19.2** (Exact memory threshold for optimal binary auditing). *Let  $n = 2m + 1$  be odd. The unconstrained reset value is  $v_n = h\|P_+ - P_-\|_{\text{TV}}$ . It is attained at the profile*

$$r_t = \min\{t + 1, n - t + 2\}, \quad 0 \leq t < n, \quad (19.3)$$

*and  $v_{n,K} = v_n$  if and only if  $K_t \geq r_t$  for all these cuts. For every cut with  $r_t \geq 2$  one has the explicit deficit*

$$v_n - v_{n,K} \geq 2h^2(1/4 - h^2)^m \frac{(r_t - K_t)_+}{r_t - 1}. \quad (19.4)$$

*These conclusions remain valid when an independent persistent selector chooses auditors of the same conditional widths. For  $n \geq 3$  the least peak training width attaining  $v_n$  is  $m + 2$ ; for  $n = 1$  it is one.*

*Proof.* The sign of  $P_+(w) - P_-(w)$  is the majority decision  $\psi(w)$ , with no zero difference since  $n$  is odd. Complementing every bit interchanges the two laws and reverses the decision. Consequently majority has equal payoffs and attains  $h\|P_+ - P_-\|_{\text{TV}}$ , as also proved in Theorem 18.3.

A prefix with  $k$  ones requires at least  $m + 1 - k$  ones in its remaining  $n - t$  places. Thresholds at most zero give the constant positive response; thresholds greater than  $n - t$  give the constant negative response; the remaining thresholds give different nonconstant responses. Counting them for  $0 \leq k \leq t$  gives (19.3). The exact realization in Theorem 19.1 implements majority at all these widths.

For an arbitrary randomized decision, its smaller payoff is bounded by the equal-prior average. The deficit of this average from the majority value is exactly

$$h \sum_w |P_+(w) - P_-(w)| e_\psi(w). \quad (19.5)$$

Put  $a = 1/2 + h$  and  $b = 1/2 - h$ . A word with  $k \geq m + 1$  ones has absolute likelihood difference  $(ab)^{n/2} \{(a/b)^{k-n/2} - (a/b)^{-(k-n/2)}\}$ , which increases with  $k$ . Symmetry treats the other half of the words. The smallest difference is therefore attained at  $k = m, m + 1$  and equals

$$a^{m+1}b^m - b^{m+1}a^m = 2h(1/4 - h^2)^m.$$

Substitution of (19.1) into (19.5) gives (19.4). Any deficient cut gives a strictly positive loss; all sufficiently wide profiles implement majority. Maximizing (19.3) proves the peak-width assertion. The same average-payoff argument works conditional on an independent selector and hence after averaging.  $\square$

The result identifies the exact memory needed to attain the optimal value, not the memory needed for a prescribed approximate value uniformly in  $h$ . The quantitative deficit can be small for large  $n$ . In particular it is not a sharp joint asymptotic tradeoff in sample size, state size and error. It complements, rather than replaces, the uniform sampling exponent in Theorem 18.3. No minimax interchange on the generally nonconvex set of fixed-width auditors has been used.

## 20. POLYNOMIAL TESTING OF THE ORIGINAL RESOURCE IMAGE

The private behavior image is usually nonconvex. Its testing criterion can nevertheless be written as a limit of finite algebraic lower certificates, without replacing that image by randomized designs. The testing weights in this section depend on the candidate simulator. Unlike Theorem 21.1, this identity is a certificate transform, not an independent variational dual. They are universal proof functions, not a hidden selector supplied to an executed experiment.

Use any one of the finite signatures of Theorem 7.2, with rational instrument data. Write its objective as  $F(q) = \max_{1 \leq i \leq m} f_i(q)$ , where  $f_i$  are all its marked event discrepancies, including the empty event  $f_1 = 0$ . For visible selectors the event and feedback rule include their selector

fibers, and the target selector law remains in  $f_i$ . Thus  $-1 \leq f_i \leq 1$  for all three signatures; the polynomials may be different.

Parameterize a row with  $d$  outcomes by  $d - 1$  variables in  $[0, 1]$ :

$$q_1 = x_1, \quad q_j = x_j \prod_{l < j} (1 - x_l) \quad (1 < j < d), \quad q_d = \prod_{l < d} (1 - x_l).$$

This map is onto the row simplex, including its boundary. Indeed, divide each desired probability by the remaining mass while that mass is positive; when it is zero choose the remaining variables arbitrarily. Taking the product of these maps, including a selector row when needed, gives an onto polynomial map  $q(x)$  from  $[0, 1]^D$  to the feasible row product. Put  $h_i(x) = f_i(q(x))$  and  $g_i = (1 + h_i)/2$ . All  $h_i$  are rational polynomials,  $0 \leq g_i \leq 1$ , and  $g_1 = 1/2$ . The case  $D = 0$  is a single feasible table and is interpreted directly.

**Theorem 20.1** (Strict polynomial lower-certificate hierarchy). *For  $p \geq 1$  define*

$$A_p(x) = \frac{\sum_{i=1}^m g_i(x)^p h_i(x)}{\sum_{i=1}^m g_i(x)^p}, \quad a_p = \min_{x \in [0, 1]^D} A_p(x), \quad \delta = \min_q F(q).$$

*Then the denominators are positive,  $a_p$  is nondecreasing, and*

$$\delta - 2(1 - m^{-1/(p+1)}) \leq a_p \leq \delta, \quad \delta = \sup_{p \geq 1} a_p. \quad (20.1)$$

*For rational  $L$  let*

$$P_{p,L}(x) = \sum_{i=1}^m g_i(x)^p (h_i(x) - L). \quad (20.2)$$

*A nonnegative tensor Bernstein expansion of  $P_{p,L}$  on  $[0, 1]^D$  certifies  $\delta \geq L$ . If  $L < \delta$ , some  $p$  and some finite Bernstein degree have strictly positive coefficients. Conversely, a strictly positive such expansion certifies  $L < \delta$ . These are lower certificates at the original state and selector budgets. No convexification of the feasible behavior image occurs.*

*Proof.* Fix  $x$  and put  $b = \max_i g_i(x) \geq 1/2$  and  $r_i = g_i(x)/b$ . At least one  $r_i$  is one. Write  $S_j = \sum_i r_i^j$ . Hölder's inequality gives

$$S_p \leq m^{1/(p+1)} S_{p+1}^{p/(p+1)}, \quad S_{p+1} \geq 1.$$

Consequently  $S_{p+1}/S_p \geq m^{-1/(p+1)}$ . Since  $A_p = 2bS_{p+1}/S_p - 1$  and  $\max_i h_i = 2b - 1$ ,

$$0 \leq \max_i h_i - A_p \leq 2(1 - m^{-1/(p+1)}).$$

Cauchy-Schwarz gives  $S_{p+2}S_p \geq S_{p+1}^2$ , so  $A_p$  is nondecreasing in  $p$ . Its denominator is at least  $2^{-p}$  and it is continuous on the cube. Taking minima proves (20.1). The bound is also at most  $2 \log m/(p+1)$ , by  $1 - e^{-u} \leq u$ .

Every tensor Bernstein basis function is nonnegative on the cube, and the basis functions sum to one. Nonnegative coefficients therefore imply  $P_{p,L} \geq 0$ . Dividing by the positive denominator gives  $F(q(x)) \geq A_p(x) \geq L$  for every  $x$ , which proves soundness. For completeness choose  $p$  so that the error in (20.1) is less than  $\delta - L$ . Then

$$P_{p,L}(x) \geq 2^{-p} \{\delta - L - 2(1 - m^{-1/(p+1)})\} > 0.$$

Lemma 20.2 below gives a finite strictly positive Bernstein expansion. Conversely strictly positive coefficients have a positive minimum, and the denominator is at most  $m$ , so they give a strict positive uniform gap above  $L$ .  $\square$

Positive Bernstein certificates and their degree elevation are classical; see de Klerk-Laurent [20]. The next elementary bound is retained for a self-contained exact verifier, not as a new general hypercube positivity theorem.

**Lemma 20.2** (An explicit positivity degree). *Let  $P(x) = \sum_k c_k x^k$  be a rational polynomial in  $D$  variables and  $n \geq \max_{k,j} k_j$ . In its tensor Bernstein expansion of degree  $n$  in each coordinate the coefficient at  $\alpha \in \{0, \dots, n\}^D$  is*

$$b_{\alpha,n} = \sum_k c_k \prod_{j=1}^D \frac{\binom{\alpha_j}{k_j}}{\binom{n}{k_j}}, \quad |b_{\alpha,n} - P(\alpha/n)| \leq \frac{C(P)}{n}, \quad C(P) = \sum_k |c_k| \sum_j \binom{k_j}{2}. \quad (20.3)$$

*In particular,  $\min P > 0$  implies positivity of every coefficient whenever  $n > C(P)/\min P$  and the degree restriction holds.*

*Proof.* For a binomial random variable  $B$  with parameters  $(n, x)$ ,  $\mathbb{E} \binom{B}{k} = \binom{n}{k} x^k$ . Expanding this expectation proves the univariate monomial formula, and products prove the displayed coefficient identity. The convention is  $\binom{a}{k} = 0$  for  $a < k$ . To compare  $\binom{a}{k}/\binom{n}{k}$  with  $(a/n)^k$ , draw  $k$  indices uniformly from  $\{1, \dots, n\}$ . Conditional on no repetition this is sampling without replacement. The probability of a repetition is at most  $\binom{k}{2}/n$ . Apply this total variation bound to the event that all drawn indices lie in a prescribed  $a$ -element subset. Hence the difference of the two factors is at most  $\binom{k}{2}/n$ . All factors lie in  $[0, 1]$ . A product telescoping bound followed by the triangle inequality proves (20.3). The final assertion follows by taking the minimum of  $P$ .  $\square$

**Corollary 20.3** (Rational lower witnesses without policy cells). *At every fixed finite rational signature, strict infeasibility above a rational level  $L$  is equivalent to the existence of the following finite rational certificate: an integer  $p$ , an integer  $n$ , and a strictly positive coefficient array for (20.2) whose identity is checked by (20.3). Dovetailing these certificates with rational original-budget upper witnesses produces nested intervals converging to  $\delta$ . If a subfamily of the original tests gives a strict gap, the same construction applies to it after adjoining the empty test.*

*Proof.* Soundness and completeness are Theorem 20.1. Each finite candidate is checked by rational polynomial arithmetic. Enumerate all  $(p, n)$  and rational levels, and retain the largest verified lower level so far, together with zero. Rational row tables are dense in the feasible product, and their continuous objectives converge to the minimum, so enumeration and retention of the best upper table converge from above. This is a dovetailed enumeration, not a claim that any fixed  $(p, n)$  test search terminates. For a requested positive interval width, convergence of both endpoints proves termination. The reduced family conclusion uses only the same pointwise maximum argument.  $\square$

*Remark 20.4* (Meaning and size of the strict certificate transform). A constant distribution on tests generally detects only the convex hull of the behavior image. The functions  $g_i^p / \sum_j g_j^p$  are instead functions of a proposed row table. Their universally quantified weighted inequality is an algebraic certificate; the tester need not observe a private state in an experiment. The displayed certificate identity is not an equality obtained by exchanging a private minimum with a fixed mixed test. Power means and Bernstein degree elevation are classical algebraic approximation devices, proved here in the precise form needed. The claim here is strict-level completeness for the original marked causal resource image, including visible selectors, and its physical transfer below. The coefficient count  $(n+1)^D$ , the number of original tests, and the algebraic degrees may be large. No polynomial complexity or intrinsic-dimension bound on this row-cube coefficient count is asserted. The independent adaptive test has the separate behavior-size bound of Theorem 21.3; its verification is a different cost.

**20.1. A sharp two-time nonconvex example.** The source has singleton reports, the control alphabet and actual mark are singleton, and the target emits  $(0, 0)$  or  $(1, 1)$  with probability  $1/2$  each. At width one, a private simulator emits two independent bits with probabilities  $p, q$ . It cannot reread its first emitted bit.

**Proposition 20.5** (A gap invisible to constant testing mixtures). *For this delayed experiment,*

$$\delta_{(1,1)}^p = \sqrt{2} - 1, \quad \delta_{(1,1),2}^h = 0, \quad \delta_{(1,1),r}^v = \sqrt{2} - 1 \quad (r \geq 1).$$

*The private objective is the maximum of the four polynomials*

$$0, \quad \frac{1}{2} - pq, \quad \frac{1}{2} - (1-p)(1-q), \quad p + q - 2pq.$$

*Every constant mixture of these tests has minimum at most zero, whereas Corollary 20.3 certifies every rational  $L < \sqrt{2} - 1$  at private width one.*

*Proof.* Put  $u = pq$  and  $v = (1-p)(1-q)$ . Direct total variation calculation gives  $F = 1 - \min(u, 1/2) - \min(v, 1/2)$  and the displayed maximum. By Cauchy–Schwarz,  $\sqrt{u} + \sqrt{v} \leq 1$ . If  $u \geq 1/2$ , then  $v \leq (1 - 1/\sqrt{2})^2$ , so the sum of the two capped terms is at most  $2 - \sqrt{2}$ ; the case  $v \geq 1/2$  is symmetric. Otherwise set  $a = \sqrt{u}$ ,  $b = \sqrt{v}$ . On  $0 \leq a, b \leq 1/\sqrt{2}$ ,  $a + b \leq 1$ , the maximum of  $a^2 + b^2$  is at a vertex of this polygon and equals  $2 - \sqrt{2}$ . Equality is attained at  $p = q = 1/\sqrt{2}$ . A hidden fair bit selects the two deterministic constant sequences and exactly reproduces the target. If it is exposed, variation is averaged over the selector fibers; each fiber has error at least the private minimum, which is itself attainable without a selector. Finally the target lies in the convex hull of the two private deterministic behaviors. The average discrepancy of any fixed test mixture at those behaviors is zero, so at least one has discrepancy at most zero. The strict polynomial certificates therefore detect information lost by constant convex separation.  $\square$

## 21. ADAPTIVE TESTING ON THE OBSERVABLE BEHAVIOR IMAGE

The obstruction to linear randomization criteria at a fixed private register is the nonconvexity of the behavior image, not a failure of compactness. We give a variational formulation in which a test is an independent function of an observable candidate law. The construction does not give the simulator an extra random variable.

**21.1. The testing game.** Let  $B$  be a nonempty compact subset of a finite-dimensional affine space, and let  $f_1, \dots, f_m$  be affine real functions, including the zero function. Put

$$F(b) = \max_{i \leq m} f_i(b), \quad \delta = \min_{b \in B} F(b).$$

For the finite comparison problem of Section 7,  $b$  is the array of discrepancies between the simulated and target marked laws, indexed by parameters, feedback trees and transcripts;  $f_i$  ranges over their signed event evaluations. In the visible case the array includes the selector and its target weights. Thus the target coordinate is part of the array when those weights vary. Private, fixed-hidden and fixed-visible signatures each give their own compact set  $B$ . No convex hull is taken.

An *adaptive test* is a continuous map  $\kappa : B \rightarrow \Delta_m$ , chosen before a candidate  $b$ . Its score against that candidate is

$$G(b, \kappa) = \sum_i \kappa_i(b) f_i(b).$$

This is a verification game: the selected candidate law is revealed to the evaluator of the already chosen function  $\kappa$ . It is not a one-observation statistical test, and does not make an unavailable parameter or mark observable to a physical controller.

**Theorem 21.1** (Revealed-behavior adaptive representation). *For every such compact behavior image,*

$$\begin{aligned} \delta &= \sup_{\kappa \in C(B, \Delta_m)} \min_{b \in B} G(b, \kappa) \\ &= \min_{\mu \in \mathcal{P}(B)} \sup_{\kappa \in C(B, \Delta_m)} \int_B G(b, \kappa) d\mu(b). \end{aligned} \tag{21.1}$$

*The minimization over probability measures is attained. If Borel adaptive tests are allowed, the first supremum is attained as well. The continuous-test assertion is a supremum; continuous attainment is not needed or asserted.*

*Proof.* Fix  $\eta > 0$ . The sets  $U_i = \{b : f_i(b) > F(b) - \eta\}$  form an open cover of the compact metric space  $B$ . Choose a continuous partition of unity subordinate to this finite cover. The resulting test has  $F(b) - \eta < G(b, \kappa) \leq F(b)$  for all  $b$ . Consequently the first supremum equals  $\delta$ . The same uniform inequality shows, for every probability  $\mu$ ,

$$\sup_{\kappa} \int G(b, \kappa) d\mu(b) = \int F d\mu.$$

Its minimum is  $\delta$ , attained by a point mass at a minimizer of  $F$ . This also proves the displayed minimax exchange without an assumption that  $B$  is convex. Equivalently one can apply the usual compact-convex minimax theorem to  $\mathcal{P}(B)$  and the convex class of continuous tests, with the pairing  $\int G d\mu$ . Finally choose the smallest index attaining  $F(b)$ . Its level sets are Borel, and its indicator vector is a Borel test with score exactly  $F$ .  $\square$

The probability  $\mu$  here describes a lottery over *revealed candidate laws*. The score is  $\int G(b, \kappa) d\mu(b)$ , not  $G(\int b d\mu, \kappa)$ . Hiding the candidate and replacing it by its barycenter is a different game; in general it lowers the value. This distinction is essential for a finite persistent-state budget.

**21.2. A size bound in behavior dimension.** Factor out directions annihilated by every  $f_i - f_i(b_0)$ , so that on the resulting difference space

$$\|v\|_* = \max_i |f_i(b_0 + v) - f_i(b_0)|$$

is a norm. Denote its dimension by  $a$  and let  $R = \text{diam}_*(B)$ . All conclusions below are unaffected by this observable quotient. The case  $a = 0$  is a single constant comparison and requires one test. Suppose henceforth that  $a \geq 1$ , so  $R > 0$ .

**Lemma 21.2** (A bounded behavior chart). *There exist  $b_0 \in B$  and vectors  $v_j \in B - b_0$ ,  $1 \leq j \leq a$ , forming a basis, such that  $\|v_j\|_* \leq R$  and every  $b \in B$  has coordinates  $b = b_0 + \sum_j t_j v_j$  with  $|t_j| \leq 2$ . If  $B$  is a rational polynomial image of a product of simplexes, the points can be chosen rational and can be found effectively.*

*Proof.* Fix  $b_0 \in B$ . In any fixed coordinates on the difference space, let  $D_0 > 0$  be the maximum absolute determinant of  $a$  vectors in  $B - b_0$ . Compactness and spanning give existence and positivity. Choose a tuple with determinant greater than  $D_0/2$ . Replacing its  $j$ th vector by  $b - b_0$  multiplies the determinant by  $t_j$ ; maximality gives  $|t_j| < 2$ . The norm bound is the definition of  $R$ . For a rational polynomial image, take  $b_0$  at rational rows. Rational row images are dense. An affine basis can be found by enumerating rational images and testing rational determinants; the true affine span and the maximum determinant are semialgebraic data. Quantifier elimination decides whether a proposed nonzero determinant exceeds half the maximum. Density therefore makes the search terminate. This is an effectiveness assertion, not a bit-complexity bound for finding the chart.  $\square$

Set  $b(x) = b_0 + \sum_j (4x_j - 2)v_j$  and  $C = \{x \in [0, 1]^a : b(x) \in B\}$ . The ambient cube is a coordinate box, not an enlargement of the feasible behavior set. Write  $\ell_i(x) = f_i(b(x))$ . Then

$$|\ell_i(x) - \ell_i(y)| \leq 4R \sum_j |x_j - y_j|. \quad (21.2)$$

For  $n \geq 0$  let  $\beta_{\alpha,n}$  be the tensor Bernstein basis of coordinatewise degree  $n$ . A feasible coefficient array has  $c_{\alpha i} \geq 0$  and  $\sum_i c_{\alpha i} = 1$  for every  $\alpha \in \{0, \dots, n\}^a$ . It specifies the independent test

$$\kappa_i^c(x) = \sum_{\alpha} c_{\alpha i} \beta_{\alpha,n}(x).$$

Define

$$d_n = \max_c \min_{x \in C} \sum_{\alpha, i} c_{\alpha i} \beta_{\alpha,n}(x) \ell_i(x). \quad (21.3)$$

**Theorem 21.3** (Intrinsic adaptive degree and support bounds). *The maxima in (21.3) are attained and  $d_n \leq d_{n+1} \leq \delta$ . For  $n \geq 1$ ,*

$$0 \leq \delta - d_n \leq \frac{4Ra}{\sqrt{n}}. \quad (21.4)$$

*There is an array with at most  $(n+1)^a$  nonzero coefficients, all equal to one, whose minimum score is at least  $\delta - 4Ra/\sqrt{n}$ . Its test has coordinatewise degree  $n$ , and its score degree at most  $n+1$ . Furthermore*

$$d_n = \min_{\mu \in \mathcal{P}(C)} \sum_{\alpha} \max_i \int_C \beta_{\alpha,n}(x) \ell_i(x) d\mu(x), \quad (21.5)$$

*and a minimizing measure can be supported on at most  $(n+2)^a$  points. In particular a strict level  $L < \delta$  admits an adaptive test of positive uniform margin with  $n > (8Ra/(\delta - L))^2$  and at most  $(n+1)^a$  occupied coefficient entries. These bounds depend on the observable image and its metric, not on the number of stochastic rows in a realization.*

*Proof.* The coefficient space is a finite product of compact simplexes, and the minimum of a jointly continuous function over compact  $C$  is continuous in its coefficients. This proves attainment. Bernstein degree elevation replaces each coefficient by convex combinations of adjacent coefficients, preserving every simplex constraint and the represented function. It proves monotonicity. All scores are convex combinations of the  $\ell_i(x)$ , proving the upper bound by  $\delta$ .

At each grid point  $\alpha/n$  choose an index  $i_{\alpha}$  maximizing  $\ell_i$  there. The choice is made even at infeasible grid points; only the final score is minimized over  $C$ . Give that index coefficient one and the others zero. For fixed  $x$  let  $A_j$  be independent  $\text{Bin}(n, x_j)$  variables. If  $i_*$  maximizes at  $x$ ,

$$\begin{aligned} \max_i \ell_i(x) - \mathbb{E} \ell_{i_A}(x) &\leq \mathbb{E} \{ \ell_{i_*}(x) - \ell_{i_*}(A/n) + \ell_{i_A}(A/n) - \ell_{i_A}(x) \} \\ &\leq 8R \sum_j \mathbb{E} |A_j/n - x_j| \leq \frac{4Ra}{\sqrt{n}}. \end{aligned}$$

Here the omitted middle difference is nonpositive, and the last bound uses  $\text{Var}(A_j/n) \leq 1/(4n)$ . This proves the rate and the sparse coefficient assertion.

For the last formula replace the minimum over  $C$  by a minimum over  $\mathcal{P}(C)$ . The pairing is bilinear and continuous, and both feasible sets are compact convex, so the compact minimax theorem [18] exchanges the extrema. Optimizing each coefficient simplex gives (21.5). The integrands are polynomials of coordinatewise degree at most  $n+1$ . Preserve all monomial moments of that degree by Carathéodory's theorem. There are  $(n+2)^a$  monomials including the constant; their moment vectors lie in an affine hyperplane of dimension at most  $(n+2)^a - 1$ . A measure with at most  $(n+2)^a$  atoms therefore has exactly the same objective. The strict-margin assertion follows from the rate with error less than  $(\delta - L)/2$ .  $\square$

The score is a nonlinear function of behavior although each event functional is affine. This is the reason the measure in (21.5) cannot be replaced by its behavior barycenter. For  $n = 0$  it can:  $d_0$  is precisely the constant-test convex relaxation. In the two-time unmarked example of Proposition 20.5, the target belongs to the convex hull of private behaviors, so  $d_0 = 0$ , whereas  $\lim_n d_n = \sqrt{2} - 1$ . Thus the hierarchy recovers a gap which every constant test misses.

*Remark 21.4* (What the size bound measures). The bound counts the nonzero entries of the independent adaptive test and controls its behavior-coordinate degree. It does not bound the cost of verifying its minimum on the generally nonconvex set  $C$ , the bit lengths of a rational chart, or the size of a description of  $C$ . Distinct row presentations of the same metric behavior image satisfy the same existence bound, although their coefficient arrays need not coincide. For the private fixed-target law array one may use  $R \leq 1$  with the maximum total-variation metric. For the visible signed-discrepancy array the uniform bound  $R \leq 2$  is sufficient. The old row-cube positivity certificate is a separate verification engine, with its own coordinate-dependent complexity.

### 21.3. A three-weight certificate invisible to constant tests.

**Proposition 21.5** (A finite intrinsic nonlinear witness). *Consider a private width-one simulator producing two independent bits, with probabilities  $p, q$ , for the target which assigns probability  $1/2$  to each of 00, 11. Put  $u = pq$ ,  $v = (1-p)(1-q)$  and  $J(t) = 3t^2 - 2t^3$ . The three behavior-dependent weights*

$$\kappa_1 = J(v), \quad \kappa_2 = J(u), \quad \kappa_3 = 1 - J(u) - J(v)$$

*are nonnegative and sum to one. Against the event discrepancies  $1/2 - u, 1/2 - v, 1 - u - v$ , respectively, their score  $G$  satisfies*

$$G \geq \frac{2}{5} + \frac{9}{8960}. \quad (21.6)$$

*The certificate uses cubic weights in observable probabilities, a nine-term nonnegative derivative identity, and seventeen positive rational Bernstein coefficients in one variable. Every constant mixture of event discrepancies has minimum at most zero.*

*Proof.* We have  $u + v \leq 1$ . Since  $J$  is increasing on  $[0, 1]$  and  $J(1-t) = 1 - J(t)$ , the weights are feasible. Their score is

$$G = 1 - u - v + J(u)(u - 1/2) + J(v)(v - 1/2).$$

Set  $a = (p + q - 1)^2$  and  $b = (p - q)^2$ . Then  $a, b \geq 0$  and  $a + b \leq 1$ . Direct expansion gives

$$\begin{aligned} 64G &= 27 - 12a + 38a^2 - 20a^3 - a^4 + 36b - 60ab + 36a^2b + 4a^3b \\ &\quad + 6b^2 - 12ab^2 - 6a^2b^2 - 4b^3 + 4ab^3 - b^4. \end{aligned}$$

Let  $c = 1 - a - b$ . Another polynomial identity, valid when  $a + b + c = 1$ , is

$$\begin{aligned} 16\partial_b G &= 4a^3 + 6a^2c + 12ab^2 + 24abc + 12ac^2 \\ &\quad + 8b^3 + 30b^2c + 30bc^2 + 9c^3 \geq 0. \end{aligned}$$

Thus  $G(a, b) \geq G(a, 0)$ . The univariate polynomial

$$G(a, 0) - \frac{2}{5} = \frac{7}{320} - \frac{3}{16}a + \frac{19}{32}a^2 - \frac{5}{16}a^3 - \frac{1}{64}a^4$$

has degree-16 Bernstein coefficients  $z_k/349440$ , where

$$\begin{aligned} (z_0, \dots, z_{16}) &= (7644, 3549, 1183, 351, 855, 2494, 5064, 8358, \\ &\quad 12166, 16275, 20469, 24529, 28233, 31356, 33670, 34944, 34944). \end{aligned}$$

The Bernstein basis is nonnegative and sums to one. Its smallest coefficient is  $351/349440 = 9/8960$ , proving (21.6). All identities are rational polynomial identities; no numerical minimization is used. Finally the target is the barycenter of the two feasible deterministic laws 00 and 11. An affine mixture of signed event discrepancies has average zero at these two laws and hence minimum at most zero. The empty event supplies the reverse constant-test bound zero.  $\square$

For comparison, the affine weights  $v, u, 1 - u - v$  already give the smaller bound  $3/8$ , with the exact identity

$$G_{\text{affine}} - \frac{3}{8} = \frac{1}{2}(p - q)^2 + 2(p - 1/2)^2(q - 1/2)^2.$$

Neither certificate changes the private feasible set. The cubic certificate is an independent test chosen once for the whole behavior image, not a mixture chosen anew by an optimizer's unknown row values. Its evaluation does use the revealed behavior, as specified in the verification game. The 17-coefficient positivity check is classical; the distinction from constant tests is the behavior-dependent feasible weight family and its resource-sensitive minimum.

The infinite-dimensional representation above holds for continuous  $f_i$  on any compact metric space: its proof uses a partition of unity, not causal factorization. The measure minimum is attained at a Dirac mass at a minimizer of  $F$ . The finite-level polynomial theorem has a different content. It is an existence-size bound for revealed-law verification; the reset-audit theorem of Section 18 imposes an explicit finite-data restriction.

**21.4. Strict certificates and effective physical input.** Given rational finite instruments, a rational chart and the sparse array constructed above, its strict minimum can be certified by real quantifier elimination on the original row constraints. Alternatively, pull the score back through the original polynomial row map and certify its strict positivity using degree-elevated Bernstein coefficients. The pullback changes the verification degree and is not covered by the behavior-coordinate bound. Generic quantifier elimination also decides the exact finite semialgebraic boundary; this classical observation does not assert that a finite nonnegative Bernstein expansion exists at  $L = \delta$ .

**Proposition 21.6** (Uniform effective presentation input). *Suppose a single algorithm, on input  $j$ , returns rational finite instruments  $E_j, F_j$  and nonnegative rational error enclosures  $a_j, c_j$  for two-sided stateless marked feedback presentations of  $E, F$ . Suppose  $a_j + c_j \rightarrow 0$ . All alphabets, widths, selector laws and finite subroutines must be computable uniformly from  $j$  and the requested signature. Then, for every positive rational  $\eta$ , an algorithm returns a rational interval of width below  $\eta$  containing  $\delta_b(E, F)$  at the same signature.*

*Proof.* Enumerate  $j$  until  $a_j + c_j < \eta/8$ . This terminates without a known rate because the rational enclosures themselves tend to zero. For the selected finite problem, enumerate rational same-budget upper tables and strict rational lower certificates, dovetailing all finite checks; include the always valid lower bound zero. Compactness, density and strict completeness provide an interval of width below  $\eta/2$ . Enlarge it by  $a_j + c_j$  at both ends using stateless comparison. The enlarged width is below  $3\eta/4$ . Every enumeration and comparison is uniform by the hypotheses. A mere sequence of individually computable presentations without a uniform enumeration is not an input satisfying this proposition.  $\square$

## 22. AN EXACT ALGORITHM FOR THE OBSERVABLE CHART

The chart in Lemma 21.2 can be found without taking its dimension as an oracle. We state the input and output explicitly. Rational polynomials are encoded by finite lists of monomial exponent vectors and rational coefficients in reduced integer form. A product of simplexes is encoded by the number of entries in each row. Eliminating the last entry of every nontrivial row leaves a full-dimensional rational polytope  $\Omega \subset \mathbb{R}^r$ . Zero-dimensional factors are omitted.

**Proposition 22.1** (Effective observable quotient and pullback). *The input consists of the preceding simplex description, a rational polynomial map  $b : \Omega \rightarrow \mathbb{R}^N$ , and finitely many rational affine functionals  $f_i$  on  $\mathbb{R}^N$ . There is a terminating algorithm which returns its observable affine*

dimension  $a$ , a rational basis and coordinate map for the observable quotient, and, when  $a > 0$ , rational parameter points  $q_0, q_1, \dots, q_a$  with the following properties. With

$$z(q) = (f_i(b(q)) - f_i(b(q_0)))_i, \quad v_j = z(q_j),$$

the vectors  $v_j$  are a basis of the observable difference space, and all coordinates  $t(q)$  in that basis satisfy  $|t_j(q)| < 2$ . The output also contains the rational polynomial cube map  $x(q) = (t(q) + 2)/4$ , a rational upper bound for the observable diameter, and the exact pullback of any subsequently supplied rational polynomial in  $x$ . The algorithm outputs the universal determinant formula it has decided. It makes no polynomial-time or coefficient-height claim.

*Proof.* Choose a rational relative interior point  $q_0$  of the input simplexes. Expand the vector polynomial  $z(q)$  in the free row coordinates. Let  $V$  be the rational span of all its coefficient vectors, including its constant coefficient. This equals  $\text{span } z(\Omega)$ : a linear functional vanishes on  $z(\Omega)$  exactly when its polynomial vanishes on the nonempty interior of  $\Omega$ , hence identically, hence on every coefficient. Gaussian elimination therefore gives  $a = \dim V$  and a rational basis matrix  $U$ . Choosing independent rows gives a rational left inverse  $L$  with  $LU = I_a$ . Thus  $y(q) = Lz(q)$  provides exact quotient coordinates. If  $a = 0$ , all discrepancies are constant and no chart is required.

For  $a > 0$  let

$$D_0 = \max_{u_1, \dots, u_a \in \Omega} |\det(y(u_1), \dots, y(u_a))|.$$

Compactness gives a maximum, and spanning gives  $D_0 > 0$ . Enumerate rational tuples  $(q_1, \dots, q_a)$  in  $\Omega^a$ . Membership and their determinant  $d$  are decided by rational arithmetic. For  $d \neq 0$ , decide the first-order real formula

$$\forall u_1, \dots, u_a \in \Omega : \quad \det(y(u_1), \dots, y(u_a))^2 < 4d^2. \quad (22.1)$$

Quantifier elimination terminates for each formula. Density of rational points and continuity of determinant imply that some enumerated tuple has  $|d| > D_0/2$ . For such a tuple the strict formula is true, so the search terminates. No computation of an exact algebraic maximizer is needed.

Invert the rational matrix with columns  $y(q_j)$  to obtain  $t(q)$ . Cramer's rule and (22.1) give  $|t_j(q)| < 2$  for every  $q$ . In the observable norm  $\|z\|_* = \max_i |z_i|$ , each  $v_j$  has norm at most the diameter of  $z(\Omega)$ . An upper bound for that diameter can be produced, for example, by bounding each free coordinate in  $[0, 1]$  and summing the absolute polynomial coefficients for  $f_i(b(q)) - f_i(b(q'))$ . This bound is rational and computable. Rational matrix multiplication and substitution give  $x(q)$  and every requested pullback. They also give its full sparse coefficient encoding. All searches have now been specified by finite encodings and terminating operations.  $\square$

There is a small but important distinction between the quotient and a projection onto a smaller set of simulator rows. The former identifies exactly the directions invisible to the chosen event family; the original row constraints remain present in every universal positivity test. The chart need not identify equivalent tasks after a change of marks or of information signature. Those are changes to the comparison problem.

### 23. A MARKED RESOURCE GAP GENERATED BY A BINARY COLLISION

We now realize a private–hidden–visible separation in a physical experiment whose information vanishes when the collision is removed. The controller chooses a later sensor gate after its first report. The gate controls acquisition, not the mechanical collision law. Both the source and the target carry the same actual, unobserved mark.

**23.1. The exact marked two-report experiment.** Let  $B, W \in \{0, 1\}$  have the joint distribution

$$\mathbb{P}(B = b, W = w) = \begin{cases} 5/16, & b = w, \\ 3/16, & b \neq w. \end{cases} \quad (23.1)$$

The blind source  $E_*$  has two constant reports and actual mark  $W$ . The target  $F_*$  reports  $Y_1 = B$ , receives  $A \in \{0, 1\}$  after that report, and reports  $Y_2 = AB$ . The feedback tester may choose  $A$  as any function of its earlier report. A width-one private simulator cannot reread its own first emission, except through the current gate  $A$ . Hidden selectors persist but are not revealed; visible selectors are included in the joint target law independently of  $(B, W)$ . Put

$$d_* = \sqrt{5/2} - 9/8.$$

**Theorem 23.1** (An exact marked causal separation). *At the width profile  $(1, 1)$ ,*

$$\delta^P(E_*, F_*) = d_*, \quad \delta_2^h(E_*, F_*) = 1/8, \quad \delta_r^v(E_*, F_*) = d_* \quad (r \geq 1). \quad (23.2)$$

*The hidden upper bound is realized by two deterministic tables. The private upper bound is realized by two independent Bernoulli variables with parameter  $\sqrt{5/8}$ , followed by the gate. These bounds hold against every feedback rule, not just open-loop gates.*

*Proof.* First choose the constant gate  $A = 1$ . The two private emissions are independent Bernoulli variables with parameters  $p, q$  and are independent of  $W$ . Let

$$u = pq, \quad v = (1 - p)(1 - q), \quad a = 3/8, \quad b = 5/8.$$

The overlap of the target and simulated marked laws is  $H(u) + H(v)$ , where

$$H(t) = \frac{1}{2} \{\min(t, a) + \min(t, b)\}.$$

Indeed the target is supported on equal report pairs, and its two  $W$ -masses at each equal pair are  $3/16$  and  $5/16$ . Total variation is one minus this overlap.

Cauchy-Schwarz gives  $\sqrt{u} + \sqrt{v} \leq 1$ . By symmetry suppose  $u \geq v$ . If  $u \leq 1/4$  the overlap is at most  $1/2$ . If  $u \geq 1/4$ , then  $v \leq (1 - \sqrt{u})^2 \leq 1/4 < a$ , so the overlap is at most

$$H(u) + (1 - \sqrt{u})^2.$$

This function is convex on each of  $[1/4, a]$  and  $[a, b]$  and nonincreasing on  $[b, 1]$ . Its maximum is therefore attained at  $1/4, a$  or  $b$ . The values at  $a$  and  $b$  are  $1 + 2a - 2\sqrt{a}$  and  $3/2 + b - 2\sqrt{b}$  respectively. The second is larger, since

$$(3/2 + b - 2\sqrt{b}) - (1 + 2a - 2\sqrt{a}) = 3/8 - \frac{1/2}{\sqrt{a} + \sqrt{b}} > 0,$$

using  $\sqrt{a} > 3/5$ ,  $\sqrt{b} > 3/4$ . It also exceeds  $1/2$ . Taking  $p = q = \sqrt{b}$  attains this maximum, and hence the minimum error is  $1 - (3/2 + b - 2\sqrt{b}) = d_*$ .

For any hidden selector, the all-on report pair is still independent of  $W$ . If its probabilities of 11 and 00 are  $u, v$ , then  $u + v \leq 1$ . Concavity and monotonicity of  $H$  give

$$H(u) + H(v) \leq 2H((u + v)/2) \leq 2H(1/2) = 7/8.$$

A fair hidden bit  $J$ , emitting  $J$  twice, attains this overlap. This requires precisely two deterministic selector tables and gives error  $1/8$ . In particular hiding a seed does not erase the actual-mark obstruction.

These all-on bounds are lower bounds for the feedback problem. For the upper bounds first generate the corresponding all-on pair  $(X_1, X_2)$ , emit  $X_1$ , and after receiving  $A$  emit  $AX_2$ . For a deterministic feedback  $A = g(X_1)$  the full gated marked transcript is the pushforward of the all-on marked pair. Applying the same map to the target pair cannot increase total variation. The construction is executable at width one: the second fresh Bernoulli variable is independent in the

private case, and the bit  $J$  is the priced persistent hidden selector in the hidden case. Randomized feedback follows by conditioning on its independent random table.

Finally, in the visible case the two compared laws are

$$\sum_j \lambda_j \delta_j \otimes P_{g_j}^{q_j} \quad \text{and} \quad \sum_j \lambda_j \delta_j \otimes Q_{g_j}.$$

The target selector is independent of  $(B, W)$ . The all-on gate in every fiber has error at least  $d_*$  in every private fiber. Joint variation is the weighted sum of these fiber errors. Ignoring the visible selector and using the private optimizer attains  $d_*$ .  $\square$

**23.2. A full-dimensional collision preparation.** Consider two labeled equal-mass hard spheres in  $\mathbb{R}^3$  with contact distance  $d$ . The center of mass  $Q = (q_1 + q_2)/2$  ranges over any fixed rational position box. Write  $r = q_1 - q_2$ ,  $g = v_1 - v_2$ , and  $V = (v_1 + v_2)/2$ . Conditional on  $(B, W)$  in (23.1), take the uniform product preparation on

$$\begin{aligned} r &= (-a_0, (2B - 1)b_0, c_0), \quad a_0 \in [29/10, 31/10], & b_0 &\in [9/20, 11/20], & (23.3) \\ |c_0| &\leq 1/100, & g_x &\in [19/10, 21/10], & |g_y|, |g_z| &\leq 1/100, \\ |V_x|, |V_y| &\leq 1/100, & |V_z - (2W - 1)| &\leq 1/100. \end{aligned}$$

The boxes have positive volume in the full phase space. The actual mark is  $W = \mathbf{1}_{\{V_z > 0\}}$ ; total momentum conservation retains it. The informative quantity will instead be the transverse velocity created at a collision. Put

$$h(z) = \text{sgn}(z) \min\{1, (|z| - 1/4)_+\}.$$

This is a bounded 1-Lipschitz detector which is identically zero on the incoming transverse-velocity range.

**Lemma 23.2** (Uniform transverse collision signal). *For every preparation in (23.3) and every  $d \in [9/10, 11/10]$ , exactly one collision occurs before time 3. Its time  $t_c$  lies in  $(4/5, 3/2)$ , and afterwards*

$$(2B - 1)v_{1,y} > 1/2, \quad (2B - 1)h(v_{1,y}) > 1/4. \quad (23.4)$$

For  $0 < d \leq 2/5$  no collision occurs before time 3, and the detector is zero throughout that interval.

*Proof.* Up to a collision  $r(t) = r + tg$ . For  $t \leq 4/5$ , its  $x$  coordinate is at most  $-29/10 + (4/5)(21/10) = -61/50$ , so its norm exceeds  $11/10$ . At time  $3/2$  the absolute coordinate bounds are  $1/4$ ,  $113/200$  and  $1/40$ , whose squared sum is less than  $(9/10)^2$ . Thus a first contact occurs in the stated interval. At the free zero of the  $x$  coordinate, whose time is at most  $31/19$ , the transverse norm is less than  $9/10$  as well. The first contact therefore has  $n_x < 0$ , where  $n = r(t_c)/d$ . The entry contact is strictly incoming. The bounds above give

$$|n_x|^2 \geq 1 - \frac{(113/200)^2 + (1/40)^2}{(9/10)^2} > (77/100)^2, \quad (2B - 1)n_y \geq \frac{87}{220}.$$

It follows that  $-g \cdot n > (19/10)(77/100) - 2/100 = 1443/1000$ . The equal-mass elastic collision rule is

$$v'_1 = V + g/2 - (g \cdot n)n, \quad g' = g - 2(g \cdot n)n.$$

Consequently

$$(2B - 1)v'_{1,y} > -3/200 + \frac{1443}{1000} \frac{87}{220} > 1/2.$$

The relative velocity is outgoing,  $r(t_c) \cdot g' > 0$ , so the squared separation increases strictly for all later times. There are only two spheres and no walls; no second collision is possible. This proves (23.4). For  $d \leq 2/5$  and  $0 \leq t \leq 3$ ,  $|(r + tg)_y| \geq 9/20 - 3/100 = 21/50 > d$ . Thus there is no collision. The incoming  $|v_{1,y}| \leq 3/200$  then makes  $h$  zero.  $\square$

At time 2 the physical target  $F_{d,\sigma}$  reports

$$Y_1 = \mathbf{1}_{\{h(v_{1,y}(2)) + \sigma\xi_1 > 0\}}.$$

It then receives a gate  $A \in \{0, 1\}$ , and at time 3 reports

$$Y_2 = A\mathbf{1}_{\{h(v_{1,y}(3)) + \sigma\xi_2 > 0\}},$$

where the  $\xi_i$  are independent standard normal variables, independent of the preparation. The source  $E_d$  has the same preparation, evolution, control interface and actual mark, but emits two constant reports. The gates do not change the particle motion. This is a feedback acquisition experiment: taking  $A = 0$  suppresses later information and taking  $A = 1$  exposes another noisy observation of a collision-generated quantity.

**Theorem 23.3** (Collision-sensitive physical resource separation). *Let  $d \in [9/10, 11/10]$  and  $0 < \sigma \leq 1/12$ . At retained width  $(1, 1)$  the physical deficiencies obey, uniformly in  $d$ ,*

$$\begin{aligned} |\delta^p(E_d, F_{d,\sigma}) - d_*| &< 1/300, & |\delta_r^y(E_d, F_{d,\sigma}) - d_*| &< 1/300 \quad (r \geq 1), \\ |\delta_2^h(E_d, F_{d,\sigma}) - 1/8| &< 1/300. \end{aligned} \quad (23.5)$$

*In particular private and visible error exceed  $9/20$ , while hidden two-selector error is less than  $13/100$ . More generally the errors in these three comparisons are at most  $2\Phi(-1/(4\sigma))$ , which tends to zero as  $\sigma \downarrow 0$ . For  $0 < d \leq 2/5$  all three deficiencies are zero. The interacting and noninteracting regimes use the same preparation and detector. The conclusions are unchanged by simultaneously scaling positions, diameter and observation times by any positive factor, with velocities and detector noise unchanged.*

*Proof.* Couple the ideal and physical target by the same  $(B, W)$  and the same feedback random table. Lemma 23.2 bounds each potential bit error by  $\Phi(-1/(4\sigma))$ . With probability at least  $1 - 2\Phi(-1/(4\sigma))$  both potential reports agree with their ideal bits; the gates and all emitted transcripts then agree as well. This gives a marked feedback variation bound uniform over all gates. The channels in both directions are the identity on the binary report alphabet and have one retained state. The blind source is already exactly  $E_*$ . Stateless comparison therefore changes each fixed-budget deficiency by at most the stated error, without adding memory or hiding an exposed selector.

For completeness, the elementary Gaussian tail bound  $\Phi(-x) \leq e^{-x^2/2}/(x\sqrt{2\pi})$  at  $x = 3$  gives  $\Phi(-3) < 1/600$ : use  $e^{9/2} > 80$  and  $\sqrt{2\pi} > 5/2$ . Hence the total error is below  $1/300$ . The inequalities  $d_* - 1/300 > 9/20$  and  $1/8 + 1/300 < 13/100$  follow by squaring positive rational bounds.

When  $d \leq 2/5$ , both potential reports are independent fair noise bits and are independent of  $W$ . A private width-one simulator draws those two bits and applies the current gate, exactly reproducing every feedback transcript. Hidden and visible versions can ignore their selectors. Finally elastic scattering is invariant under  $(q, d, t) \mapsto (sq, sd, st)$  with  $v$  unchanged. This proves the scaling statement; it is geometric similarity, not a particle-number or Boltzmann–Grad limit.  $\square$

The theorem combines three effects. Collisions create the sign of the informative transverse velocity. A gate chosen after the first report changes future information. A retained hidden bit, but not a visible one, permits temporal correlation without charging the width-one register. The actual mark remains partially inaccessible in every signature. The conserved longitudinal momentum labels that mark; it does not generate the observed transverse signal.

**23.3. Uniformly effective finite presentations.** The binary physical interface is already finite, but its probabilities are not generally rational. We make their effective approximation explicit rather than treating individual computability as a uniform algorithm.

**Proposition 23.4** (Collision-chart rational presentations). *For computable  $d \in [9/10, 11/10]$  and  $\sigma > 0$ , one algorithm produces rational marked causal instruments and certified two-sided stateless errors tending to zero for  $(E_d, F_{d,\sigma})$ . On a compact computable parameter interval with  $\sigma \geq \sigma_0 > 0$ , the errors and the construction are uniform. Thus Proposition 21.6 applies at every fixed finite state and selector signature, not only at  $(1, 1)$ .*

*Proof.* On every preparation box the entry time and outgoing velocity are

$$t_c = \frac{-r \cdot g - \sqrt{(r \cdot g)^2 - |g|^2(|r|^2 - d^2)}}{|g|^2}, \quad n = (r + t_c g)/d, \quad v'_1 = V + g/2 - (g \cdot n)n.$$

The positive square root is separated from zero: it equals  $-d(g \cdot n) > (9/10)(1443/1000)$ . All denominators are likewise bounded away from zero. These explicit bounds and the compact boxes allow interval differentiation of the displayed formulas, producing a rational common Lipschitz upper bound  $C_{\text{geo}}$  for  $v'_{1,y}$  in the packet variables and  $d$ . This computation terminates because only addition, multiplication, division by separated positive quantities and a separated square root occur.

Conditional on the microscopic preparation the two potential all-on bits are independent Bernoulli with probability  $p = \Phi(h(v'_{1,y})/\sigma)$ . Their four probabilities are  $p^2$ ,  $p(1-p)$ ,  $p(1-p)$  and  $(1-p)^2$ . The normal distribution function is uniformly computable on bounded intervals, for example by integrating its convergent exponential series with a remainder bound. Its Lipschitz constant is less than one. Together with the 1-Lipschitz detector and the geometric bound, this yields a computable Lipschitz constant at most  $2C_{\text{geo}}/\sigma_0$  for these four integrands on fixed-noise compact parameter sets. Equal-box Riemann sums of mesh  $h$  therefore have explicit error at most a computable constant times  $h$ , plus the chosen rational evaluation error. Parameter uncertainty is included by its interval enclosure.

Integrate the four all-on probabilities separately on each packet, with the exact rational weights (23.1). For each  $W$ , round its conditional probability vector to a rational simplex point on a sufficiently fine grid; the rounding error is bounded by the sum of the coordinate errors and the grid mesh. Keep  $\mathbb{P}(W = 0) = \mathbb{P}(W = 1) = 1/2$  exact. Sample this finite joint law once at initialization, emit its first bit, and gate its second bit. This is a finite latent realization of the target instrument, not a simulator with extra free state. It makes every causal prefix consistent and never divides by a possibly small prefix probability. Every gated law is a pushforward of the all-on law, so the same marked variation bound holds uniformly under feedback. Identity report channels give both stateless directions. Choosing summable evaluation and mesh errors produces the asserted uniform sequence.  $\square$

## 24. UNIFORM STABILITY OF OPTIONAL PROJECTIONS

Marked comparison controls more than terminal bounded risk when the compared laws share their latent variable. We prove a whole-process estimate for the resulting posterior martingales. The distinction between a probabilistic coupling and an executable causal channel is important in this section.

Let  $Z$  take values in a standard Borel space and let  $Y$  take values in a standard Borel canonical path space on  $[0, T]$ , with a right-continuous observation filtration. Consider equivalent joint probability measures  $P, Q$  on  $(Z, Y)$ , with the same  $Z$ -marginal  $\nu$ . Use the usual completions, which agree for equivalent output laws. For a bounded measurable latent variable  $f(Z)$  write

$$M_t^P = \mathbb{E}_P[f(Z) \mid \mathcal{F}_t^Y], \quad M_t^Q = \mathbb{E}_Q[f(Z) \mid \mathcal{F}_t^Y].$$

Take their right-continuous martingale versions. All suprema below include  $T$  and can be evaluated on a countable dense time set.

**Theorem 24.1** (Marked variation controls the whole posterior process). *Let  $\varepsilon = \|P - Q\|_{\text{TV}}$  and  $|f| \leq 1$ . When both posterior functions are evaluated on the same canonical output path,*

$$\mathbb{E}_Q \sup_{t \leq T} |M_t^P(Y) - M_t^Q(Y)|^2 \leq 80\varepsilon. \quad (24.1)$$

*There is a coupling of  $(Z, Y^P)$  and  $(Z, Y^Q)$  which retains exactly the same latent variable and satisfies*

$$\mathbb{P}(Y^P \neq Y^Q) \leq \varepsilon, \quad \mathbb{E} \sup_{t \leq T} |M_t^P(Y^P) - M_t^Q(Y^Q)|^2 \leq 84\varepsilon. \quad (24.2)$$

*The coupling is not asserted to be causal or to have finite state. The variation bound itself, not this coupling, is used for resource transport.*

*Proof.* Let  $D = dP/dQ$ ,  $D_t = \mathbb{E}_Q[D \mid \mathcal{F}_t^Y]$ , and set

$$A_t = \mathbb{E}_Q[(D - 1)f \mid \mathcal{F}_t^Y], \quad B_t = D_t - 1.$$

Bayes' formula gives

$$M_t^P - M_t^Q = \frac{A_t - B_t M_t^Q}{1 + B_t}.$$

Since  $\mathbb{E}_Q|D - 1| = 2\varepsilon$ , both martingales  $A, B$  have terminal absolute expectation at most  $2\varepsilon$ . Doob's weak  $L^1$  inequality gives, for  $0 < u \leq 2$ ,

$$\begin{aligned} Q\{\sup_t |M_t^P - M_t^Q| > u\} &\leq Q\{\sup_t |B_t| > 1/2\} + Q\{\sup_t |A_t| > u/4\} + Q\{\sup_t |B_t| > u/4\} \\ &\leq 4\varepsilon + 16\varepsilon/u. \end{aligned}$$

Integrating  $2u$  times this bound on  $(0, 2)$  gives  $16\varepsilon + 64\varepsilon = 80\varepsilon$ , proving (24.1). No tightness conclusion is being inferred from finite-dimensional convergence.

Disintegrate both joint laws over their common latent marginal. Measurable maximal coupling of the two output kernels, conditional on  $Z$ , has disagreement probability

$$\int \|P(dy \mid z) - Q(dy \mid z)\|_{\text{TV}} d\nu(z) = \|P - Q\|_{\text{TV}}.$$

Such a coupling can be constructed by using the minimum of the two kernel densities with respect to their sum, then their residual kernels. It is measurable on standard Borel spaces. On the event of identical full output paths use (24.1) with the  $Q$ -marginal; on its complement the squared difference is at most four. This proves (24.2). The maximal coupling may depend on the full output path; it has no asserted online implementation.  $\square$

**Corollary 24.2** (Changing-filtration convergence from marked comparison). *Let  $P_n$  and  $P$  be equivalent joint laws with the same latent marginal  $\nu$ , and  $\|P_n - P\|_{\text{TV}} \rightarrow 0$ . They admit a common probability-space realization  $(Z, Y, Y^1, Y^2, \dots)$  such that, for every  $f \in L^2(\nu)$ ,*

$$\mathbb{E} \sup_{t \leq T} \left| \mathbb{E}[f(Z) \mid \mathcal{F}_t^{Y^n}] - \mathbb{E}[f(Z) \mid \mathcal{F}_t^Y] \right|^2 \rightarrow 0.$$

*The same realization gives convergence uniformly in time in probability for  $f \in L^1(\nu)$ . It also permits  $f_n \rightarrow f$  in  $L^2(\nu)$ , respectively in  $L^1(\nu)$ , in the first conditional expectation.*

*Proof.* Glue the conditional maximal couplings of  $(Z, Y^n)$  with the fixed reference  $(Z, Y)$  by taking their conditional kernels independently on a countable product. The coupling does not depend on  $f$ . For the truncation  $f^{(K)} = (-K) \vee (f \wedge K)$ , Theorem 24.1 bounds the middle difference in the  $L^2$  norm of the supremum by  $K\sqrt{84\varepsilon_n}$ . Doob's  $L^2$  inequality bounds each truncation tail by  $2\|f - f^{(K)}\|_{L^2(\nu)}$ . The triangle inequality therefore gives

$$\left\| \sup_t |M_t^{P_n, f} - M_t^{P, f}| \right\|_2 \leq 4\|f - f^{(K)}\|_2 + K\sqrt{84\varepsilon_n}.$$

First let  $n \rightarrow \infty$ , then  $K \rightarrow \infty$ . For  $L^1$  use instead the weak maximal inequality for each tail and the bounded-case estimate for the middle term. An additional difference  $f_n - f$  is handled by the same maximal inequalities under  $P_n$ , whose latent marginal remains  $\nu$ .  $\square$

**24.1. A microscopic sufficient condition.** Let  $(\Phi_t)_{t \in \mathbb{R}}$  be an almost-everywhere regular hard-sphere flow on a labeled phase space, with invariant probability  $\mu$ . Fix a prepared law  $\nu$  with  $d\nu/d\mu \leq C$ , and bounded real observables  $h, h_n$ . These may be collision-sensitive tagged observables. Put  $\eta_n = \|h_n - h\|_{L^2(\mu)}$ . With a common latent initial state  $Z \sim \nu$ , consider the continuous observation laws

$$\begin{aligned} Y_t &= \int_0^t h(\Phi_s Z) ds + \sigma B_t, \\ Y_t^n &= \int_0^t h_n(\Phi_s Z) ds + \sigma B_t^n, \quad \sigma > 0, \end{aligned}$$

where the Brownian noise is independent of  $Z$  in each model. The notation does not prescribe a synchronous coupling.

**Theorem 24.3** (Fixed-flow observation-approximation limit). *The joint latent-output laws are equivalent and satisfy*

$$\|P_n - P\|_{\text{TV}} \leq \frac{\sqrt{CT}}{2\sigma} \eta_n. \quad (24.3)$$

For every  $|f(Z)| \leq 1$  they admit a latent-preserving coupling with

$$\mathbb{E} \sup_{t \leq T} |M_t^{P_n, f} - M_t^{P, f}|^2 \leq \frac{42\sqrt{CT}}{\sigma} \eta_n. \quad (24.4)$$

In particular  $\eta_n \rightarrow 0$  supplies whole-process optional-projection convergence, not merely convergence at finitely many times. This applies when  $h_n$  are orbit-mollified graph-core approximants to any bounded  $h \in L^2(\mu)$ .

*Proof.* Conditional on  $Z$ , the signals are deterministic bounded drifts. The exponential change-of-measure identity for Brownian motion gives

$$D_{\text{KL}}(P_n \| P) = \frac{1}{2\sigma^2} \mathbb{E}_\nu \int_0^T |(h_n - h)(\Phi_s Z)|^2 ds \leq \frac{CT}{2\sigma^2} \eta_n^2.$$

The last inequality uses  $\nu \leq C\mu$  and invariance of  $\mu$ ; it does not require mixing, differentiability across a collision, or a claim that a tagged velocity belongs to the generator domain. Bounded drifts ensure equivalence and justify the exponential identity. Pinsker's inequality gives (24.3). Applying Theorem 24.1 proves (24.4).

For the last assertion choose a nonnegative smooth approximate identity  $\rho_n$  on the time line and set  $h_n = \int \rho_n(s) h \circ \Phi_s ds$ . Strong continuity of the Koopman group in  $L^2(\mu)$  gives  $\eta_n \rightarrow 0$  and  $\|h_n\|_\infty \leq \|h\|_\infty$ . Repeated integration by parts puts  $h_n$  in every power domain of the generator, with derivatives obtained from  $\rho_n^{(k)}$ . This is the orbit-core construction already used in the microscopic domain theory; the new conclusion is the uniform posterior estimate.  $\square$

Sampling these observation paths at finitely many checkpoints and applying a common causal output postprocessing are contractions in marked variation. Thus the identity report comparison transfers every bounded finite-register risk at its original state and selector budgets with error bounded by (24.3). That is the resource-comparison consequence. The latent-preserving coupling in (24.4) has a different role: it realizes convergence of the changing observation filtrations and is not used as a finite-register simulator.

The theorem discharges a sufficient conditional-law hypothesis for optional projection in a genuine microscopic observation class. The constants depend on the fixed preparation, time

and noise level. No particle-uniform kinetic estimate, changing microscopic path limit, limiting stochastic-exponential identification or nonlinear BSDE limit is implied without its additional hypotheses. The whole-process estimate is what replaces an unsupported appeal to Doob's inequality as a tightness argument.

## 25. CHANGING TRAJECTORIES, LIKELIHOODS, AND CONDITIONAL CONSUMERS

**25.1. A common preparation, not a common flow.** Let  $(\mathcal{Z}, \nu)$  be a standard Borel probability space, and let  $H, H_n : [0, T] \times \mathcal{Z} \rightarrow \mathbb{R}$  be jointly measurable, with  $|H|, |H_n| \leq M$ . They may be observations of different flows on different phase spaces, pulled back by specified preparation maps from  $\mathcal{Z}$ . No common microscopic generator or invariant measure is assumed. Set

$$\eta_n^2 = \int_{\mathcal{Z}} \int_0^T |H_n(t, z) - H(t, z)|^2 dt d\nu(z).$$

On  $\mathcal{Z} \times C([0, T])$  let  $R$  be the law of independent  $Z \sim \nu$  and  $Y = \sigma B$ , where  $\sigma > 0$ . Define

$$L_t^n = \exp \left\{ \frac{1}{\sigma} \int_0^t H_n(s, Z) dB_s - \frac{1}{2\sigma^2} \int_0^t H_n(s, Z)^2 ds \right\}, \quad (25.1)$$

$$dP_n = L_T^n dR. \quad (25.2)$$

The reference model  $P, L$  uses  $H$ . Conditional on  $Z$ , these are Gaussian shifts, so under  $P_n$  the observed path has law  $Y_t = \int_0^t H_n(s, Z) ds + \sigma B_t^n$ . Boundedness gives true strictly positive density martingales. Write  $\mathcal{F}_t$  for the usual canonical observation filtration and  $\mathcal{H}_t = \sigma(Z, B_s : s \leq t)$  for the larger reference filtration. Equivalent laws have the same completed observation stopping times.

**Theorem 25.1** (Likelihood and posterior transport for changing paths). *The measures  $P_n, P, R$  are equivalent and have common  $Z$ -marginal  $\nu$ . With  $A = M^2 T / \sigma^2$  and  $\varepsilon_n = \min\{1, \eta_n / (2\sigma)\}$ , one has*

$$\|P_n - P\|_{\text{TV}} \leq \varepsilon_n, \quad (25.3)$$

$$\mathbb{E}_R \sup_{t \leq T} |L_t^n - L_t|^2 \leq \frac{8}{\sigma^2} e^{3A} \eta_n^2. \quad (25.4)$$

For  $|f(Z)| \leq K$  put

$$N_t^{n,f} = \mathbb{E}_R[L_T^n f(Z) \mid \mathcal{F}_t], \quad \ell_t^n = N_t^{n,1}.$$

Then

$$\mathbb{E}_R \sup_t |N_t^{n,f} - N_t^f|^2 \leq \frac{8K^2}{\sigma^2} e^{3A} \eta_n^2. \quad (25.5)$$

In particular this applies to the projected likelihood  $\ell^n$ . For every  $|f| \leq 1$ , the posterior functions satisfy the same-path bound  $80\varepsilon_n$  of Theorem 24.1, and there is one latent-preserving coupling, independent of  $f$ , on which

$$\mathbb{E} \sup_t |\mathbb{E}_{P_n}[f(Z) \mid \mathcal{F}_t^{Y^n}] - \mathbb{E}_P[f(Z) \mid \mathcal{F}_t^Y]|^2 \leq 84\varepsilon_n. \quad (25.6)$$

If  $\eta_n \rightarrow 0$  and deterministic microscopic paths  $X_n(Z) \rightarrow X(Z)$  in a specified Polish path metric in  $\nu$ -probability, then on this coupling the microscopic paths, the full and projected likelihood processes evaluated on their own observation paths, and each bounded posterior process converge jointly in probability in that metric and uniformly in time for the last three coordinates.

*Proof.* Conditional Gaussian change of measure gives

$$\text{KL}(P_n \| P) = \frac{1}{2\sigma^2} \mathbb{E}_\nu \int_0^T |H_n - H|^2 dt = \frac{\eta_n^2}{2\sigma^2}.$$

The same calculation proves conditional equivalence, and the conditional density has mean one, so the preparation marginal is unchanged. Integrating and applying Pinsker proves (25.3).

For the quantitative density estimate, condition first on  $Z = z$  and write  $D_t = L_t^n - L_t$ . The stochastic differential equation is

$$dD_t = \sigma^{-1}\{D_t H_n(t, z) + L_t(H_n - H)(t, z)\} dB_t.$$

The conditional second moment of  $L_t$  is at most  $e^A$ . Itô's isometry and  $(u + v)^2 \leq 2u^2 + 2v^2$  therefore imply

$$\mathbb{E}_R[D_t^2 | z] \leq \frac{2M^2}{\sigma^2} \int_0^t \mathbb{E}_R[D_s^2 | z] ds + \frac{2e^A}{\sigma^2} \int_0^t |H_n - H|^2(s, z) ds.$$

Gronwall, followed by integration in  $z$ , gives  $\mathbb{E}_R D_T^2 \leq (2/\sigma^2) e^{3A} \eta_n^2$ . The difference is a square-integrable  $\mathcal{H}_t$ -martingale. Doob's  $L^2$  inequality proves (25.4). Applying the same maximal inequality to the  $\mathcal{F}_t$ -martingale  $\mathbb{E}_R[(L_T^n - L_T)f | \mathcal{F}_t]$  proves (25.5). These are direct process estimates, not a claim that finite-dimensional convergence alone implies tightness.

The posterior assertions follow from Theorem 24.1 and its countable conditional-coupling construction. For the last claim, on the event  $Y^n = Y$  the two likelihood functions are evaluated on the same  $(Z, Y)$ . Their uniform difference tends to zero in  $R$ -probability by the estimates just proved, and therefore in  $P$ -probability by absolute continuity of the fixed  $P$  with respect to  $R$ . The complementary event has probability at most  $\varepsilon_n$ . The same argument applies to  $\ell^n$ , and (25.6) handles the posterior. The microscopic convergence holds on any coupling retaining the same  $Z$ . A finite union bound proves joint convergence. Stochastic integral versions are chosen measurably on the canonical product space; equivalence makes these common versions valid under every law in the countable sequence.  $\square$

For  $f \in L^2(\nu)$  the posterior conclusion follows by truncation exactly as in Corollary 24.2; it also permits  $f_n \rightarrow f$  in  $L^2(\nu)$ . Boundedness of  $H_n$  is being used for the uniform likelihood second moments. It is not replaced by an unverified uniform-integrability assertion in a singular or zero-noise limit.

**25.2. The projected stochastic exponential.** Let  $\hat{H}_t^n = \mathbb{E}_{P_n}[H_n(t, Z) | \mathcal{F}_t]$ , using a predictable version for Lebesgue-almost every  $t$ . Put  $\theta_t^n = \hat{H}_t^n / \sigma$ .

**Proposition 25.2** (Identification before passage to the limit). *The projected likelihood and the innovation satisfy*

$$\ell_t^n = \exp \left\{ \int_0^t \theta_s^n dB_s - \frac{1}{2} \int_0^t (\theta_s^n)^2 ds \right\}, \quad (25.7)$$

$$I_t^n = B_t - \int_0^t \theta_s^n ds. \quad (25.8)$$

Here  $I^n$  is a  $P_n$ -Brownian motion in  $\mathcal{F}_t$ . In particular the limit of the projected likelihoods in (25.5) is the projected stochastic exponential of the limiting model. Change of measure commutes with this limit on bounded measurable path tests.

*Proof.* Project  $L_t^n = 1 + \int_0^t L_s^n H_n(s, Z) dB_s / \sigma$  onto the Brownian observation filtration. The integrands are square integrable; testing against bounded elementary predictable stochastic integrals and using Itô's isometry gives

$$d\ell_t^n = \sigma^{-1} \mathbb{E}_R[L_t^n H_n(t, Z) | \mathcal{F}_t] dB_t = \ell_t^n \theta_t^n dB_t.$$

The last equality is Bayes' formula. Since  $|\theta_t^n| \leq M/\sigma$ , the solution is the positive stochastic exponential (25.7); Girsanov gives the stated innovation. The same argument with  $H$  identifies the limiting exponential. Finally  $|\mathbb{E}_{P_n} F - \mathbb{E}_P F| \leq 2\|F\|_\infty \varepsilon_n$  for bounded signed  $F$ . There is no interchange based only on a formal limit of logarithms.  $\square$

**25.3. A bounded entropic backward-equation consumer.** Fix  $\gamma > 0$  and a latent payoff  $f$  with  $|f| \leq 1$ . Define

$$U_t^n = \frac{1}{\gamma} \log \mathbb{E}_{P_n}[e^{\gamma f(Z)} \mid \mathcal{F}_t] = \frac{1}{\gamma} \log \frac{N_t^{n,e^{\gamma f}}}{\ell_t^n}. \quad (25.9)$$

The terminal condition here is the observable conditional certainty equivalent  $U_T^n$ , not the generally unobserved  $f(Z)$  itself. This specification avoids imposing a latent terminal value on the smaller observation filtration.

**Theorem 25.3** (Entropic values and localized backward integrands). *There is a unique bounded entropic value process with terminal value  $U_T^n$ ; for a predictable integrand  $Z^n$  it satisfies*

$$U_t^n = U_T^n + \int_t^T \frac{\gamma}{2} |Z_s^n|^2 ds - \int_t^T Z_s^n dI_s^n. \quad (25.10)$$

On the coupling of Theorem 25.1,

$$\mathbb{E} \sup_t |U_t^n(Y^n) - U_t(Y)|^2 \leq 84 \left( \frac{e^{2\gamma} - 1}{\gamma} \right)^2 \varepsilon_n. \quad (25.11)$$

For each  $r > e^\gamma$  let  $\tau_r^n$  be the first exit of any of  $\ell^n, \ell, N^{n,e^{\gamma f}}, N^{e^{\gamma f}}$  from  $(1/r, r)$ , capped at  $T$ . If  $\eta_n \rightarrow 0$ , then

$$\mathbb{E}_R \int_0^{\tau_r^n} |Z_s^n - Z_s|^2 ds \rightarrow 0, \quad \mathbb{E}_R \int_0^{\tau_r^n} |\theta_s^n - \theta_s|^2 ds \rightarrow 0. \quad (25.12)$$

Furthermore  $\lim_{r \rightarrow \infty} \sup_n R(\tau_r^n < T) = 0$ . Thus the localizations exhaust the observation experiment in probability.

*Proof.* For a positive bounded latent  $g$ , write  $N_t^{n,g} = \mathbb{E}_R[L_T^n g \mid \mathcal{F}_t]$  and  $dN_t^{n,g} = a_t^{n,g} dB_t$ . Projection of the full integral gives

$$a_t^{n,g} = \sigma^{-1} \mathbb{E}_R[L_t^n g H_n(t, Z) \mid \mathcal{F}_t], \quad |a_t^{n,g}| \leq (M/\sigma) N_t^{n,g}.$$

The same representation with  $g = 1$  gives  $d\ell_t^n = b_t^n dB_t$  and  $b_t^n/\ell_t^n = \theta_t^n$ . Put  $N^n = N^{n,e^{\gamma f}}$  and  $a^n = a^{n,e^{\gamma f}}$ . Itô's formula in (25.9) gives the martingale coefficient

$$Z_t^n = \gamma^{-1} (a_t^n/N_t^n - b_t^n/\ell_t^n).$$

Replacing  $dB_t$  by  $dI_t^n + \theta_t^n dt$  reduces its drift to  $-\gamma|Z_t^n|^2/2$ , which proves (25.10). The ratios are bounded by  $M/\sigma$ , so the integrals are well defined. Conversely, exponentiating any bounded solution of (25.10) produces a bounded  $P_n$ -martingale with terminal value  $e^{\gamma U_T^n}$ . Its conditional-expectation representation is unique, and martingale representation then identifies its integrand. This proves uniqueness in the bounded class.

Apply Theorem 24.1 to  $g_0 = (e^{\gamma f} - e^{-\gamma})/(e^\gamma - e^{-\gamma}) \in [0, 1]$ . The map taking its conditional expectation to  $\gamma^{-1} \log \mathbb{E}[e^{\gamma f} \mid \mathcal{F}_t]$  has Lipschitz constant at most  $(e^{2\gamma} - 1)/\gamma$ . This proves (25.11).

The initial values of  $N^n$  and  $N$  agree, since  $Z$  has the same marginal. Itô's isometry and the terminal version of (25.5) imply

$$\mathbb{E}_R \int_0^T |a_s^n - a_s|^2 ds \rightarrow 0, \quad \mathbb{E}_R \int_0^T |b_s^n - b_s|^2 ds \rightarrow 0.$$

Before  $\tau_r^n$ , all denominators lie in  $[1/r, r]$ , and the limiting numerators  $a, b$  are bounded in absolute value by  $(M/\sigma)r$ . For example,

$$\left| \frac{a^n}{N^n} - \frac{a}{N} \right| \leq r|a^n - a| + (M/\sigma)r^3|N^n - N|.$$

The supremum estimates (25.5), followed by integration in time, prove (25.12). The same inequality applies to  $b^n/\ell^n$ .

Finally  $e^{-\gamma\ell^n} \leq N^n \leq e^{\gamma\ell^n}$ . Each  $\ell^n$  is a stochastic exponential with uniformly bounded integrand  $\theta^n$ . Its positive and negative moments of the supremum are bounded uniformly in  $n$ : write any power as a stochastic exponential times its bounded compensator and apply Doob's inequality to a higher positive power. The same calculation applies to its inverse. Markov's inequality, the preceding comparison of  $N^n$  with  $\ell^n$ , and a union bound prove the exhaustion assertion. This is a localized integrand theorem; it does not assert an unspecified global topology for backward equations with unbounded terminal data or different nonlinear drivers.  $\square$

**Corollary 25.4** (A changing-filtration stopping consumer). *Let  $\psi(t, x) \in [0, 1]$  be measurable and  $L_\psi$ -Lipschitz in  $x$ , uniformly in  $t$ . For a bounded latent  $f$  with  $|f| \leq 1$ , put  $M_t^n = \mathbb{E}_{P_n}[f(Z) \mid \mathcal{F}_t]$ . Then*

$$\left| \sup_{\tau \leq T} \mathbb{E}_{P_n} \psi(\tau, M_\tau^n) - \sup_{\tau \leq T} \mathbb{E}_P \psi(\tau, M_\tau) \right| \leq \varepsilon_n + L_\psi \sqrt{80\varepsilon_n}.$$

*The same statement for the entropic value  $U$  has the additional Lipschitz factor  $(e^{2\gamma} - 1)/\gamma$  on the square-root term. The suprema range over the common canonical stopping times; attainment is not needed for the estimate.*

*Proof.* For a fixed stopping time, first change the measure while keeping its  $[0, 1]$  reward function, at cost at most  $\varepsilon_n$ . Then compare the two reward functions on the same canonical path under  $P$ , using Theorem 24.1, Cauchy-Schwarz and the Lipschitz bound. The estimate is uniform in the stopping time, so it survives both suprema. Equivalence of the observation laws is what allows the same stopping-time class. The entropic assertion follows from the Lipschitz calculation in the preceding theorem.  $\square$

**25.4. Resource transport is not the posterior coupling.** Apply any common finite causal acquisition map to  $Y$  and retain a fixed finite mark  $w(Z)$ . Data processing makes its marked row variations at most  $\varepsilon_n$ , uniformly over a declared finite feedback family. If the source and target have respective bounds  $\alpha_n, \beta_n$ , Theorem 7.2 gives same-budget deficiency perturbation at most  $\alpha_n + \beta_n$ , and Proposition 18.4 transports a fixed reset audit. A subsequent consumer of width  $S$  composed with a simulator of width  $K$  has width  $KS$ , with the stated selector price. None of these executable claims uses the latent-preserving maximal coupling. That coupling belongs to the proof of conditional-process convergence, not to the finite-state machine.

These results provide a direct changing-trajectory, likelihood, Girsanov and bounded entropic-value input for a conditional-law theory. They do not assert the strict-dual, rigidity, covariant-form or full kinetic conclusions of a larger program without their separate analytic proofs.

**Example 25.5** (Why an amplitude bound is not a tightness argument). Let  $\xi_1, \xi_2$  be independent symmetric signs, and, for  $n \geq 5$ , let  $\mathcal{G}_t^n$  reveal  $\xi_1$  at  $1/2 - 2/n$  and  $\xi_2$  at  $1/2 - 1/n$ . On  $[0, 1]$  the bounded martingale

$$M_t^n = \mathbb{E}[\xi_1 + \xi_2 \mid \mathcal{G}_t^n]$$

converges at every finite collection of fixed times to the martingale  $M_t = \mathbf{1}_{[1/2, 1]}(t)(\xi_1 + \xi_2)$ . Nevertheless its laws are not tight in the Skorokhod  $J_1$  topology. On the event  $\xi_2 = -\xi_1$ , of probability  $1/2$ , its path has an excursion of height one on an interval of length  $1/n$  and is zero outside that interval. The three-time oscillation modulus of such a path is one at every scale greater than  $2/n$ . This violates the necessary  $J_1$  tightness modulus criterion. All maximal moments are uniformly bounded by  $2^p$ .

This example concerns the inference from finite-dimensional convergence and a maximal amplitude estimate alone. It does not claim that every possible stronger conditional-kernel hypothesis fails. The uniform estimates in Theorem 25.1 remove the need for that inference in the observation class treated here.

## 26. OBSERVATION DENSITIES AND COUPLED PROCESS VERSIONS

We record three measure-theoretic facts used in the global transport argument. Their purpose is to make explicit the passage from a tilted physical law to an observation law and from two marginal processes to one joint realization.

**Lemma 26.1** (Observation-level return from a bounded tilt). *Let  $dP^g/dP = g(Z)/c$ , where  $c = \mathbb{E}_P g$  and  $e^{-\gamma} \leq g \leq e^\gamma$ . For any observation sub- $\sigma$ -field  $\mathcal{F}$ ,*

$$\frac{d(P|_{\mathcal{F}})}{d(P^g|_{\mathcal{F}})} = \mathbb{E}_{P^g} \left[ \frac{c}{g} \middle| \mathcal{F} \right] = \frac{c}{\mathbb{E}_P[g | \mathcal{F}]}. \quad (26.1)$$

*Both this density and its reciprocal lie in  $[e^{-2\gamma}, e^{2\gamma}]$ . In particular, for any nonnegative  $\mathcal{F}$ -measurable  $V$ ,  $\mathbb{E}_P V \leq e^{2\gamma} \mathbb{E}_{P^g} V$ .*

*Proof.* For  $A \in \mathcal{F}$ , integrate  $c/g$  over  $A$  under  $P^g$  to obtain  $P(A)$ . Conditioning proves the first identity. In the other direction,  $d(P^g|_{\mathcal{F}})/d(P|_{\mathcal{F}}) = \mathbb{E}_P[g | \mathcal{F}]/c$ ; equivalence and inversion prove the second. The bounds follow from the bounds on  $g$ , its conditional mean, and  $c$ .  $\square$

**Lemma 26.2** (Domination of the common-path measure). *Let  $(Y', Y)$  be a coupling on a standard Borel path space, with marginal laws  $P', P$ , and let  $E = \{Y' = Y\}$ . The subprobability measure  $\kappa(A) = \Pr(E, Y \in A)$  is dominated by both  $P$  and  $P'$ . Consequently, for any nonnegative measurable path functional  $V$ ,*

$$\mathbb{E}[\mathbf{1}_E V(Y)] \leq \mathbb{E}_P V, \quad \mathbb{E}[\mathbf{1}_E V(Y')] \leq \mathbb{E}_{P'} V.$$

*The assertion also holds on a common latent–observation space when the latent coordinate is shared by the coupling.*

*Proof.* The event defining  $\kappa(A)$  is contained in  $\{Y \in A\}$  and, on  $E$ , in  $\{Y' \in A\}$ . This proves domination on sets. Integration of simple functions followed by monotone convergence proves the rest. Apply the same argument to the product coordinate for the last assertion.  $\square$

**Lemma 26.3** (Marginal stochastic integrals on an arbitrary coupling). *On a canonical standard Borel observation path space, suppose that under each of two marginal laws there are a continuous adapted process  $U$ , a predictable square-integrable process  $Z$ , and an innovation  $I$  such that, in that marginal's own filtration,*

$$\int_0^t Z_s dI_s = U_t - U_0 + \frac{\gamma}{2} \int_0^t |Z_s|^2 ds, \quad 0 \leq t \leq T. \quad (26.2)$$

*Assume  $Z$  is bounded, as in the entropic model here. There are measurable versions of the two continuous integral processes which can be pulled back to any coupling of the observation laws. Each pulled-back version has the correct marginal law and satisfies its own identity (26.2). Neither integral thereby acquires a martingale or Itô-integral interpretation in the enlarged joint filtration.*

*Proof.* A continuous process is determined by its values at rational times. Completed-measurable random variables on the canonical space have Borel versions. Choose such versions at the countably many rational times and extend by continuity on the measurable set where a continuous extension exists, using the zero path elsewhere. This gives a Borel  $C([0, T])$ -valued version of  $U$ . Likewise take a jointly measurable version of  $Z$  modulo  $dt \otimes P$ ; its bounded time integral has a continuous path, and its rational-time values give a measurable continuous version by the same construction. The right side of (26.2) is consequently a measurable continuous path functional. Marginal equality at all rational times, and continuity of the stochastic integral, make it indistinguishable from that integral. Repeat for the other marginal. Pullback along the two coordinate maps of any coupling preserves their respective almost-sure identities and laws. No enlargement theorem for innovations is used.  $\square$

In Theorem 27.2, Lemma 26.1 is applied with  $\mathcal{F} = \mathcal{F}_T$  to the integrated squared coefficient comparison. Lemma 26.2 justifies restricting a same-path estimate to the equality event of the latent-preserving coupling. Lemma 26.3 fixes the meaning of the coupled backward martingale integrals before their difference is estimated. Thus the coupled notation retains the marginal observation filtrations throughout.

## 27. GLOBAL TRANSPORT OF THE BACKWARD EQUATION

We retain exactly the common-preparation, bounded-signal and positive-noise hypotheses of Section 25. In particular the canonical joint laws  $P_n, P$  are equivalent and have the same latent marginal  $\nu$ . All comparisons on a single observation path use common measurable versions of the conditional expectations. The following estimate avoids division by a small observation density in the final bound.

**Lemma 27.1** (An integrated posterior comparison). *Let  $P, Q$  be equivalent laws on a standard Borel product carrying a latent variable  $Z$  and an observation  $Y$ , and let  $\|P - Q\|_{\text{TV}} \leq \epsilon$ . If  $|u(Z)| \leq M$  and  $\mathcal{F}$  is an observation sub- $\sigma$ -field, then, under either  $S = P$  or  $S = Q$ ,*

$$\mathbb{E}_S |\mathbb{E}_Q[u \mid \mathcal{F}] - \mathbb{E}_P[u \mid \mathcal{F}]| \leq 4M\epsilon, \quad (27.1)$$

$$\mathbb{E}_S |\mathbb{E}_Q[u \mid \mathcal{F}] - \mathbb{E}_P[u \mid \mathcal{F}]|^2 \leq 8M^2\epsilon. \quad (27.2)$$

*A common latent marginal is not needed for these two inequalities.*

*Proof.* Use a dominating finite measure on  $\mathcal{F}$ . Write  $p, q$  for the densities of the restricted probability laws and  $a, b$  for the densities of the signed measures  $\mathbb{E}_P[u \mathbf{1}_A], \mathbb{E}_Q[u \mathbf{1}_A]$  on  $\mathcal{F}$ . Their conditional means are  $m_P = a/p$  and  $m_Q = b/q$ . Outside null sets,  $|m_P|, |m_Q| \leq M$ , and

$$p(m_Q - m_P) = m_Q(p - q) + (b - a).$$

The integral of  $|p - q|$  is at most  $2\epsilon$ , by contraction of total variation. The integral of  $|b - a|$  is at most  $2M\epsilon$ , since multiplication by  $u$  followed by restriction cannot increase signed variation by more than  $M$ . Integrating the displayed identity proves (27.1) under  $P$ . Interchanging the two laws proves it under  $Q$ . The squared bound follows from  $|m_Q - m_P| \leq 2M$ .  $\square$

Let  $|f| \leq 1$ ,  $\gamma > 0$ , and use the notation  $\theta^n, U^n, Z^n, I^n$  of Proposition 25.2 and Theorem 25.3. Here  $Z^n$  denotes the scalar backward integrand, whereas the unadorned latent argument of  $H_n$  is the preparation variable. Define the deterministic bounds

$$A_n = \sigma^{-2} \{2\eta_n^2 + 16M^2T\epsilon_n\}, \quad (27.3)$$

$$C_n = \frac{2(1 + e^{4\gamma})}{\gamma^2} A_n, \quad (27.4)$$

where  $\epsilon_n = \min\{1, \eta_n/(2\sigma)\}$  as before.

**Theorem 27.2** (Global innovation and entropic-integrand transport). *Under the hypotheses of Theorem 25.1, under either physical law  $S = P$  or  $S = P_n$  on the same canonical path,*

$$\mathbb{E}_S \int_0^T |\theta_t^n - \theta_t|^2 dt \leq A_n, \quad \mathbb{E}_S \int_0^T |Z_t^n - Z_t|^2 dt \leq C_n. \quad (27.5)$$

*No stopping at a density level is required. If  $\eta_n \rightarrow 0$ , both integrals also converge to zero in expectation under the reference law  $R$ .*

On the single latent-preserving coupling of Theorem 25.1, evaluate each process on its own observation path, denoting these evaluations by a bar. Then

$$\mathbb{E} \int_0^T |\bar{\theta}_t^n - \bar{\theta}_t|^2 dt \leq A_n + 4M^2 T \varepsilon_n / \sigma^2, \quad (27.6)$$

$$\mathbb{E} \int_0^T |\bar{Z}_t^n - \bar{Z}_t|^2 dt \leq C_n + 16M^2 T \varepsilon_n / (\gamma^2 \sigma^2). \quad (27.7)$$

If  $\eta_n \rightarrow 0$ , then  $\bar{I}^n \rightarrow \bar{I}$  uniformly in probability. Writing  $\bar{J}_t^n = \int_0^t \bar{Z}_s^n d\bar{I}_s^n$  for the stochastic integral in its own observation filtration, and  $\bar{J}$  for its limit, one has

$$\mathbb{E} \sup_{t \leq T} |\bar{J}_t^n - \bar{J}_t|^2 \leq 2 \mathbb{E} \sup_{t \leq T} |\bar{U}_t^n - \bar{U}_t|^2 + \frac{8M^2 T}{\sigma^2} \mathbb{E} \int_0^T |\bar{Z}_t^n - \bar{Z}_t|^2 dt. \quad (27.8)$$

The first term on the right has the explicit bound in (25.11). Thus the full bounded entropic backward representation, including its martingale integral, is transported globally. The coupling need not make either innovation Brownian in the joined filtration; each integral is defined under its own marginal law.

*Proof.* For each deterministic  $t$ , under  $P$  split

$$\sigma(\theta_t^n - \theta_t) = \mathbb{E}_{P_n}[H_n(t, Z) | \mathcal{F}_t] - \mathbb{E}_P[H_n(t, Z) | \mathcal{F}_t] + \mathbb{E}_P[H_n(t, Z) - H(t, Z) | \mathcal{F}_t].$$

Lemma 27.1, conditional Jensen and  $(x + y)^2 \leq 2x^2 + 2y^2$  bound its expected square by  $16M^2 \varepsilon_n + 2\mathbb{E}_\nu |H_n(t, Z) - H(t, Z)|^2$ . Integration gives the first bound in (27.5) under  $P$ . Under  $P_n$  use the same decomposition with the signal-difference term conditioned under  $P_n$  and the law-change term applied to  $H$ . The common latent marginal gives the identical bound. Jointly measurable conditional versions, and predictable versions equal for  $dt$ -almost every time, give the same integrated statements.

Put  $g = e^{\gamma f}$  and  $c = \mathbb{E}_\nu g$ . Tilt the two full joint laws by  $g(Z)/c$ , writing  $P^g, P_n^g$ . They still have the same latent marginal  $\nu_g = g\nu/c$ , and their observation signals remain  $H, H_n$ . Since  $e^{-\gamma} \leq g, c \leq e^\gamma$ ,

$$\|P_n^g - P^g\|_{\text{TV}} \leq e^{2\gamma} \varepsilon_n, \quad \eta_{n,g}^2 \leq e^{2\gamma} \eta_n^2.$$

Moreover, the reference martingale coefficient  $a^{n,g}$  from the proof of Theorem 25.3 satisfies

$$\alpha_t^n := \frac{a_t^{n,g}}{N_t^{n,g}} = \sigma^{-1} \mathbb{E}_{P_n^g}[H_n(t, Z) | \mathcal{F}_t].$$

Apply the preceding innovation argument to these tilted laws. It bounds the squared integral of  $\alpha^n - \alpha$  by  $e^{2\gamma} A_n$  under either tilted physical law. For an observation-measurable nonnegative random variable, passage back to the corresponding original physical law costs at most  $e^{2\gamma}$ : the full density  $c/g$  is bounded by this constant, and so is its observation projection. Consequently

$$\mathbb{E}_S \int_0^T |\alpha_t^n - \alpha_t|^2 dt \leq e^{4\gamma} A_n.$$

The identity  $Z^n = (\alpha^n - \theta^n)/\gamma$  proves the second bound in (27.5).

The pointwise bounds, valid for all models, are

$$|\theta^n|, |\alpha^n| \leq M/\sigma, \quad |Z^n| \leq 2M/(\gamma\sigma). \quad (27.9)$$

The squared time integrals are thus uniformly bounded random variables. Convergence in  $P$ -probability, followed by absolute continuity of the fixed  $R$  with respect to  $P$ , gives convergence in  $R$ -probability. Boundedness then gives convergence of their  $R$ -expectations. This argument establishes global reference convergence without claiming a new explicit reference rate.

For the coupling, let  $E_n = \{Y^n = Y\}$ , so that  $\mathbb{P}(E_n^c) \leq \varepsilon_n$ . On  $E_n$  both processes are functions of the same observation path. The restricted expectation of their squared difference is at most the

corresponding unrestricted expectation under the limiting marginal  $P$ . On  $E_n^c$  apply (27.9) and integrate for time  $T$ . This proves (27.6)–(27.7).

On  $E_n$ , the Brownian reference coordinates  $Y^n/\sigma, Y/\sigma$  agree, so

$$\sup_{t \leq T} |\bar{I}_t^n - \bar{I}_t|^2 \leq T \int_0^T |\bar{\theta}_t^n - \bar{\theta}_t|^2 dt.$$

Markov's inequality and  $\mathbb{P}(E_n^c) \rightarrow 0$  prove uniform convergence in probability. This assertion does not require any moment estimate on the observation difference on the exceptional event.

Finally, the backward equation already proved gives, under each marginal,

$$\bar{J}_t^n = \bar{U}_t^n - U_0 + \frac{\gamma}{2} \int_0^t |\bar{Z}_s^n|^2 ds.$$

The common initial value is  $U_0 = \gamma^{-1} \log \mathbb{E}_\nu g$ . By (27.9),

$$||\bar{Z}_s^n|^2 - |\bar{Z}_s|^2| \leq \frac{4M}{\gamma\sigma} |\bar{Z}_s^n - \bar{Z}_s|.$$

Subtract the two integral identities, use Cauchy–Schwarz in time and  $(x + y)^2 \leq 2x^2 + 2y^2$ , and take expectations. This gives (27.8). The integral identity also defines compatible measurable versions on the coupling, without asserting a martingale property for its joint filtration.  $\square$

The theorem strengthens the localized conclusion of Theorem 25.3 without changing its terminal condition or its driver. The terminal condition remains the observation-measurable conditional certainty equivalent, not the unobserved latent payoff. Positive fixed noise, bounded signals, and a common preparation are used in the proof. A singular zero-noise limit, an unbounded terminal condition, or a different nonlinear driver would require additional arguments.

## 28. A UNIFORM CERTIFICATE THROUGH A MOVING COLLISION

We now use all three parts of the argument on one family. The finite marked reference law and the uniform scattering geometry are those of Theorem 23.1 and Lemma 23.2. They are proved above, including the no-collision control. We use a continuous observation of the same detector so that finite reports and conditional processes are generated by one experiment.

Let  $z$  denote a preparation in the boxes of (23.3), and let  $\nu$  be that prepared law. The sign of the impact orientation is  $2B - 1$ , and the conserved center-of-mass longitudinal sign is the actual mark  $W$ . Their correlation is prepared:  $\mathbb{P}(B = b, W = w) = 5/16$  for  $b = w$  and  $3/16$  otherwise. The contact diameter  $d$  ranges over  $I = [9/10, 11/10]$ . Let  $X_d(t, z)$  be the two-particle phase path, with outgoing velocities used at the collision, and define

$$H_d(t, z) = h(v_{1,y}^d(t, z)), \quad Y_t^d = \int_0^t H_d(s, z) ds + \sigma B_t^d, \quad 0 < \sigma \leq 1/24.$$

The Brownian noise is independent of the preparation. The source experiment has the same physical preparation and mark but constant reports. The target reports at times 2 and 3 are

$$Z_1^d = \mathbf{1}\{2(Y_2^d - Y_{3/2}^d) > 0\}, \quad Z_2^d = A\mathbf{1}\{2(Y_3^d - Y_{5/2}^d) > 0\}. \quad (28.1)$$

The acquisition gate  $A \in \{0, 1\}$  is chosen after  $Z_1^d$ ; it does not act on the mechanical trajectory. The continuous path is the auxiliary observation experiment for conditional consumers; the finite simulator is not given this path or an uncharged buffer for computing its increments. The target sensor implements the declared window acquisition.

**Lemma 28.1** (Quantitative change of the microscopic path). *For all preparations in the specified boxes, the collision time  $t_c(d)$  and outgoing tagged velocities obey*

$$|t_c(d') - t_c(d)| \leq |d' - d|, \quad |v_i^+(d') - v_i^+(d)| \leq 30|d' - d| \quad (i = 1, 2).$$

Writing  $\Delta = |d' - d|$ , one has

$$\sup_z \int_0^3 |H_{d'}(t, z) - H_d(t, z)|^2 dt \leq \Delta + 2700\Delta^2. \quad (28.2)$$

The phase paths converge uniformly over the preparation in the Skorokhod  $J_1$  metric as  $d' \rightarrow d$ . More precisely, for the product metric taking the maximum of the per-particle Euclidean position and velocity distances, a time change aligning the collision times gives  $J_1$  distance at most  $100\Delta$ .

*Proof.* Write  $r$  and  $g$  for the incoming relative position and velocity, and  $n(d) = (r + t_c(d)g)/d$  for the contact normal. The collision root satisfies  $|r + t_c g| = d$ . The nongrazing estimate from Lemma 23.2 is  $-g \cdot n > 1443/1000$ . Differentiating the root with respect to  $d$  gives

$$t'_c(d) = \frac{1}{g \cdot n(d)}, \quad |t'_c(d)| < 1.$$

The incoming bound is  $|g| < 3$ , so

$$|n'(d)| \leq \frac{|t'_c(d)| |g| + 1}{d} < 5.$$

Since  $v_1^+ = V + g/2 - (g \cdot n)n$  and  $v_2^+ = V - g/2 + (g \cdot n)n$ , differentiation bounds either velocity derivative by  $2|g| |n'| < 30$ .

Before collision the detector is zero, and after collision it is a constant of absolute value at most one. Its Lipschitz constant is one. The two signals therefore differ on the interval between the two collision times by at most one and afterwards by at most  $30\Delta$ . The intervening interval has length at most  $\Delta$ , and the whole observation lasts three units. This proves (28.2).

Choose the increasing piecewise affine time change fixing 0, 3 and sending  $t_c(d)$  to  $t_c(d')$ . Its uniform displacement is at most  $\Delta$ . Aligned velocities differ by at most  $30\Delta$ , with the same outgoing convention at the jump. Each particle's speed is below four and its velocity jump has norm below three. Without time change, the position difference is bounded by  $3\Delta + 3(30\Delta) = 93\Delta$ , by integrating the velocity difference before and after the two jump times. Aligning time adds at most  $4\Delta$ . The asserted bound follows, with a harmless rounding to  $100\Delta$ .  $\square$

**Theorem 28.2** (Microscopic-to-audit and conditional-law composition). *For the single family (28.1), all of the following hold.*

(a) *At the same width-one private register,*

$$\delta^p > 9/20, \quad \delta_r^v > 9/20 \quad (r \geq 1), \quad \delta_2^h < 13/100,$$

*uniformly for  $d \in I$  and  $0 < \sigma \leq 1/24$ . When  $d \leq 2/5$  the detector is zero on  $[0, 3]$ , and all three finite-experiment deficiencies are zero.*

(b) *There is one explicit rational reset-audit rule with one all-on training row, eight marked outcomes and  $n = 2800$  training runs, whose expected validation score exceeds  $2/5$  against every private width-one simulator throughout that same parameter region. In detail, for counts  $C$  choose an event  $A_C \subseteq \{0, 1\}^3$  maximizing*

$$Q_*(A_C) - C(A_C)/2800, \quad (28.3)$$

*with lexicographic tie breaking. Here  $Q_*$  is the rational marked reference law of  $(B, B, W)$ . The independent validation uses the actual physical target, not  $Q_*$ . This finite rule has at most  $\binom{2807}{7}$  training-count states at any scheduled epoch; a conservative complete auditor bound is  $8(256 + 1)\binom{2807}{7}$ . The state cost belongs to the auditor. The certificate is an expected-score inequality, not a confidence claim about one realized score.*

(c) Fix  $\sigma > 0$  and let  $d_n, d \in I$  with  $d_n \rightarrow d$ . Set

$$\epsilon_n = \min \left\{ 1, \frac{\sqrt{|d_n - d| + 2700|d_n - d|^2}}{2\sigma} \right\}. \quad (28.4)$$

The joint preparation–continuous-observation laws differ by at most  $\epsilon_n$ . Every finite resource deficiency above changes by at most  $\epsilon_n$ , and a fixed audit changes by at most  $\epsilon_n$  because its source behavior is unchanged. On a latent-preserving coupling,  $X_{d_n} \rightarrow X_d$  in  $J_1$  and each bounded posterior converges in supremum  $L^2$  with bound  $84\epsilon_n$ . The full and projected likelihoods converge in reference supremum  $L^2$ , and jointly in probability with the microscopic paths on that coupling. The projected stochastic exponentials, bounded entropic backward values, localized integrands and stopping consumers have the conclusions of Proposition 25.2, Theorem 25.3, and Corollary 25.4.

(d) On compact parameter sets with  $\sigma \geq \sigma_0 > 0$ , the finite marked probabilities have uniform rational enclosures. The observable chart, strict same-budget polynomial verification and rational upper tables are therefore effective in the exact sense of Propositions 22.1 and 21.6.

*Proof.* Every collision occurs before time  $3/2$ . Conditional on preparation, the two normalized window increments in (28.1) are independent Gaussians with mean  $h(v_{1,y}^+)$  and standard deviation  $\sqrt{2}\sigma \leq 1/12$ . The outgoing detector has sign  $2B - 1$  and absolute value greater than  $1/4$ . Coupling each noisy report to  $B$  gives total marked variation less than  $1/300$  from the exact finite marked experiment, uniformly for every acquisition gate. The finite calculation of Theorem 23.1 gives

$$d_* = \sqrt{5/2} - 9/8, \quad \delta_*^p = \delta_*^v = d_*, \quad \delta_{*,2}^h = 1/8.$$

Thus private and visible values exceed  $d_* - 1/300 > 9/20$ , and the hidden value is less than  $1/8 + 1/300 < 13/100$ . The two-valued hidden witness stores its selector, not an observed mark. In the no-collision regime both window reports before gating are independent fair noise, independent of  $W$ . Fresh private coins reproduce them exactly, including feedback gates. This proves (a).

For (b), use only the all-on feedback row. Any private width-one simulator in this row emits independent bits with probabilities  $p, q$ , independently of the actual  $W$ . The calculation in Theorem 23.1 already gives minimum variation  $d_*$  for this row. Its alphabet  $(z_1, z_2, W)$  has eight elements, hence  $D = 7$ . The explicit empirical audit in Theorem 18.1, trained using  $Q_*$ , has expected ideal score at least

$$d_* - \sqrt{7/2800} = d_* - 1/20.$$

The candidate training and validation laws do not change when the target is replaced by the physical target. Conditional on any selected event, its target probability changes by less than  $1/300$ . Therefore the actual score is strictly greater than

$$d_* - \frac{1}{20} - \frac{1}{300} > \frac{2}{5}. \quad (28.5)$$

For completeness, the last strict inequality is the positive-root comparison  $\sqrt{5/2} > 947/600$ ; its squared margin is  $5/2 - (947/600)^2 = 3191/360000 > 0$ . All probabilities in  $Q_*$  are 0,  $3/16$  or  $5/16$ , so (28.3) is a finite rational rule independent of  $d, \sigma, p, q$ . At training epoch  $k$  the number of eight-category count vectors is  $\binom{k+7}{7} \leq \binom{2807}{7}$ . A buffer of eight states records the current two reports and terminal mark; 256 event masks and an idle symbol suffice during event selection and validation. The conservative product bound follows. The clock and the source-reset interface are the declared resources. In particular the proof does not enumerate or claim to store a small complete coefficient table.

For (c), Lemma 28.1 gives the signal-distance hypothesis of Theorem 25.1, with  $T = 3$  and  $M = 1$ . It also supplies its microscopic  $J_1$  hypothesis. That theorem gives (28.4) and all the joint process assertions. The finite acquisition is a common measurable causal map of the continuous

observation, so marked variation contracts for every gate. The source is blind and independent of  $d$ . Consequently its executable candidate behaviors are identical across  $d$ , and Proposition 18.4 has  $\alpha = 0$  and  $\beta = \epsilon_n$ . The same same-budget comparison applies in each visible fiber and in each hidden mixture. The exponential and backward claims now follow from the identified projected density and the explicitly bounded entropic consumer. This is where the finite certificate and the conditional-law theorem meet the same microscopic approximation.

Finally, the collision root is uniformly separated from grazing, its formula is algebraic on the rational preparation boxes, and the normalized window noise has variance  $2\sigma^2$  bounded away from zero on the stated compact sets. The box subdivision and Gaussian-tail enclosure argument in Proposition 23.4 therefore applies with that variance. It returns rational enclosures with a computable uniform error. The rational quotient algorithm and same-budget strict certificate procedure then prove (d). Uniformity as  $\sigma \downarrow 0$  is not asserted.  $\square$

The all-on audit in part (b) is a single witness for the lower bound in the full feedback problem: a maximum over feedback trees includes this row. The visible lower bound is instead the exact fiber theorem; no claim is made that an auditor with a seed-independent state bound can store an arbitrarily large visible-seed transcript. This separates the two resource budgets rather than silently moving cost from one to the other.

The finite certificate is also preserved under an additional rational presentation error  $\rho$ : its lower score decreases by at most  $\rho$  when only the target is changed, and by the reset-cost estimate when the source is changed. Thus the certificate is an effective consumer of the physical presentation theorem, not an isolated exact finite example.

Theorem 28.2 and the preceding results prove Theorem C.3. The C2-type consequence is a joint changing-trajectory/likelihood/posterior theorem with an identified stochastic exponential and a fully specified bounded entropic backward consumer. Nothing in that conclusion identifies geometric similarity with kinetic scaling, or supplies particle-uniform recollision estimates by renaming this fixed-particle model.

## 29. SHARP DECISION MEMORY FOR THE COLLISION EXPERIMENT

We now apply the continuation spectrum to the same marked experiment that supplies the microscopic certificate. Both its impossibility statement and its construction concern the same score, the same private candidate family, and the same training-validation checkpoint.

**29.1. The marked family and its first two spectral values.** In the all-on row of Section 28, a private width-one candidate has two independent report bits with probabilities  $p, q \in [0, 1]$ , independently of the fair actual mark. Denote its law by  $b(p, q)$  and put

$$a = (1 - p)(1 - q), \quad c = pq.$$

Let  $B = \{b(p, q) : p, q \in [0, 1]\}$ . The ideal target  $Q_*$  is supported on 000, 001, 110, 111, with masses  $5/16, 3/16, 3/16, 5/16$ , respectively. On these four atoms the candidate masses are  $a/2, a/2, c/2, c/2$ . The elementary continuation constraint implies

$$\sqrt{a} + \sqrt{c} \leq 1, \quad \min(a, c) \leq \frac{1}{4}. \quad (29.1)$$

Indeed the first inequality is Cauchy-Schwarz applied to  $(\sqrt{1-p}, \sqrt{p})$  and  $(\sqrt{1-q}, \sqrt{q})$ ; the second follows from the first. If  $a \geq c$ , then  $c \leq 1/4$  and

$$a + 3c \leq (1 - \sqrt{c})^2 + 3c = 1 - 2\sqrt{c} + 4c \leq 1. \quad (29.2)$$

The symmetric inequality holds when  $c \geq a$ .

**Theorem 29.1** (A sharp two-state obstruction). *For the ideal marked collision family,*

$$\mathfrak{V}_1(B, Q_*) = \frac{1}{8}, \quad \mathfrak{V}_2(B, Q_*) = \frac{3}{8}. \quad (29.3)$$

*If  $\|Q - Q_*\|_{\text{TV}} \leq \beta$ , every reset auditor retaining at most two states at the training-validation cut has worst-case expected score at most  $3/8 + \beta$ , regardless of its finite training length and its upstream or downstream memory. The assertion allows mark-dependent validation events and stochastic state transitions.*

*Proof.* For one state, use the event  $\{000, 111\}$ . Its score is  $5/8 - (a + c)/2 \geq 1/8$ . Conversely, average the two candidates with  $(a, c) = (1, 0)$  and  $(0, 1)$ . Their average is uniform on the four supported atoms and is at total variation distance  $1/8$  from  $Q_*$ . Every fixed response has average score at most  $1/8$ , so its minimum over the two candidates is at most  $1/8$ . This proves the first equality; the average is a bound on scores, not an allowed private candidate.

For the upper bound with two states, consider the three candidates  $b_0 = b(0, 0)$ ,  $b_1 = b(1, 1)$  and  $b_* = b(1/2, 1/2)$ . A response may be set to zero outside the support of  $Q_*$  without decreasing its payoff at any candidate. Write its four remaining coordinates as  $(x, y, z, t)$ . Its three payoffs are

$$\begin{aligned} f_0 &= (-3x - 5y + 3z + 5t)/16, \\ f_1 &= (5x + 3y - 5z - 3t)/16, \\ f_* &= (3x + y + z + 3t)/16. \end{aligned}$$

Since all four coordinates are in  $[0, 1]$ ,

$$f_0 + f_1 \leq \frac{1}{4}, \quad f_0 + f_* \leq \frac{3}{4}, \quad f_1 + f_* \leq \frac{3}{4}. \quad (29.4)$$

Suppose two responses covered all three candidates with payoff strictly greater than  $3/8$ . The first inequality forces different responses to cover  $b_0$  and  $b_1$ . The other two inequalities then force both responses to have payoff less than  $3/8$  at  $b_*$ . This is a contradiction. Hence  $\mathfrak{V}_2 \leq 3/8$ .

For attainment take the responses, in the same four-atom order,

$$h_0 = (2/3, 0, 1, 1), \quad h_1 = (1, 1, 0, 2/3),$$

with zero response elsewhere. Both have target mean  $17/24$ . Their payoffs are  $17/24 - a/3 - c$  and  $17/24 - a - c/3$ . If  $a \geq c$ , the first is larger and (29.2) makes it at least  $17/24 - 1/3 = 3/8$ . The other case is symmetric. This proves equality. For the perturbed target, apply (9.4) and the operational upper bound of Theorem 9.2.  $\square$

The obstruction has an immediate continuation interpretation. Each post-training state supplies one validation response. The three witness candidates in the proof cannot be covered above  $3/8$  by two such responses. No increase of sample size can compensate for losing the third continuation at that cut. This argument does not use the unrelated Bernoulli majority calibration.

**Lemma 29.2** (Feedback completion of the physical lower bound). *The upper bound  $3/8 + \beta$  in Theorem 29.1 remains valid when the auditor may train on any of the original feedback rows and may select a row-event pair after the decision cut. Here every target row is the declared feedback pushforward of  $Q$ , with  $\|Q - Q_*\|_{\text{TV}} \leq \beta$ . In particular, two states cannot evade the bound by using a different sensor gate during training or validation.*

*Proof.* It suffices to restrict the adversary to an admissible subfamily. For  $p, q \in [0, 1]$ , let its first emission be  $X_1 \sim \text{Ber}(p)$ , and, after gate  $A$ , let its second emission be  $AX_2$ , with an independent  $X_2 \sim \text{Ber}(q)$  and the independent fair actual mark. These are genuine width-one private rows: the gate is a current input, and the second emission uses no retained copy of  $X_1$ .

For any deterministic gate policy  $g : \{0, 1\} \rightarrow \{0, 1\}$ , the marked row is the pushforward of  $b(p, q)$  under  $T_g(x_1, x_2, w) = (x_1, g(x_1)x_2, w)$ . The physical target row is the pushforward of  $Q$  by the same map, since acquisition does not act on the path. Including the gate in the transcript

changes nothing: it is also a deterministic function of the displayed coordinates. For a selected row event, the response pulls back to  $\mathbf{1}_A \circ T_g$  on the all-on alphabet. A randomized row-event continuation pulls back to a function  $h_m \in [0, 1]^\Omega$ . Hence, conditional on cut state  $m$ , its expected score on this subfamily is exactly  $(Q - b(p, q))h_m$ .

Whatever training rows were used, their effect is solely the distribution of the retained state. The two-state score is thus a convex combination of two such responses and is bounded above by their envelope. Apply the three-candidate argument of Theorem 29.1, and then the uniform target perturbation bound. Since this is a subfamily of the full private candidate class, it is a valid lower-bound witness for that full class. Randomized feedback is covered by conditioning on its independent random table and then averaging the pulled-back response.  $\square$

**29.2. A three-response construction.** Define three deterministic events, all ignoring the mark,

$$A_D = \{00, 11\} \times \{0, 1\}, \quad A_0 = \{00\} \times \{0, 1\}, \quad A_1 = \{11\} \times \{0, 1\}.$$

Their ideal scores are  $1 - a - c$ ,  $1/2 - a$  and  $1/2 - c$ .

**Lemma 29.3** (The three-response envelope). *For the original private candidate image,*

$$\min_{p, q} \max\{1 - a - c, \tfrac{1}{2} - a, \tfrac{1}{2} - c\} = \sqrt{2} - 1. \quad (29.5)$$

*In particular  $\mathfrak{V}_3(B, Q_*) \geq \sqrt{2} - 1$ .*

*Proof.* By symmetry suppose  $a \geq c$ . Then  $c \leq 1/4$  and the maximum is  $1 - a - c$  for  $a \leq 1/2$ , and  $1/2 - c$  for  $a \geq 1/2$ . If  $a \leq 1/4$ , the first expression is at least  $1/2$ . If  $1/4 \leq a \leq 1/2$ , (29.1) gives

$$a + c \leq 1 - 2\sqrt{a} + 2a \leq 2 - \sqrt{2},$$

since the last function is increasing on  $[1/4, 1/2]$ . If  $a \geq 1/2$ , then  $c \leq (1 - \sqrt{a})^2 \leq (1 - 1/\sqrt{2})^2 = 3/2 - \sqrt{2}$ . Both cases give the asserted lower bound. It is attained at  $p = q = 1 - 1/\sqrt{2}$ , where  $a = 1/2$  and  $c = 3/2 - \sqrt{2}$ . The symmetric point gives the same value.  $\square$

**Lemma 29.4** (Odd-sample majority selection with a uniform regret bound). *Let  $n = 2h - 1$  be odd. In  $n$  independent candidate trials, let  $C_0, C_1$  count report pairs 00, 11. Choose  $A_1$  if  $C_0 \geq h$ , choose  $A_0$  if  $C_1 \geq h$ , and otherwise choose  $A_D$ . The first two cases are mutually exclusive. Its expected ideal score satisfies*

$$g_n(p, q) \geq \sqrt{2} - 1 - \frac{1}{4\sqrt{en}} - \frac{1}{4}e^{-n/8}. \quad (29.6)$$

*Its event label has three possible values at the decision cut.*

*Proof.* Because  $a + c \leq 1$ ,

$$\max\{1 - a - c, \tfrac{1}{2} - a, \tfrac{1}{2} - c\} = 1 - a - c + (a - 1/2)_+ + (c - 1/2)_+.$$

The selected payoff is  $1 - a - c + (a - 1/2)\mathbf{1}_{\{C_0 \geq h\}} + (c - 1/2)\mathbf{1}_{\{C_1 \geq h\}}$ . Its expected loss from this envelope is exactly the sum, for  $u = a, c$ , of  $|u - 1/2|$  times the probability that the binomial majority selects the wrong side of  $u = 1/2$ . At  $u = 1/2$  the contribution is zero. No independence between  $C_0$  and  $C_1$  is used.

For  $0 < u < 1/2$  and  $k \geq h$ , the ratio of the binomial mass at  $u$  to that at  $1/2$  is

$$[4u(1 - u)]^{n/2} \left( \frac{u}{1 - u} \right)^{k - n/2} \leq [4u(1 - u)]^{n/2}.$$

The fair binomial upper tail is exactly  $1/2$  because  $n$  is odd. Reflecting  $k$  treats  $u > 1/2$ . The endpoint cases follow directly or by continuity. Thus the wrong-side probability is at most

$$\tfrac{1}{2}[1 - 4(u - 1/2)^2]^{n/2} \leq \tfrac{1}{2}e^{-2n(u - 1/2)^2}.$$

For  $x \geq 0$ , the maximum of  $xe^{-2nx^2}/2$  is  $1/(4\sqrt{en})$ , reached at  $x = 1/(2\sqrt{n})$ . At least one of  $a, c$  is at most  $1/4$  by (29.1); that coordinate has  $|u - 1/2| \in [1/4, 1/2]$  and contributes at most  $e^{-n/8}/4$ . Bound the other coordinate by the unrestricted maximum and use Lemma 29.3.  $\square$

**29.3. Simultaneous exact widths and the full acquisition schedule.** The preceding construction admits more compression than storing its two raw counts. Write 0, 1, \* for the three report-pair categories 00, 11 and the two off-diagonal pairs. For  $n = 2h - 1$ , let  $F_n$  be the terminal event-label function of this word. At a trial cut  $t$ , let  $r = n - t$  and let  $(u, v)$  be the two prefix counts. Associate the residual key

$$\mathcal{R}_t(u, v) = \begin{cases} \text{L}, & u \geq h, \\ \text{R}, & v \geq h, \\ (\min(h - u, r + 1), \min(h - v, r + 1)), & u, v < h. \end{cases} \quad (29.7)$$

The symbols L, R mean the constant decisions  $A_1, A_0$ . In a pair key, a coordinate  $r + 1$  means that this majority is no longer reachable. The pair  $(r + 1, r + 1)$  represents the constant decision  $A_D$ .

**Theorem 29.5** (Exact profile of the physical audit rule). *The keys in (29.7) are exactly the distinct continuation residuals of  $F_n$ . Their number at trial cut  $t$  is*

$$r_t(F_n) = \begin{cases} \binom{t+2}{2}, & 0 \leq t \leq h - 1, \\ \binom{n-t+3}{2}, & h \leq t \leq n. \end{cases} \quad (29.8)$$

*This is the minimum simultaneous width profile for exact computation of this rule, for deterministic and stochastic machines alike. Its maximum is  $\binom{h+2}{2}$  at  $t = h$ .*

*For  $n = 399$ , the maximum trial-cut width is 20301, and the terminal training cut has exactly three states. Acquiring each report pair one bit at a time, discarding its training mark, and then executing independent candidate and target validations gives a deterministic machine with at most  $40602 < 2^{16}$  states at every scheduled epoch. One additional ignored training trial may be inserted to give the same 400 training slots and 402 total trials as the earlier certificate. It changes neither the payoff nor these width bounds.*

*Proof.* If a majority has already been reached, its label cannot change. Otherwise, the first coordinate of the pair key is exactly the number of additional 0 symbols needed, with the unreachable threshold clipped to  $r + 1$ ; the second coordinate has the analogous meaning. These data determine the suffix function. Two different reachable pair keys can be distinguished by a suffix containing only one of the two symbols and enough \* symbols to fill the remaining positions: use a count between the two different thresholds. The other majority cannot be reached by this suffix. The constant-majority keys are distinct from every pair key because an all-\* suffix returns  $A_D$  for the latter. Thus the keys are exactly the residuals.

For  $t < h$ , no majority has been reached and every threshold is at most  $r + 1$ . The distinct pairs  $(u, v)$  with  $u + v \leq t$  give  $\binom{t+2}{2}$  keys. For  $t \geq h$ , the two constant-majority keys are reachable. The remaining keys are precisely

$$(i, j) \in \{1, \dots, r + 1\}^2, \quad i + j \geq r + 1.$$

To see surjectivity, use  $u = h - i, v = h - j$ ; these counts are nonnegative, less than  $h$ , and sum to at most  $t$  because  $2h - t = r + 1$ . To see necessity before clipping, use the same inequality on  $h - u, h - v$ ; if either coordinate is clipped, the inequality remains automatic. There are  $(r + 1)^2 - (r - 1)r/2$  such pairs, with the expression valid also for  $r = 0, 1$ . Adding the two constant keys gives  $(r + 2)(r + 3)/2$ . This proves (29.8). The finite-valued realization theorem, Theorem 16.1, proves both the simultaneous realization and stochastic minimality for the specified rule. The two polynomial pieces of the profile give its maximum as stated.

For an explicit transition definition, order the reachable keys lexicographically, putting L, R first. For each key choose the lexicographically first prefix-count pair representing it. After the next category, increment the appropriate count and apply  $\mathcal{R}_{t+1}$ . Equality of residual functions implies equality of the shifted residuals, so this definition is independent of the chosen representative. The representative is part of the time-indexed transition table, not another stored register. The clock supplies  $t$  but no sample history. All these maps are deterministic and rational.

At a bit-level epoch, the state consists of a residual key and, only between the two report bits, the first bit. It therefore has at most  $2 \max_t r_t$  values. On reading the second bit, determine the category, update the key and discard both bits. The mark is read and discarded; all-on controls and resets are prescribed by the free schedule. After training, keep just one of the three event labels. During validation, keep that label, the completed candidate-event indicator, and a first-bit buffer when needed. At most  $3 \cdot 2 \cdot 2 = 12$  states suffice there; a completed target pair emits its event indicator minus the stored candidate indicator. The final score has three possible values. These phase-specific alphabets may be embedded in a single alphabet of size 40602 because the schedule clock identifies the phase.

The same trial-cut residuals remain distinct for the complete signed-score function, not merely for an externally emitted event name. Any two of  $A_0, A_1, A_D$  have different indicator functions. Take an off-diagonal candidate-validation pair, which belongs to none, and a target-validation pair distinguishing the two events. The resulting scores differ. Thus passing to the validation suffix does not merge the residuals already counted.  $\square$

**Theorem 29.6** (Matched physical decision complexity and stable certification). *For the two-sphere collision family of Theorem 28.2, let  $d \in [9/10, 11/10]$  and  $0 < \sigma \leq 1/24$ , and let  $Q_{d,\sigma}$  be its all-on marked target. At the charged training-validation cut of the reset interface,*

$$\kappa_{2/5}(B, Q_{d,\sigma}) = 3. \quad (29.9)$$

*More concretely, no auditor retaining at most two states at this cut can have expected score greater than  $2/5$  uniformly against all private width-one candidates, at any finite training length, even with feedback-row selection as in Lemma 29.2. One rational auditor with three states at this cut does so with 399 informative training trials and two validation trials. With a redundant ignored training trial, it uses exactly 402 total trials, at most 40602 states at every scheduled epoch, and the exact trial-cut profile (29.8) on its informative training segment.*

*For fixed positive  $\sigma$  and  $d_k \rightarrow d$ , the same machine changes its expected score by at most*

$$\epsilon_k = \min \left\{ 1, \frac{\sqrt{|d_k - d| + 2700|d_k - d|^2}}{2\sigma} \right\}. \quad (29.10)$$

*The private, hidden and visible deficiencies, the no-collision control, and the joint microscopic, likelihood, posterior, innovation and global bounded entropic backward convergence retain all conclusions of Theorems 28.2 and 27.2.*

*Proof.* Theorem 28.2 discharges the physical hypotheses and proves  $\|Q_{d,\sigma} - Q_*\|_{\text{TV}} < 1/300$ , uniformly on the stated parameters. Theorem 29.1 therefore gives the universal cut-width-two upper bound

$$\mathfrak{V}_2(B, Q_{d,\sigma}) < \frac{3}{8} + \frac{1}{300} < \frac{2}{5}.$$

Lemma 29.2 makes this a bound for the full original feedback-row interface, not only all-on training and not only the constructed rule. The upper construction uses all-on trials and works for every private candidate because only its two all-on parameters enter.

Use the deterministic selector of Lemma 29.4 with  $n = 399$ , but validate against the actual physical target. For each selected event, changing only the target from  $Q_*$  loses less than  $1/300$ .

Its physical expected score is consequently greater than

$$L_{399} := \sqrt{2} - 1 - \frac{1}{4\sqrt{399e}} - \frac{1}{4}e^{-399/8} - \frac{1}{300} > \frac{2}{5}. \quad (29.11)$$

Here is a rational verification of the last strict inequality, independent of decimal evaluation. The bounds  $e > 2$ ,  $\sqrt{798} > 28$ ,  $\sqrt{2} > 707/500$ , and  $399/8 > 49$  imply

$$L_{399} > \frac{207}{500} - \frac{1}{112} - \frac{1}{300} - 2^{-51} > \frac{2}{5},$$

since  $207/500 - 1/112 - 1/300 - 2/5 = 73/42000 > 2^{-51}$ . The number  $L_{399}$  is approximately 0.4032891; the rational inequalities, not this approximation, establish the certificate. Its state realization was proved in Theorem 29.5. The general operational classification now yields (29.9) with both inequalities proved for this same physical task.
